Bayesian networks can be adopted to model the dynamics of plain beliefs by replacing ordinary probabilities with nonstandard probabilities, that is, probabilities that are infinitesimally close to either zero or one. This amounts to taking an “order of magnitude” approximation of empirical frequencies and adopting new combination rules tailored to reflect this approximation. The result is an integer-addition calculus, very similar to probability calculus, with summation replacing multiplication and

minimization replacing addition. A plain belief is then identified as a proposition whose negation obtains an infinitesimal probability (i.e., an integer greater than zero). The connection between infinitesimal probabilities, nonmonotonic logic, and iterative belief revision is described in Pearl (1994a), Goldszmidt and Pearl (1996), Darwiche and Pearl (1997), and Spohn (2012).

This combination of infinitesimal probabilities with the causal information encoded by the structure of Bayesian networks facilitates linguistic communication of belief commitments, explanations, actions, goals, and preferences and serves as the basis for qualitative planning under uncertainty (Goldszmidt and Pearl, 1992; Pearl, 1993b; Darwiche and Goldszmidt, 1994; Darwiche and Pearl, 1994). Some of these aspects will be presented in the next section.

44.4 Bayesian Networks as Carriers of Causal Information

The interpretation of DAGs as carriers of independence assumptions does not necessarily imply causation and will in fact be valid for any set of Markovian independencies along any ordering (not necessarily causal or chronological) of the variables. However, the patterns of independencies portrayed in a DAG are typical of causal organizations, and some of these patterns can only be given meaningful interpretation in terms of causation. Consider, for example, two independent events, E_1 and E_2 , that have a common effect E_3 . This triple represents an intransitive pattern of dependencies: E_1 and E_3 are dependent, E_3 and E_2 are dependent, yet E_1 and E_2 are independent. Such a pattern cannot be represented in undirected graphs because connectivity in undirected graphs is transitive. Likewise, it is not easily represented in neural networks, because E_1 and E_2 should turn dependent once E_3 is known. The DAG representation provides a convenient language for intransitive dependencies via the converging pattern $E_1 \rightarrow E_3 \leftarrow E_2$, which implies the independence of E_1 and E_2 as well as the dependence of E_1 and E_3 and of E_2 and E_3 . The distinction between transitive and intransitive dependencies is the basis for the causal discovery systems of Pearl and Verma (1991) and Spirtes et al. (1993) (see Section 44.3.4.1).

However, the Markovian account still leaves open the question of how such intricate patterns of independencies relate to the more basic notions associated with causation, such as influence, manipulation, and control, which reside outside the province of probability theory. The connection is made in the mechanism-based account of causation.

The basic idea behind this account goes back to structural equation models (Wright, 1921; Haavelmo, 1943; Simon, 1953), and it was adapted in Pearl and Verma (1991) for defining probabilistic causal theories, as follows. Each child–parent family in a DAG G represents a deterministic function

$$X_i = f_i(\mathbf{pa}_i, \epsilon_i) \quad (44.5)$$

where \mathbf{pa}_i are the parents of variable X_i in G , and ϵ_i , $0 < i < n$, are mutually independent, arbitrarily distributed random disturbances. Characterizing each child–parent relationship as a deterministic function, instead of the usual conditional probability $P(x_i | \mathbf{pa}_i)$, imposes equivalent independence constraints on the resulting distributions and leads to the same recursive decomposition that characterizes DAG models (see Equation 44.1). However, the functional characterization $X_i = f_i(\mathbf{pa}_i, \epsilon_i)$ also specifies how the resulting distributions would change in response to external interventions, since each function is presumed to represent a stable mechanism in the domain and therefore remains constant unless specifically altered. Thus, once we know the identity of the mechanisms altered by the intervention and the nature of the alteration, the overall effect of an intervention can be predicted by modifying the appropriate equations in the model of Equation 44.5 and using the modified model to compute a new probability function of the observables.

The simplest type of external intervention is one in which a single variable, say X_i , is forced to take on some fixed value x'_i . Such *atomic* intervention amounts to replacing the old functional mechanism $X_i = f_i(\mathbf{pa}_i, \epsilon_i)$ with a new mechanism $X_i = x'_i$ governed by some external force that sets the value x'_i . If we imagine that each variable X_i could potentially be subject to the influence of such an external force, then we

can view each Bayesian network as an efficient code for predicting the effects of atomic interventions and of various combinations of such interventions, without representing these interventions explicitly.

44.4.1 Causal Theories, Actions, Causal Effect, and Identifiability

Definition 44.2

A causal theory is a 4-tuple

$$T = \langle V, U, P(\mathbf{u}), \{f_i\} \rangle$$

where

$V = \{X_1, \dots, X_n\}$ is a set of observed variables

$U = \{U_1, \dots, U_m\}$ is a set of unobserved variables that represent disturbances, abnormalities, or assumptions

$P(\mathbf{u})$ is a distribution function over U_1, \dots, U_m

$\{f_i\}$ is a set of n deterministic functions, each of the form

$$X_i = f_i(PA_i, u) \quad i = 1, \dots, n \quad (44.6)$$

where PA_i is a subset of V not containing X_i .

The variables PA_i (connoting parents) are considered the direct causes of X_i , and they define a directed graph G that may, in general, be cyclic. Unlike the probabilistic definition of “parents” in Bayesian networks (Equation 44.1), PA_i is selected from V by considering functional mechanisms in the domain, not by conditional independence considerations. We will assume that the set of equations in (44.6) has a unique solution for X_1, \dots, X_n , given any value of the disturbances U_1, \dots, U_m . Therefore, the distribution $P(\mathbf{u})$ induces a unique distribution on the observables, which we denote by $P_T(\mathbf{v})$.

We will consider concurrent actions of the form $do(X = x)$, where $X \subseteq V$ is a set of variables and x is a set of values from the domain of X . In other words, $do(X = x)$ represents a combination of actions that forces the variables in X to attain the values x .

Definition 44.3 (effect of actions)

The effect of the action $do(X = x)$ on a causal theory T is given by a subtheory T_x of T , where T_x obtains by deleting from T all equations corresponding to variables in X and substituting the equations $X = x$ instead.

The framework provided by Definitions 44.2 and 44.3 permits the coherent formalization of many subtle concepts in causal discourse, such as causal influence, causal effect, causal relevance, average causal effect, identifiability, counterfactuals, and exogeneity. Examples are the following:

- **X influences Y** in context u if there are two values of X , x and x' , such that the solution for Y under $U = u$ and $do(X = x)$ is different from the solution under $U = u$ and $do(X = x')$.
- **X can potentially influence Y** if there exist both a subtheory T_x of T and a context $U = u$ in which X influences Y .
- **Event $X = x$ is the (singular) cause of event $Y = y$** if (1) $X = x$ and $Y = y$ are true, and (2) in every context u compatible with $X = x$ and $Y = y$, and for all $x' \neq x$, the solution of Y under $do(X = x')$ is not equal to y .

The definitions earlier are deterministic. Probabilistic causality emerges when we define a probability distribution $P(u)$ for the U variables, which, under the assumption that the equations have a unique solution, induces a unique distribution on the endogenous variables for each combination of atomic interventions.

Definition 44.4 (causal effect)

Given two disjoint subsets of variables, $X \subseteq V$ and $Y \subseteq V$, the causal effect of X on Y , denoted $P_T(y|\hat{x})$, is a function from the domain of X to the space of probability distributions on Y , such that

$$P_T(y|x) = P_{T_x}(y) \quad (44.7)$$

for each realization x of X . In other words, for each $x \in \text{dom}(X)$, the causal effect $P_T(y|\hat{x})$ gives the distribution of Y induced by the action $do(X = x)$.

Note that causal effects are defined relative to a given causal theory T , though the subscript T is often suppressed for brevity.

Definition 44.5 (identifiability)

Let $Q(T)$ be any computable quantity of a theory T ; Q is identifiable in a class M of theories if for any pair of theories T_1 and T_2 from M , $Q(T_1) = Q(T_2)$ whenever $P_{T_1}(v) = P_{T_2}(v)$.

Identifiability is essential for estimating quantities Q from P alone, without specifying the details of T , so that the general characteristics of the class M suffice. The question of interest in planning applications is the identifiability of the causal effect $Q = P_T(y|\hat{x})$ in the class M_G of theories that share the same causal graph G . Relative to such classes we now define

Definition 44.6 (causal-effect identifiability)

The causal effect of X on Y is said to be identifiable in M_G if the quantity $P(y|\hat{x})$ can be computed uniquely from the probabilities of the observed variables, that is, if for every pair of theories T_1 and T_2 in M_G such that $P_{T_1}(v) = P_{T_2}(v)$, we have $P_{T_1}(y|\hat{x}) = P_{T_2}(y|\hat{x})$.

The identifiability of $P(y|\hat{x})$ ensures that it is possible to infer the effect of action $do(X = x)$ on Y from two sources of information:

1. Passive observations, as summarized by the probability function $P(v)$
2. The causal graph, G , which specifies, qualitatively, which variables make up the stable mechanisms in the domain or, alternatively, which variables participate in the determination of each variable in the domain

Simple examples of identifiable causal effects will be discussed in the next section.

44.4.2 Acting vs. Observing

Consider the example depicted in Figure 44.1. The corresponding theory consists of five functions, each representing an autonomous mechanism:

$$\begin{aligned}
 X_1 &= U_1 \\
 X_2 &= f_2(X_1, U_2) \\
 X_3 &= f_3(X_1, U_3) \\
 X_4 &= f_4(X_3, X_2, U_4) \\
 X_5 &= f_5(X_4, U_5)
 \end{aligned} \tag{44.8}$$

To represent the action “turning the sprinkler ON,” $do(X_3 = \text{ON})$, we delete the equation $X_3 = f_3(x_1, u_3)$ from the theory of Equation 44.8 and replace it with $X_3 = \text{ON}$. The resulting subtheory, $T_{X_3=\text{ON}}$, contains all the information needed for computing the effect of the actions on other variables. It is easy to see from this subtheory that the only variables affected by the action are X_4 and X_5 , that is, the descendant of the manipulated variable X_3 .

The probabilistic analysis of causal theories becomes particularly simple when two conditions are satisfied:

1. The theory is recursive, that is, there exists an ordering of the variables $V = \{X_1, \dots, X_n\}$ such that each X_i is a function of a subset PA_i of its predecessors

$$X_i = f_i(PA_i, U_i), \quad PA_i \subseteq \{X_1, \dots, X_{i-1}\} \tag{44.9}$$

2. The disturbances U_1, \dots, U_n are mutually independent, that is,

$$P(u) = \prod_i P(u_i) \tag{44.10}$$

These two conditions, also called Markovian, are the bases of the independencies embodied in Bayesian networks (Equation 44.1), and they enable us to compute causal effects directly from the conditional probabilities $P(x_i | \mathbf{pa}_i)$, without specifying the functional form of the functions f_i , or the distributions $P(u_i)$ of the disturbances. This is seen immediately from the following observations: the distribution induced by any Markovian theory T is given by the product in Equation 44.1

$$P_T(x_1, \dots, x_n) = \prod_i P(x_i | \mathbf{pa}_i) \tag{44.11}$$

where \mathbf{pa}_i are (values of) the parents of X_i in the diagram representing T . At the same time, the subtheory $T_{x'_j}$, representing the action $do(X_j = x'_j)$, is also Markovian, hence it also induces a product-like distribution

$$P_{T_{x'_j}}(x_1, \dots, x_n) = \begin{cases} \prod_{i \neq j} P(x_i | \mathbf{pa}_i) = \frac{P(x_1, \dots, x_n)}{P(x_j | \mathbf{pa}_j)} & \text{if } x_j = x'_j \\ 0 & \text{if } x_j \neq x'_j \end{cases} \tag{44.12}$$

where the partial product reflects the surgical removal of the

$$X_j = f_j(\mathbf{pa}_j, U_j)$$

from the theory of equation (44.9) (see Pearl, 1993a).

In the example of Figure 44.1, the pre-action distribution is given by the product

$$P_T(x_1, x_2, x_3, x_4, x_5) = P(x_1)P(x_2|x_1)P(x_3|x_1)P(x_4|x_2, x_3)P(x_5|x_4) \quad (44.13)$$

while the surgery corresponding to the action $do(X_3 = \text{ON})$ amounts to deleting the link $X_1 \rightarrow X_3$ from the graph and fixing the value of X_3 to ON, yielding the post-action distribution

$$P_T(x_1, x_2, x_4, x_5 | do(X_3 = \text{ON})) = P(x_1)P(x_2|x_1)P(x_4|x_2, x_3 = \text{ON})P(x_5|x_4) \quad (44.14)$$

Note the difference between the action $do(X_3 = \text{ON})$ and the observation $X_3 = \text{ON}$. The latter is encoded by ordinary Bayesian conditioning, while the former by conditioning a mutilated graph, with the link $X_1 \rightarrow X_3$ removed. This mirrors indeed the difference between seeing and doing: after observing that the sprinkler is ON, we wish to infer that the season is dry, that it probably did not rain, and so on; no such inferences should be drawn in evaluating the effects of the deliberate action “turning the sprinkler ON.” The amputation of $X_3 = f_3(X_1, U_3)$ from (44.8) ensures the suppression of any abductive inferences from X_3 , the action’s recipient.

Note also that Equations 44.11 through 44.14 are independent of T ; in other words, the pre-action and post-action distributions depend only on observed conditional probabilities but are independent of the particular functional form of $\{f_i\}$ or the distribution $P(\mathbf{u})$ that generates those probabilities. This is the essence of identifiability as given in Definition 44.6, which stems from the Markovian assumptions (44.9) and (44.10). Section 44.4.3 will demonstrate that certain causal effects, though not all, are identifiable even when the Markovian property is destroyed by introducing dependencies among the disturbance terms.

Generalization to multiple actions and conditional actions is reported in Pearl and Robins (1995). Multiple actions $do(X = x)$, where X is a compound variable, result in a distribution similar to (44.12), except that all factors corresponding to the variables in X are removed from the product in (44.11). Stochastic conditional strategies (Pearl, 1994b) of the form

$$do(X_j = x_j) \text{ with probability } P^*(x_j | \mathbf{pa}_j^*) \quad (44.15)$$

where \mathbf{pa}_j^* is the support of the decision strategy, also result in a product decomposition similar to (44.11), except that each factor $P(x_j | \mathbf{pa}_j)$ is replaced with $P^*(x_j | \mathbf{pa}_j^*)$.

The surgical procedure described earlier is not limited to probabilistic analysis. The causal knowledge represented in Figure 44.1 can be captured by logical theories as well, for example,

$$\begin{aligned} x_2 &\Leftrightarrow [(X_1 = \text{Winter}) \vee (X_1 = \text{Fall}) \vee ab_2] \wedge \neg ab'_2 \\ x_3 &\Leftrightarrow [(X_1 = \text{Summer}) \vee (X_1 = \text{Spring}) \vee ab_3] \wedge \neg ab'_3 \\ x_4 &\Leftrightarrow (x_2 \vee x_3 \vee ab_4) \wedge \neg ab'_4 \\ x_5 &\Leftrightarrow (x_4 \vee ab_5) \wedge \neg ab'_5 \end{aligned} \quad (44.16)$$

where x_i stands for $X_i = true$, and ab_i and ab'_i stand, respectively, for triggering and inhibiting abnormalities. The double arrows represent the assumption that the events on the r.h.s. of each equation are the *only* direct causes for the l.h.s, thus identifying the surgery implied by any action.

It should be emphasized though that the models of a causal theory are not made up merely of truth value assignments that satisfy the equations in the theory. Since each equation represents an autonomous process, the content of each individual equation must be specified in any model of the theory, and this can be encoded using either the graph (as in Figure 44.1) or the generic description of the theory, as in (44.8). Alternatively, we can view a model of a causal theory to consist of a mutually consistent set of submodels, with each submodel being a standard model of a single equation in the theory.

44.4.3 Action Calculus

The identifiability of causal effects demonstrated in Section 44.4.1 relies critically on the Markovian assumptions (44.9) and (44.10). If a variable that has two descendants in the graph is unobserved, the disturbances in the two equations are no longer independent; the Markovian property (44.9) is violated and identifiability may be destroyed. This can be seen easily from Equation 44.12; if any parent of the manipulated variable X_j is unobserved, one cannot estimate the conditional probability $P(x_j|\mathbf{pa}_j)$, and the effect of the action $do(X_j = x_j)$ may not be predictable from the observed distribution $P(x_1, \dots, x_n)$. Fortunately, certain causal effects are identifiable even in situations where members of \mathbf{pa}_j are unobservable (Pearl, 1993a), and, moreover, polynomial tests are now available for deciding when $P(x_i|\hat{x}_j)$ is identifiable and for deriving closed-form expressions for $P(x_i|\hat{x}_j)$ in terms of observed quantities (Galles and Pearl, 1995).

These tests and derivations are based on a symbolic calculus (Pearl, 1994a, 1995) to be described in the sequel, in which interventions, side by side with observations, are given explicit notation and are permitted to transform probability expressions. The transformation rules of this calculus reflect the understanding that interventions perform “local surgeries” as described in Definition 44.3, that is, they overrule equations that tie the manipulated variables to their pre-intervention causes.

Let X , Y , and Z be arbitrary disjoint sets of nodes in a DAG G . We denote by $G_{\bar{X}}$ the graph obtained by deleting from G all arrows pointing to nodes in X . Likewise, we denote by $G_{\underline{X}}$ the graph obtained by deleting from G all arrows emerging from nodes in X . To represent the deletion of both incoming and outgoing arrows, we use the notation $G_{\bar{X}\underline{Z}}$. Finally, the expression $P(y|\hat{x}, z) \triangleq P(y, z|\hat{x})/P(z|\hat{x})$ stands for the probability of $Y = y$ given that $Z = z$ is observed and X is held constant at x .

Theorem 44.2

Let G be the directed acyclic graph associated with a Markovian causal theory, and let $P(\cdot)$ stand for the probability distribution induced by that theory. For any disjoint subsets of variables X , Y , Z , and W , we have

Rule 1 (*Insertion/deletion of observations*)

$$P(y|\hat{x}, z, w) = P(y|\hat{x}, w) \quad \text{if} \left(Y \perp\!\!\!\perp Z | X, W \right)_{G_{\bar{X}}} \quad (44.17)$$

Rule 2 (*Action/observation exchange*)

$$P(y|\hat{x}, \hat{z}, w) = P(y|\hat{x}, z, w) \quad \text{if} \left(Y \perp\!\!\!\perp Z | X, W \right)_{G_{\bar{X}\underline{Z}}} \quad (44.18)$$

Rule 3 (*Insertion/deletion of actions*)

$$P(y|\hat{x},\hat{z},w)=P(y|\hat{x},w) \quad \text{if} \left(Y \perp\!\!\!\perp Z|X,W \right)_{G_{\bar{x},Z(W)}} \quad (44.19)$$

where $Z(W)$ is the set of Z -nodes that are not ancestors of any W -node in $G_{\bar{x}}$.

Each of the inference rules presented earlier follows from the basic interpretation of the “ \hat{x} ” operator as a replacement of the causal mechanism that connects X to its pre-action parents by a new mechanism $X = x$ introduced by the intervening force. The result is a submodel characterized by the subgraph $G_{\bar{x}}$ (named “manipulated graph” in Spirtes et al. (1993)) that supports all three rules.

Corollary 44.1

A causal effect $q: P(y_1, \dots, y_k | \hat{x}_1, \dots, \hat{x}_m)$ is identifiable in a model characterized by a graph G if there exists a finite sequence of transformations, each conforming to one of the inference rules in Theorem 44.2, which reduces q into a standard (i.e., hat-free) probability expression involving observed quantities.

Although Theorem 44.2 and Corollary 44.1 require the Markovian property, they can also be applied to non-Markovian, recursive theories because such theories become Markovian if we consider the unobserved variables as part of the analysis and represent them as nodes in the graph. To illustrate, assume that variable X_1 in Figure 44.1 is unobserved, rendering the disturbances U_3 and U_2 dependent since these terms now include the common influence of X_1 . Theorem 44.2 tells us that the causal effect $P(x_4 | \hat{x}_3)$ is identifiable, because

$$P(x_4 | \hat{x}_3) = \sum_{x_2} P(x_4 | \hat{x}_3, x_2) P(x_2 | \hat{x}_3)$$

Rule 3 permits the deletion

$$P(x_2 | \hat{x}_3) = P(x_2), \quad \text{because} \left(X_2 \perp\!\!\!\perp X_3 \right)_{G_{\bar{x}_3}}$$

while Rule 2 permits the exchange

$$P(x_4 | \hat{x}_3, x_2) = P(x_4 | x_3, x_2), \quad \text{because} \left(X_4 \perp\!\!\!\perp X_3 | X_2 \right)_{G_{\bar{x}_3}}$$

This gives

$$P(x_4 | \hat{x}_3) = \sum_{x_2} P(x_4 | x_3, x_2) P(x_2)$$

which is a “hat-free” expression, involving only observed quantities.

In general, it can be shown (Pearl, 1995) that

1. The effect of interventions can often be identified (from nonexperimental data) without resorting to parametric models
2. The conditions under which such nonparametric identification is possible can be determined by simple graphical tests*
3. When the effect of interventions is not identifiable, the causal graph may suggest nontrivial experiments that, if performed, would render the effect identifiable

The ability to assess the effect of interventions from nonexperimental data has immediate applications in the medical and social sciences, since subjects who undergo certain treatments often are not representative of the population as a whole. Such assessments are also important in AI applications where an agent needs to predict the effect of the next action on the basis of past performance records and where that action has never been enacted under controlled experimental conditions, but in response to environmental needs or to other agent's requests.

44.4.4 Recent Developments

44.4.4.1 Complete Identification Results

A key identification condition, which operationalizes Theorem 44.2, has been derived by Jin Tian. It reads:

Theorem 44.3

(Tian and Pearl, 2002) A sufficient condition for identifying the causal effect $P(y|do(x))$ is that there exists no bidirected path (i.e., a path composed entirely of bidirected arcs) between X and any of its children.†

Remarkably, the theorem asserts that, as long as every child of X (on the pathways to Y) is not reachable from X via a bidirected path, then, regardless of how complicated the graph, the causal effect $P(y|do(x))$ is identifiable. In Figure 44.1, for example, adding unobserved confounders for the pairs (X_1, X_3) , (X_2, X_4) , (X_3, X_5) , and (X_2, X_5) will still permit the identification of $P(X_5|\hat{x}_3)$, but adding (X_2, X_4) to this list will prohibit identification.

Tian and Pearl (2002) further showed that the condition is both sufficient and necessary for the identification of $P(v|do(x))$, where V includes all variables except X . A necessary and sufficient condition for identifying $P(w|do(z))$, with W and Z two arbitrary sets, was established by Shpitser and Pearl (2006b). Subsequently, a complete graphical criterion was established for determining the identifiability of *conditional* interventional distributions, namely, expressions of the type $P(y|do(x),z)$ where X, Y , and Z are arbitrary sets of variables (Shpitser and Pearl, 2006a).

These results constitute a complete characterization of causal effects in graphical models. They provide us with polynomial time algorithms for determining whether an arbitrary quantity invoking the

* These graphical tests offer, in fact, a complete formal solution to the “covariate-selection” problem in statistics: finding an appropriate set of variables that need be adjusted for in any study that aims to determine the effect of one factor upon another. This problem has been lingering in the statistical literature since Karl Pearson, the founder of modern statistics, discovered (1899) what in modern terms is called the “Simpson’s paradox”; any statistical association between two variables may be reversed or negated by including additional factors in the analysis (Aldrich, 1995).

† Before applying this criterion, one may delete from the causal graphs all nodes that are not ancestors of Y .

$do(x)$ operator is identified in a given semi-Markovian model, and if so, what the estimand of that quantity is. Remarkably, one corollary of these results also states that the do -calculus is complete, namely, a quantity $Q = P(y|do(x), z)$ is identified if and only if it can be reduced to a do -free expression using the three rules of Theorem 44.2.* This turns Corollary 44.1 into an “if-and-only-if” assertion. Tian and Shpitser (2010) provide a comprehensive summary of these results.

44.4.5 Transportability and Transfer Learning

In applications involving identification, the role of the do -calculus is to remove the do -operator from the query expression. We now discuss a totally different application, to decide if experimental findings can be transported to a new, potentially different environment, where only passive observations can be performed. This problem, labeled “transportability” in Pearl and Bareinboim (2011), is at the heart of every scientific investigation. For example, experiments performed in the laboratory are invariably intended to be used elsewhere, where conditions differ substantially from the laboratory. A robot trained by a simulator should be able to use the knowledge acquired through training to a new environment, in which experiments are costly or infeasible.

To formalize problems of this sort, Pearl and Bareinboim devised a graphical representation called “selection diagrams” that encodes knowledge about differences and commonalities between populations. A selection diagram is a causal diagram annotated with new variables, called S -nodes, which point to the mechanisms where discrepancies between the two populations are suspected to take place. The task of deciding if transportability is feasible now reduces to a syntactic problem (using the do -calculus) aiming to separate the do -operator from the S -variables.

Theorem 44.4

(Pearl and Bareinboim, 2011) Let D be the selection diagram characterizing two populations, π and π^* , and S a set of selection variables in D . The relation $R = P^*(y|do(x), z)$ is transportable from π and π^* if and only if the expression $P(y|do(x), z, s)$ is reducible, using the rules of do -calculus, to an expression in which S appears only as a conditioning variable in do -free terms.

Theorem 44.4 does not specify the sequence of rules leading to the needed reduction when such a sequence exists. Bareinboim and Pearl (2012) established a complete and effective graphical procedure of confirming transportability that also synthesizes the transport formula whenever possible. Each transport formula determines for the investigator what information need to be taken from the experimental and observational studies and how they ought to be combined to yield an unbiased estimate of R .

A generalization of transportability theory to multi-environment has led to a principled solution to “meta-analysis.” “Meta-analysis” is a data fusion problem aimed at combining results from many experimental and observational studies, each conducted on a different population and under a different set of conditions, so as to synthesize an aggregate measure of effect size that is “better,” in some sense, than any one study in isolation. This fusion problem has received enormous attention in the health and social sciences, where data are scarce and experiments are costly (Pearl, 2012a,c).

Using multiple “selection diagrams” to encode commonalities among studies, Bareinboim and Pearl (2013) were able to “synthesize” an estimator that is guaranteed to provide unbiased estimate of the desired quantity based on information that each study shares with the target environment.

* This was independently established by Huang and Valtorta (2006).

44.4.6 Inference with Missing Data

It is commonly assumed that causal knowledge is necessary only when interventions are contemplated and that in purely predictive tasks, probabilistic knowledge suffices. Not so. One predictive task in which causal information is essential and which have thus far been treated in purely statistical terms is the problem of drawing valid inferences from statistical data in which some items are “missing” or failed to be recorded.

The “missing data” problem is pervasive in machine learning and every experimental science; users fail to answer certain items on a questionnaire, sensors may miss certain signal due to bad weather, and so on. The problem is causal in nature, because the mechanism that determines the *reasons* for missingness makes a difference in whether/how we can recover from the data, and that mechanism requires causal language to be properly described, statistics is insufficient.

Mohan and Pearl (2013) have shown that current practices of handling missing data, by relying exclusively on statistical considerations (Rubin, 1976; Little and Rubin, 2002), are deficient in several key areas and could be remedied using causal diagrams. In particular they showed that

1. It is possible to define precisely what relations can be *recovered* from missing data and what causal and statistical knowledge need to be assumed to ensure bias-free recovery
2. Different causal assumptions lead to different routines for recovering a relation from the data
3. Adding auxiliary variables to the data, a popular technique in current practice (Schafer and Graham, 2002) may or may not help the recovery process, depending on conditions that can be read from the causal diagram
4. It is possible to determine when the conditions necessary for bias-free recovery have testable implications

44.4.7 Historical Remarks

An explicit translation of interventions to “wiping out” equations from linear econometric models was first proposed by Strotz and Wold (1960) and later used in Fisher (1970) and Sobel (1990). Extensions to action representation in nonmonotonic systems were reported in Goldszmidt and Pearl (1992) and Pearl (1993a). Graphical ramifications of this translation were explicated first in Spirtes et al. (1993) and later in Pearl (1993b). A related formulation of causal effects, based on event trees and counterfactual analysis, was developed by Robins (1986, pp. 1422–1425). Calculi for actions and counterfactuals based on this interpretation are developed in Pearl (1994b) and Balke and Pearl (1994), respectively.

44.5 Counterfactuals

A counterfactual sentence has the form

If A were true, then C would have been true?

where *A*, the counterfactual antecedent, specifies an event that is contrary to one’s real-world observations, and *C*, the counterfactual consequent, specifies a result that is expected to hold in the alternative world where the antecedent is true. A typical example is “If Oswald were not to have shot Kennedy, then Kennedy would still be alive” that presumes the factual knowledge of Oswald’s shooting Kennedy, contrary to the antecedent of the sentence.

The majority of the philosophers who have examined the semantics of counterfactual sentences have resorted to some version of Lewis’ “closest world” approach; “*C* if it were *A*” is true, if *C* is true in worlds that are “closest” to the real world yet consistent with the counterfactual antecedent *A* (Lewis, 1973). Ginsberg (1986) followed a similar strategy. While the “closest world” approach leaves the precise specification of the closeness measure almost unconstrained, causal knowledge imposes very specific

preferences as to which worlds should be considered closest to any given world. For example, considering an array of domino tiles standing close to each other. The manifestly closest world consistent with the antecedent “tile i is tipped to the right” would be a world in which just tile i is tipped, while all the others remain erect. Yet, we all accept the counterfactual sentence “Had tile i been tipped over to the right, tile $i + 1$ would be tipped as well” as plausible and valid. Thus, distances among worlds are not determined merely by surface similarities but require a distinction between disturbed mechanisms and naturally occurring transitions. The local surgery paradigm expounded in Section 44.4.1 offers a concrete explication of the closest world approach that respects causal considerations. A world w_1 is “closer” to w than a world w_2 is, if the set of atomic surgeries needed for transforming w into w_1 is a subset of those needed for transforming w into w_2 . In the domino example, finding tile i tipped and $i + 1$ erect requires the breakdown of two mechanism (e.g., by two external actions) compared with one mechanism for the world in which all j -tiles, $j > i$ are tipped. This paradigm conforms to our perception of causal influences and lends itself to economical machine representation.

44.5.1 Formal Underpinning

The structural equation framework offers an ideal setting for counterfactual analysis.

Definition 44.7 (context-based potential response)

Given a causal theory T and two disjoint sets of variables, X and Y , the potential response of Y to X in a context u , denoted $Y(x, u)$ or $Y_x(u)$, is the solution for Y under $U = u$ in the subtheory T_x . $Y(x, u)$ can be taken as the formal definition of the counterfactual English phrase: “the value that Y would take in context u , had X been x ,”*

Note that this definition allows for the context $U = u$ and the proposition $X = x$ to be incompatible in T . For example, if T describes a logic circuit with input U , it may well be reasonable to assert the counterfactual: “given $U = u$, Y would be high if X were low,” even though the input $U = u$ may preclude X from being low. It is for this reason that one must invoke some notion of intervention (alternatively, a theory change or a “miracle” [Lewis, 1973]) in the definition of counterfactuals.

If U is treated as a random variable, then the value of the counterfactual $Y(x, u)$ becomes a random variable as well, denoted as $Y(x)$ of Y_x . Moreover, the distribution of this random variable is easily seen to coincide with the causal effect $P(y|\hat{x})$, as defined in Equation 44.7, that is,

$$P(Y(x) = y) = P(y|\hat{x})$$

The probability of a counterfactual conditional $x \rightarrow y|o$ may then be evaluated by the following procedure:

- Use the observations o to update $P(u)$ thus forming a causal theory $T^o = \langle V, U, \{f_i\}, P(u|o) \rangle$.
- Form the mutilated theory T_x^o (by deleting the equation corresponding to variables in X), and compute the probability $P_{T^o}(y|\hat{x})$ that T_x^o induces on Y .

* The term *unit* instead of *context* is often used in the statistical literature Rubin (1974), where it normally stands for the identity of a specific individual in a population, namely, the set of attributes u that characterize that individual. In general, u may include the time of day and the experimental conditions under study. Practitioners of the counterfactual notation do not explicitly mention the notions of “solution” or “intervention” in the definition of $Y(x, u)$. Instead, the phrase “the value that Y would take in unit u , had X been x ,” viewed as basic, is posited as the definition of $Y(x, u)$.

Unlike causal effect queries, counterfactual queries are not identifiable even in Markovian theories, but require that the functional form of $\{f_i\}$ be specified. In Balke and Pearl (1994), a method is devised for computing sharp bounds on counterfactual probabilities that, under certain circumstances, may collapse to point estimates. This method has been applied to the evaluation of causal effects in studies involving noncompliance and to the determination of legal liability.

44.5.2 Applications to Policy Analysis

Counterfactual reasoning is at the heart of every planning activity, especially real-time planning. When a planner discovers that the current state of affairs deviates from the one expected, a “plan repair” activity need be invoked to determine what went wrong and how it could be rectified. This activity amounts to an exercise of counterfactual thinking, as it calls for rolling back the natural course of events and determining, based on the factual observations at hand, whether the culprit lies in previous decisions or in some unexpected, external eventualities. Moreover, in reasoning forward to determine if things would have been different, a new model of the world must be consulted, one that embodies hypothetical changes in decisions or eventualities, hence, a breakdown of the old model or theory.

The logic-based planning tools used in AI, such as STRIPS and its variants or those based on the situation calculus, do not readily lend themselves to counterfactual analysis; as they are not geared for coherent integration of abduction with prediction, and they do not readily handle theory changes. Remarkably, the formal system developed in economics and social sciences under the rubric “structural equation models” does offer such capabilities, but, as will be discussed in the succeeding text, these capabilities are not well recognized by current practitioners of structural models. The analysis presented in this chapter could serve both to illustrate to AI researchers the basic formal features needed for counterfactual and policy analysis and to call the attention of economists and social scientists to capabilities that are dormant within structural equation models.

Counterfactual thinking dominates reasoning in political science and economics. We say, for example, “If Germany were not punished so severely at the end of World War I, Hitler would not have come to power,” or “If Reagan did not lower taxes, our deficit would be lower today.” Such thought experiments emphasize an understanding of generic laws in the domain and are aimed toward shaping future policy making, for example, “defeated countries should not be humiliated,” or “lowering taxes (contrary to Reaganomics) tends to increase national debt.”

Strangely, there is very little formal work on counterfactual reasoning or policy analysis in the behavioral science literature. An examination of a number of econometric journals and textbooks, for example, reveals a glaring imbalance: while an enormous mathematical machinery is brought to bear on problems of estimation and prediction, policy analysis (which is the ultimate goal of economic theories) receives almost no formal treatment. Currently, the most popular methods driving economic policy making are based on so-called *reduced-form* analysis: to find the impact of a policy involving decision variables X on outcome variables Y , one examines past data and estimates the conditional expectation $E(Y|X = x)$, where x is the particular instantiation of X under the policy studied.

The assumption underlying this method is that the data were generated under circumstances in which the decision variables X act as exogenous variables, that is, variables whose values are determined outside the system under analysis. However, while new decisions should indeed be considered exogenous for the purpose of evaluation, past decisions are rarely enacted in an exogenous manner. Almost every realistic policy (e.g., taxation) imposes control over some endogenous variables, that is, variables whose values are determined by other variables in the analysis. Let us take taxation policies as an example. Economic data are generated in a world in which the government is reacting to various indicators and various pressures; hence, taxation is endogenous in the data analysis phase of the study. Taxation becomes exogenous when we wish to predict the impact of a specific decision to raise or lower taxes. The reduced-form method is valid only when past decisions are nonresponsive to other variables

in the system, and this, unfortunately, eliminates most of the interesting control variables (e.g., tax rates, interest rates, quotas) from the analysis.

This difficulty is not unique to economic or social policy making; it appears whenever one wishes to evaluate the merit of a plan on the basis of the past performance of other agents. Even when the signals triggering the past actions of those agents are known with certainty, a systematic method must be devised for selectively ignoring the influence of those signals from the evaluation process. In fact, the very essence of *evaluation* is having the freedom to imagine and compare trajectories in various counterfactual worlds, where each world or trajectory is created by a hypothetical implementation of a policy that is free of the very pressures that compelled the implementation of such policies in the past.

Balke and Pearl (1995) demonstrate how linear, nonrecursive structural models with Gaussian noise can be used to compute counterfactual queries of the type: “Given an observation set O , find the probability that Y would have attained a value greater than y , had X been set to x .” The task of inferring “causes of effects,” that is, of finding the probability that $X = x$ is the cause for effect E , amounts to answering the counterfactual query: “Given effect E and observations O , find the probability that E would not have been realized, had X not been x .” The technique developed in Balke and Pearl (1995) is based on probability propagation in dual networks; one representing the actual world, the other the counterfactual world. The method is not limited to linear functions but applies whenever we are willing to assume the functional form of the structural equations. The noisy OR-gate model (Pearl, 1988) is a canonical example where such functional form is normally specified. Likewise, causal theories based on Boolean functions (with exceptions), such as the one described in Equation 44.16, lend themselves to counterfactual analysis in the framework of Definition 44.7.

44.5.3 The Algorithmization of Counterfactuals

Prospective counterfactual expressions of the type $P(Y_x = y)$ are concerned with predicting the average effect of hypothetical actions and policies and can, in principle, be assessed from experimental studies in which X is randomized. Retrospective counterfactuals, on the other hand, consist of variables at different hypothetical worlds (different subscripts), and these may or may not be testable experimentally. In epidemiology, for example, the expression $P(Y_{x'} = y' | x, y)$ may stand for the fraction of patients who recovered (y) under treatment (x) that would not have recovered (y') had they not been treated (x'). This fraction cannot be assessed in experimental study, for the simple reason that we cannot retest patients twice, with and without treatment. A different question is therefore posed: which counterfactuals can be tested, be it in experimental or observational studies? This question has been given a mathematical solution in Shpitser and Pearl (2007). It has been shown, for example, that in linear systems, $E(Y_x | e)$ is estimable from experimental studies whenever the prospective effect $E(Y_x)$ is estimable in such studies. Likewise, the counterfactual probability $P(Y_{x'} | x)$, also known as the effect of treatment on the treated (ETT), is estimable from observational studies whenever an admissible S exists for $P(Y_x = y)$ (Shpitser and Pearl, 2009).

Retrospective counterfactuals have also been indispensable in conceptualizing direct and indirect effects (Robins and Greenland, 1992; Pearl, 2001), which require nested counterfactuals in their definitions. For example, to evaluate the direct effect of treatment $X = x'$ on individual u , unmediated by a set Z of intermediate variables, we need to construct the nested counterfactual $Y_{x', Z_x(u)}$ where Y is the effect of interest, and $Z_x(u)$ stands for whatever values the intermediate variables Z would take had treatment not been given.* Likewise, the average *indirect effect*, of a transition from x to x' , is defined as the expected change in Y affected by holding X constant, at $X = x$, and changing Z , hypothetically, to whatever value it would have attained had X been set to $X = x'$.

* Note that conditioning on the intermediate variables in Z would generally yield the wrong answer, due to unobserved “confounders” affecting both Z and Y . Moreover, in nonlinear systems, the value at which we hold Z constant will affect the result (Pearl, 2000, pp. 126–132).

This counterfactual formulation has enabled researchers to derive conditions under which direct and indirect effects are estimable from empirical data (Pearl, 2001; Petersen et al., 2006) and to answer such questions as “Can data prove an employer guilty of hiring discrimination?” or, phrased counterfactually, “what fraction of employees owes its hiring to sex discrimination?”

These tasks are performed using a general estimator, called the mediation formula (Pearl, 2001, 2009, 2012b), which is applicable to nonlinear models with discrete or continuous variables and permits the evaluation of path-specific effects with minimal assumptions regarding the data-generating process.

Independent Consultant

In this chapter, we examine the communications software needed to interconnect computers, workstations, servers, and other devices across networks. Then, we look at some of the networks in contemporary use. This chapter focuses exclusively on wired networks. Wireless networks are examined elsewhere, such as in the chapter “Mobile Operating Systems,” which has an extensive discussion on wireless networks.

45.1 Transmission Control Protocol/ Internet Protocol Architecture

When communication is desired among computers from different vendors, the software development effort can be a nightmare. Different vendors use different data formats and data exchange protocols. Even within one vendor’s product line, different model computers may communicate in unique ways.

As the use of computer communications and computer networking proliferates, a one-at-a-time special-purpose approach to communications software development is too costly to be acceptable. The only alternative is for computer vendors to adopt and implement a common set of conventions. For this to happen, standards are needed. Such standards would have two benefits:

- Vendors feel encouraged to implement the standards because of an expectation that, because of wide usage of the standards, their products will be more marketable with them.
- Customers are in a position to require that the standards be implemented by any vendor wishing to propose equipment to them.

It should become clear from the ensuing discussion that no single standard will suffice. Any distributed application, such as electronic mail or client/server interaction, requires a complex set of communications functions for proper operation. Many of these functions, such as reliability mechanisms, are common across many or even all applications. Thus, the communications task is best viewed as consisting of a modular architecture, in which the various elements of the architecture perform the various required functions. Hence, before one can develop standards, there should be a structure, or *protocol architecture*, that defines the communications tasks.

Transmission control protocol (TCP)/Internet protocol (IP) is a result of protocol research and development conducted on the experimental packet-switched network, ARPANET, funded by the Defense Advanced Research Projects Agency, and is generally referred to as the TCP/IP protocol suite. This protocol suite consists of a large collection of protocols that have been issued as Internet standards by the Internet Activities Board.

45.1.1 TCP/IP Layers

In general terms, communications can be said to involve three agents: applications, computers, and networks. Examples of applications include file transfer and electronic mail. The applications that we are concerned with in this study are distributed applications that involve the exchange of data between two computer systems. These applications, and others, execute on computers that can often support multiple simultaneous applications. Computers are connected to networks, and the data to be exchanged are transferred by the network from one computer to another. Thus, the transfer of data from one application to another involves first getting the data to the computer in which the application resides and then getting it to the intended application within the computer.

There is no official TCP/IP protocol model. However, based on the protocol standards that have been developed, we can organize the communication task for TCP/IP into five relatively independent layers, from bottom to top (Stallings, 2013):

- Physical layer
- Network access layer
- Internet layer
- Host-to-host, or transport layer
- Application layer

The *physical layer* covers the physical interface between a data transmission device (e.g., workstation and computer) and a transmission medium or network. This layer is concerned with specifying the characteristics of the transmission medium, the nature of the signals, the data rate, and related matters.

The *network access layer* is concerned with the exchange of data between an end system (ES) (server, workstation, etc.) and the network to which it is attached. The sending computer must provide the network with the address of the destination computer, so that the network may route the data to the appropriate destination. The sending computer may wish to invoke certain services, such as priority, that might be provided by the network. The specific software used at this layer depends on the type of network to be used; different standards have been developed for circuit switching, packet switching (e.g., frame relay), local-area networks (LANs) (e.g., Ethernet), and others. Thus, it makes sense to separate those functions having to do with network access into a separate layer. By doing this, the remainder of the communications software, above the network access layer, need not be concerned about the specifics of the network to be used. The same higher-layer software should function properly regardless of the particular network to which the computer is attached.

The network access layer is concerned with access to and routing data across a network for two ESs attached to the same network. In those cases where two devices are attached to different networks, procedures are needed to allow data to traverse multiple interconnected networks. This is the function of

the *Internet layer*. The IP is used at this layer to provide the routing function across multiple networks. This protocol is implemented not only in the ESs but also in routers. A router is a processor that connects two networks and whose primary function is to relay data from one network to the other on its route from the source to the destination ES.

Regardless of the nature of the applications that are exchanging data, there is usually a requirement that data be exchanged reliably. That is, we would like to be assured that all of the data arrive at the destination application and that the data arrive in the same order in which they were sent. As we shall see, the mechanisms for providing reliability are essentially independent of the nature of the applications. Thus, it makes sense to collect those mechanisms in a common layer shared by all applications; this is referred to as the *host-to-host layer* or the *transport layer*. The TCP provides this functionality.

Finally, the *application layer* contains the logic needed to support the various user applications. For each different type of application, such as file transfer, a separate module is needed that is peculiar to that application.

45.1.2 Operation of TCP and IP

Figure 45.1 indicates how these protocols are configured for communications. To make clear that the total communications facility may consist of multiple networks, the constituent networks are usually referred to as *subnetworks*. Some sort of network access protocol, such as the Ethernet logic, is used to connect a computer to a subnetwork. This protocol enables the host to send data across the subnetwork to another host or, in the case of a host on another subnetwork, to a router. IP is implemented in all of the ESs and the routers. It acts as a relay to move a block of data from one host, through one or more routers,

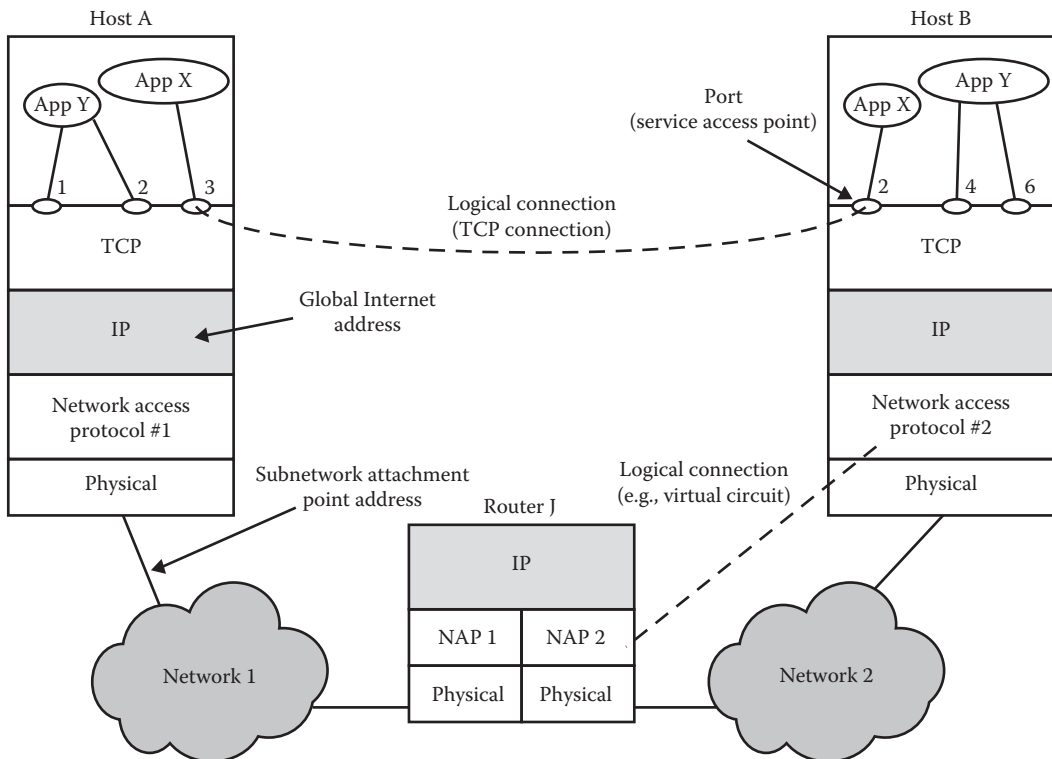

FIGURE 45.1 TCP/IP Concepts.

to another host. TCP is implemented only in the ESs; it keeps track of the blocks of data to assure that all are delivered reliably to the appropriate application.

For successful communication, every entity in the overall system must have a unique address. Actually, two levels of addressing are needed. Each host on a subnetwork must have a unique global Internet address; this allows the data to be delivered to the proper host. Each process with a host must have an address that is unique within the host; this allows the host-to-host protocol (TCP) to deliver data to the proper process. These latter addresses are known as ports.

Let us trace a simple operation. Suppose that a process, associated with port 1 at host *A*, wishes to send a message to another process, associated with port 2 at host *B*. The process at *A* hands the message down to TCP with instructions to send it to host *B*, port 2. TCP hands the message down to IP with instructions to send it to host *B*. Note that IP need not be told the identity of the destination port. All this it needs to know is that the data are intended for host *B*. Next, IP hands the message down to the network access layer (e.g., Ethernet logic) with instructions to send it to router *X* (the first hop on the way to *B*).

To control this operation, control information as well as user data must be transmitted, as suggested in Figure 45.2. Let us say that the sending process generates a block of data and passes this to TCP. TCP may break this block into smaller pieces to make the transmission more manageable. To each of these pieces, TCP appends control information known as the TCP header, forming a *TCP segment*. The control information is to be used by the peer TCP protocol entity at host *B*. Examples of items that are included in this header include the following:

- *Destination port*: When the TCP entity at *B* receives the segment, it must know to whom the data are to be delivered.
- *Sequence number*: TCP numbers the segments that it sends to a particular destination port sequentially, so that if they arrive out of order, the TCP entity at *B* can reorder them.
- *Checksum*: The sending TCP includes a code that is a function of the contents of the remainder of the segment. The receiving TCP performs the same calculation and compares the result with the incoming code. A discrepancy results if there has been some error in transmission.

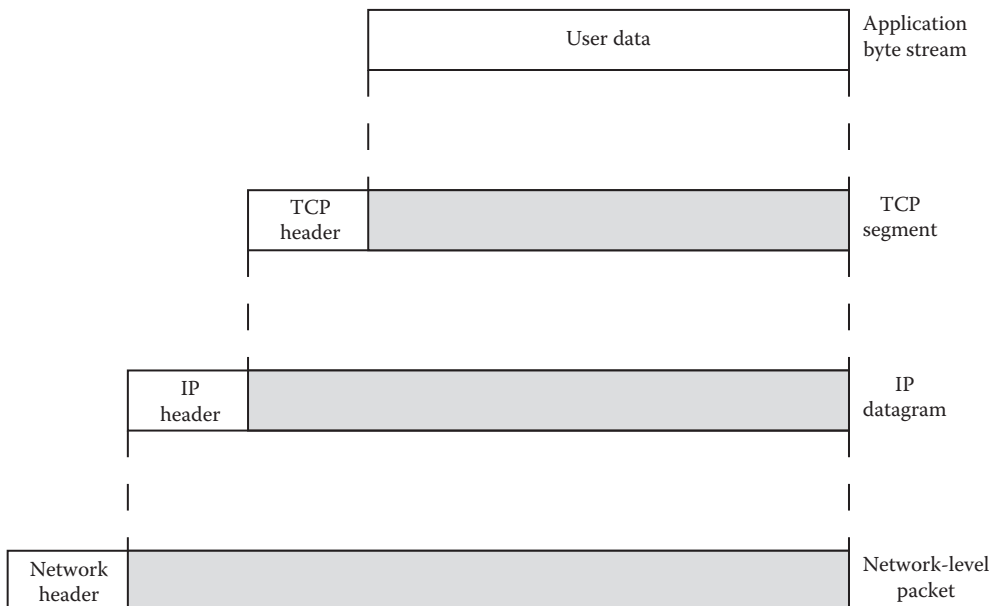

FIGURE 45.2 Protocol data units in the TCP/IP architecture.

Next, TCP hands each segment over to IP, with instructions to transmit it to *B*. These segments must be transmitted across one or more subnetworks and relayed through one or more intermediate routers. This operation, too, requires the use of control information. Thus, IP appends a header of control information to each segment to form an *IP datagram*. An example of an item stored in the IP header is the destination host address (in this example, *B*).

Finally, each IP datagram is presented to the network access layer for transmission across the first subnetwork in its journey to the destination. The network access layer appends its own header, creating a packet, or frame. The packet is transmitted across the subnetwork to router X. The packet header contains the information that the subnetwork needs to transfer the data across the subnetwork. Examples of items that may be contained in this header include the following:

- *Destination subnetwork address*: The subnetwork must know to which attached device the packet is to be delivered.
- *Facilities requests*: The network access protocol might request the use of certain subnetwork facilities, such as priority.

At router X, the packet header is stripped off and the IP header examined. On the basis of the destination address information in the IP header, the IP module in the router directs the datagram out across subnetwork 2 to *B*. To do this, the datagram is again augmented with a network access header.

When the data are received at *B*, the reverse process occurs. At each layer, the corresponding header is removed, and the remainder is passed on to the next higher layer, until the original user data are delivered to the destination process.

45.1.3 TCP/IP Applications

A number of applications have been standardized to operate on top of TCP. We mention three of the most common in this study.

The *simple mail transfer protocol (SMTP)* provides a basic electronic mail facility. It provides a mechanism for transferring messages among separate hosts. Features of SMTP include mailing lists, return receipts, and forwarding. The SMTP protocol does not specify the way in which messages are to be created; some local editing or native electronic mail facility is required. Once a message is created, SMTP accepts the message and makes use of TCP to send it to an SMTP module on another host. The target SMTP module will make use of a local electronic mail package to store the incoming message in a user's mailbox.

The *file transfer protocol (FTP)* is used to send files from one system to another under user command. Both text and binary files are accommodated, and the protocol provides features for controlling user access. When a user wishes to engage in file transfer, FTP sets up a TCP connection to the target system for the exchange of control messages. These allow user ID and password to be transmitted and allow the user to specify the file and file actions desired. Once a file transfer is approved, a second TCP connection is set up for the data transfer. The file is transferred over the data connection, without the overhead of any headers or control information at the application level. When the transfer is complete, the control connection is used to signal the completion and to accept new file transfer commands.

Secure Shell (SSH) provides a secure remote logon capability, which enables a user at a terminal or personal computer to logon to a remote computer and function as if directly connected to that computer. SSH also supports file transfer between the local host and a remote server. SSH enables the user and the remote server to authenticate each other; it also encrypts all traffic in both directions. SSH traffic is carried on a TCP connection.

45.2 Internetworking

In most cases, a LAN or wide-area network (WAN) is not an isolated entity. An organization may have more than one type of LAN at a given site to satisfy a spectrum of needs. An organization may have multiple LANs of the same type at a given site to accommodate performance or security requirements.

Furthermore, an organization may have LANs at various sites and need them to be interconnected via WANs for central control of distributed information exchange.

An interconnected set of networks, from a user's point of view, may appear simply as a larger network. However, if each of the constituent networks retains its identity, and special mechanisms are needed for communicating across multiple networks, then the entire configuration is often referred to as an *Internet*, and each of the constituent networks as a *subnetwork*. The most important example of an Internet is referred to simply as the Internet. As the Internet has evolved from its modest beginnings as a research-oriented packet-switching network, it has served as the basis for the development of internetworking technology and as the model for private Internets within organizations. These latter are also referred to as *intranets*. If an organization extends access to its intranet, over the Internet, to selected customers and suppliers, then the resulting configuration is often referred to as an *extranet*.

Each constituent subnetwork in an Internet supports communication among the devices attached to that subnetwork; these devices are referred to as *hosts* or *ESs*. Within an Internet, subnetworks are connected by devices referred to as *routers*. The differences between them have to do with the types of protocols used for the internetworking logic. The role and functions of routers were introduced in the context of IP earlier in this chapter. However, because of the importance of routers in the overall networking scheme, it is worth providing additional comment in this section.

45.2.1 Routers

Internetworking is achieved by using intermediate systems, or routers, to interconnect a number of independent networks. Essential functions that the router must perform include the following:

1. Provide a link between networks.
2. Provide for the routing and delivery of data between ESs attached to different networks.
3. Provide these functions in such a way as to not require modifications of the networking architecture of any of the attached networks.

Point 3 means that the router must accommodate a number of differences among networks, such as the following:

- *Addressing schemes*: The networks may use different schemes for assigning addresses to devices. For example, an IEEE 802 LAN uses 48 bit binary addresses for each attached device; an ATM network typically uses 15 digit decimal addresses (encoded as 4 bits per digit for a 60 bit address). Some form of global network addressing must be provided, as well as a directory service.
- *Maximum packet sizes*: Packets from one network may have to be broken into smaller pieces to be transmitted on another network, a process known as *fragmentation*. For example, Ethernet imposes a maximum packet size of 1500 bytes; a maximum packet size of 1600 bytes is common on frame relay networks. A packet that is transmitted on a frame relay network and picked up by a router for forwarding on an Ethernet LAN may have to be fragmented into two smaller ones.
- *Interfaces*: The hardware and software interfaces to various networks differ. The concept of a router must be independent of these differences.
- *Reliability*: Various network services may provide anything from a reliable end-to-end virtual circuit to an unreliable service. The operation of the routers should not depend on an assumption of network reliability.

The preceding requirements are best satisfied by an internetworking protocol, such as IP, that is implemented in all ESs and routers.

45.2.2 Internetworking Example

Figure 45.3 depicts a configuration that we will use to illustrate the interactions among protocols for internetworking. In this case, we focus on a server attached to a frame relay WAN and a workstation attached to an IEEE 802 LAN, such as Ethernet, with a router connecting the two networks. The router provides a link between the server and the workstation that enables these ESs to ignore the details of the intervening networks. For the frame relay network, what we have referred to as the network access layer consists of a single frame relay protocol. In the case of the IEEE 802 LAN, the network access layer consists of two sublayers: the logical link control layer and the media access control layer. For purposes of this discussion, we need not describe these layers in any detail.

Consider the typical steps in the transfer of a block of data, such as a file or a Web page, from the server, through an Internet, and ultimately to an application in the workstation. In this example, the message passes through just one router. Before data can be transmitted, the application and transport layers in the server establish, with the corresponding layers in the workstation, the applicable ground rules for a communication session. These include character code to be used, error-checking method, and the like. The protocol at each layer is used for this purpose and then is used in the transmission of the message.

For the actual transmission, the application in the server passes data down to TCP. TCP divides the data into a sequence of data blocks. Each block is assembled as a TCP segment by adding the TCP header, containing protocol control information. Each segment is then passed down to IP, which appends an IP header. A frame relay header and trailer are added to each IP packet. Each frame is then transmitted over the medium as a sequence of bits. The router strips off the frame relay header and trailer and examines the IP header to determine routing information. The router then appends the IEEE 802 headers and trailers and transmits the resulting frame to the destination workstation. At the workstation, all the headers and trailers are stripped off in turn, and the data are delivered to the application.

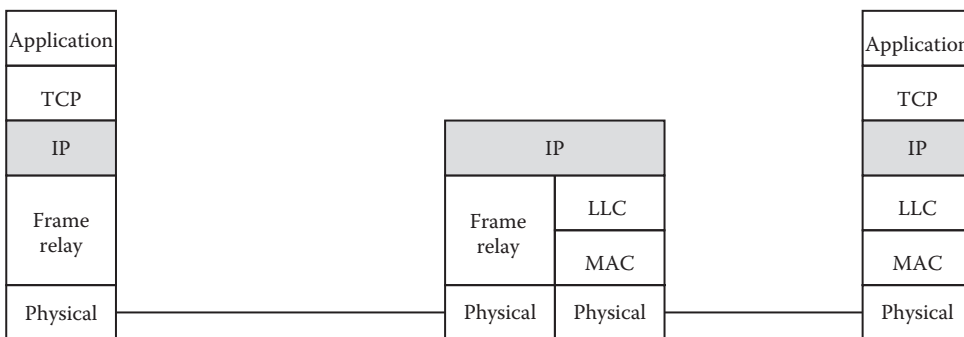

FIGURE 45.3 Configuration for TCP/IP example.

45.3 WAN Organization

Traditionally, data networks have been classified as either WAN or LAN. Although there has been some blurring of this distinction, it is still a useful one. We look first at WANs.

45.3.1 Traditional WANs

Traditional WANs are switched communications networks, consisting of an interconnected collection of nodes, in which information is transmitted from source station to destination station by being routed through the network of nodes. Figure 45.4 is a simplified illustration of the concept. The nodes are connected by transmission paths. Signals entering the network from a station are routed to the destination by being switched from node to node. Two quite different technologies are used in wide-area switched networks: circuit switching and packet switching. These two technologies differ in the way the nodes switch information from one link to another on the way from source to destination.

45.3.1.1 Circuit Switching

Circuit switching is the dominant technology for both voice and data communications today and will remain so for the foreseeable future. Communication via circuit switching implies that there is a dedicated communication path between two stations. That path is a connected sequence of links between network nodes. On each physical link, a channel is dedicated to the connection. The most common example of circuit switching is the telephone network.

FIGURE 45.4 Simple switching network.

Communication via circuit switching involves three phases, which can be explained with reference to Figure 45.4.

1. *Circuit establishment*: Before any signals can be transmitted, an end-to-end (station-to-station) circuit must be established. For example, station *A* sends a request to node 4 requesting a connection to station *E*. Typically, the link from *A* to 4 is a dedicated line, so that part of the connection already exists. Node 4 must find the next leg in a route leading to node 6. Based on routing information and measures of availability and perhaps cost, node 4 selects the link to node 5, allocates a free channel (using frequency-division multiplexing, FDM, or time-division multiplexing, TDM) on that link and sends a message requesting connection to *E*. So far, a dedicated path has been established from *A* through 4 to 5. Since a number of stations may attach to 4, it must be able to establish internal paths from multiple stations to multiple nodes. The remainder of the process proceeds similarly. Node 5 dedicates a channel to node 6 and internally ties that channel to the channel from node 4. Node 6 completes the connection to *E*. In completing the connection, a test is made to determine if *E* is busy or is prepared to accept the connection.
2. *Information transfer*: Information can now be transmitted from *A* through the network to *E*. The transmission may be analog voice, digitized voice, or binary data, depending on the nature of the network. As the carriers evolve to fully integrated digital networks, the use of digital (binary) transmission for both voice and data is becoming the dominant method. The path is: *A*-4 link, internal switching through 4, 4-5 channel, internal switching through 5, 5-6 channel, internal switching through 6 and 6-*E* link. Generally, the connection is full duplex, and signals may be transmitted in both directions simultaneously.
3. *Circuit disconnect*: After some period of information transfer, the connection is terminated, usually by the action of one of the two stations. Signals must be propagated to nodes 4, 5, and 6 to deallocate the dedicated resources.

Note that the connection path is established before data transmission begins. Thus channel capacity must be reserved between each pair of nodes in the path and each node must have available internal switching capacity to handle the requested connection. The switches must have the intelligence to make these allocations and to devise a route through the network.

Circuit switching can be rather inefficient. Channel capacity is dedicated for the duration of a connection, even if no data are being transferred. For a voice connection, utilization may be rather high, but it still does not approach 100%. For a terminal-to-computer connection, the capacity may be idle during most of the time of the connection. In terms of performance, there is a delay prior to signal transfer for call establishment. However, once the circuit is established, the network is effectively transparent to the users. Information is transmitted at a fixed data rate with no delay other than the propagation delay through the transmission links. The delay at each node is negligible.

Circuit-switching technology has been driven by those applications that handle voice traffic. One of the key requirements for voice traffic is that there must be virtually no transmission delay and certainly no variation in delay. A constant signal transmission rate must be maintained, since transmission and reception occur at the same signal rate. These requirements are necessary to allow normal human conversation. Furthermore, the quality of the received signal must be sufficiently high to provide, at a minimum, intelligibility.

45.3.1.2 Packet Switching

A *packet-switching network* is a switched communications network that transmits data in short blocks called packets. The network consists of a set of interconnected packet-switching nodes. A device attaches to the network at one of these nodes and presents data for transmission in the form of a stream of packets. Each packet is routed through the network. As each node along the route is encountered, the packet is received, stored briefly, and then transmitted along a link to the next node in the route. Two approaches are used to manage the transfer and routing of these streams of packets: datagram and virtual circuit.

FIGURE 45.5 (a) Internal Datagram and (b) virtual circuit operation.

In the datagram approach, each packet is treated independently, with no reference to packets that have gone before. This approach is illustrated in Figure 45.5a. Each node chooses the next node on a packet's path, taking into account information received from neighboring nodes on traffic, line failures, and so on. So the packets, each with the same destination address, do not all follow the same route, and they may arrive out of sequence at the exit point. In some networks, the exit node restores the packets to their original order before delivering them to the destination. In other datagram networks, it is up to the destination rather than the exit node to do the reordering. Furthermore, it is possible for a packet to be destroyed in the network. For example, if a packet-switching node crashes momentarily, all of its queued packets may be lost. Again, it is up to either the exit node or the destination to detect the loss of a packet and decide how to recover it. In this technique, each packet, treated independently, is referred to as a datagram.

In the virtual circuit approach, a preplanned route is established before any packets are sent. Once the route is established, all of the packets between a pair of communicating parties follow this same route through the network. This is illustrated in Figure 45.5b. Because the route is fixed for the duration of the logical connection, it is somewhat similar to a circuit in a circuit-switching network and is referred to as a virtual circuit. Each packet now contains a virtual circuit identifier as well as data. Each node on the preestablished route knows where to direct such packets; no routing

decisions are required. At any time, each station can have more than one virtual circuit to any other station and can have virtual circuits to more than one station.

If two stations wish to exchange data over an extended period of time, there are certain advantages to virtual circuits. First, the network may provide services related to the virtual circuit, including sequencing and error control. *Sequencing* refers to the fact that, since all packets follow the same route, they arrive in the original order. *Error control* is a service that assures not only that packets arrive in proper sequence but also that all packets arrive correctly. For example, if a packet in a sequence from node 4 to node 6 fails to arrive at node 6, or arrives with an error, node 6 can request a retransmission of that packet from node 4. Another advantage is that packets should transit the network more rapidly with a virtual circuit; it is not necessary to make a routing decision for each packet at each node.

One advantage of the datagram approach is that the call setup phase is avoided. Thus, if a station wishes to send only one or a few packets, datagram delivery will be quicker. Another advantage of the datagram service is that, because it is more primitive, it is more flexible. For example, if congestion develops in one part of the network, incoming datagrams can be routed away from the congestion. With the use of virtual circuits, packets follow a predefined route, and thus it is more difficult for the network to adapt to congestion. A third advantage is that datagram delivery is inherently more reliable. With the use of virtual circuits, if a node fails, all virtual circuits that pass through that node are lost. With datagram delivery, if a node fails, subsequent packets may find an alternate route that bypasses that node.

45.3.2 High-Speed WANs

As the speed and number of LANs continue their relentless growth, increasing demand is placed on wide-area packet-switching networks to support the tremendous throughput generated by these LANs. In the early days of wide-area networking, X.25 was designed to support direct connection of terminals and computers over long distances. At speeds up to 64 kbps or so, X.25 copes well with these demands. As LANs have come to play an increasing role in the local environment, X.25, with its substantial overhead, is being recognized as an inadequate tool for wide-area networking. Fortunately, several new generations of high-speed switched services for wide-area networking have moved rapidly from the research laboratory and the draft standard stage to the commercially available, standardized-product stage. We look briefly at the most important alternatives in this section.

45.3.2.1 Frame Relay

Both frame relay and X.25 use a virtual-circuit, packet-switching approach to data transmission. Frame relay provides a streamlined technique for wide-area packet switching, compared to X.25. It provides superior performance by eliminating as much as possible of the overhead of X.25. The key differences of frame relaying from a conventional X.25 packet-switching service are the following:

- Call control signaling (e.g., requesting that a connection be set up) is carried on a logical connection that is separate from the connections used to carry user data. Thus, intermediate nodes need not maintain state tables or process messages relating to call control on an individual per-connection basis.
- There are only physical and link layers of processing for frame relay, compared to physical, link, and packet layers for X.25. Thus, one entire layer of processing is eliminated with frame relay.
- There is no hop-by-hop flow control and error control. End-to-end flow control and error control is the responsibility of a higher layer, if it is employed at all.

Frame relay takes advantage of the reliability and fidelity of modern digital facilities to provide faster packet switching than X.25. Whereas X.25 typically operates only up to speeds of about 64 kbps, frame relay is designed to work at access speeds up to 2 Mbps.

Frame relay at one time enjoyed widespread market share. However, today legacy frame relay systems are gradually being phased out in favor of more efficient techniques.

45.3.2.2 Asynchronous Transfer Mode

Frame relay was designed to support access speeds up to 2 Mbps. Although it has evolved to provide services up to 42 Mbps, frame relay is not able to meet the needs of businesses that require wide area access speeds in the hundreds or thousands of megabits per second. One of the first technologies developed to accommodate such gargantuan requirements was asynchronous transfer mode (ATM), also known as *cell relay*.

ATM is similar in concept to frame relay. Both frame relay and ATM take advantage of the reliability and dependability of modern digital facilities to provide faster packet switching than X.25. ATM is even more streamlined than frame relay in its functionality and can support data rates several orders of magnitude greater than frame relay.

The most noteworthy difference between ATM and frame relay is that ATM uses fixed-size packets, called cells, which are of length 53 octets. There are several advantages to the use of small, fixed-size cells. First, the use of small cells may reduce queuing delay for a high-priority cell, because it waits less if it arrives slightly behind a lower-priority cell that has gained access to a resource (e.g., the transmitter). Second, fixed-size cells can be switched more efficiently, which is important for the very high data rates of ATM. With fixed-size cells, it is easier to implement the switching mechanism in hardware.

An ATM network is designed to be able to transfer many different types of traffic simultaneously, including real-time flows such as voice, video, and bursty TCP flows. Although each such traffic flow is handled as a stream of 53 octet cells traveling through a virtual channel (ATM terminology for virtual circuit), the way in which each data flow is handled within the network depends on the characteristics of the traffic flow and the QoS requirements of the application. For example, real-time video traffic must be delivered within minimum variation in delay.

Although the switching mechanism for ATM transmission is very efficient, and very high data rates can be achieved, ATM as a whole is very complex and expensive to implement. As with frame relay, ATM is gradually losing ground to newer approaches to wide-area networking.

45.3.3 Multiprotocol Label Switching

Multiprotocol Label Switching (MPLS) refers to IP-based networking services that are available from a number of carriers. MPLS services are designed to speed up the IP packet-forwarding process while retaining the types of traffic management and connection-oriented QoS mechanisms found in ATM networks.

MPLS is often described as being “protocol agnostic” because it can carry many different kinds of traffic, including ATM cells, IP packets, and Ethernet or SONET frames. Carriers have been able to cost effectively implement MPLS infrastructure because it is possible for MPLS-enabled routers to coexist with ordinary IP routers. MPLS has also been designed to work with ATM and frame relay networks via MPLS-enabled ATM switches and MPLS-enabled frame relay switches.

Because of its ability to provide higher performance network capabilities, MPLS has the potential to completely replace frame relay and ATM. MPLS recognizes that small ATM cells are not needed in the core of modern optical networks with speeds of 40 Gbps or more. In these environments, neither 53-byte cells nor full-length 1500-byte packets experience real-time queuing delays. In addition, MPLS preserves many of the same traffic engineering and out-of-band network control mechanisms that have made frame relay and ATM attractive WAN services for business subscribers.

45.3.3.1 MPLS Operation

An MPLS network or Internet consists of a set of nodes, called *Label Switched Routers (LSRs)* that are capable of switching and routing packets on the basis of a label that has been appended to each packet. Labels define a flow of packets between two endpoints. For each distinct flow, a specific path through the network of LSRs is defined. This path is called a *Forwarding Equivalence Class (FEC)* and each FEC has an associated traffic characterization that defines the QoS requirements for that flow. LSRs forward each packet based on its label value; they do not need to examine or process the packet’s IP header. This means that an LSR’s forwarding process is simpler and faster than that for an IP router.

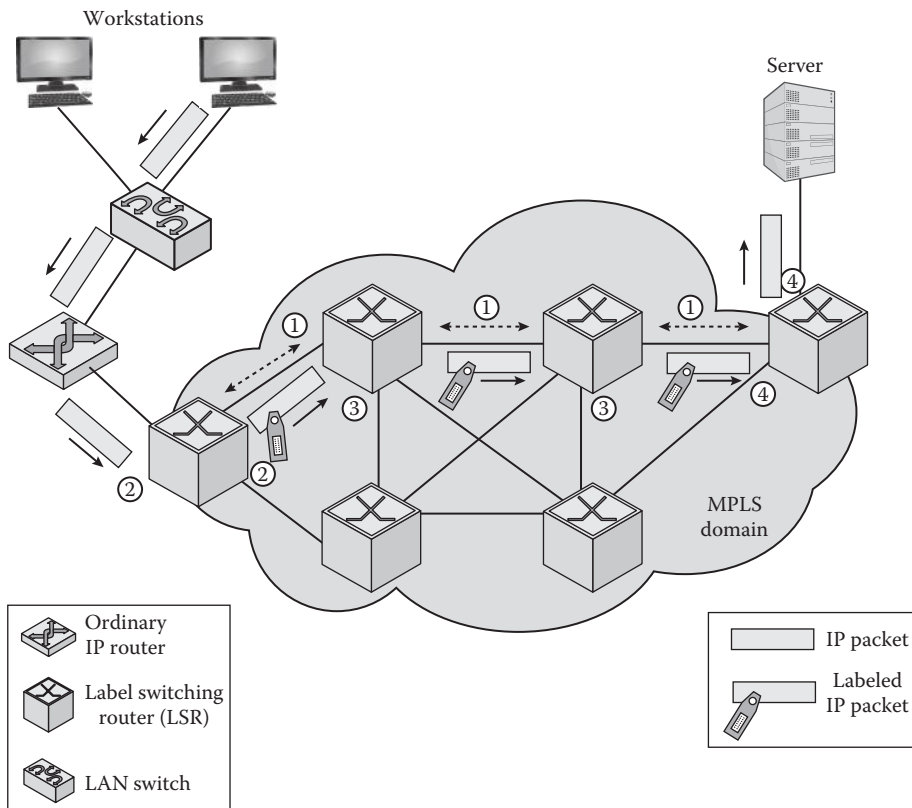

FIGURE 45.6 MPLS operation.

Figure 45.6 illustrates depicts the operation of MPLS within a domain of MPLS-enabled routers. The first step in the process involves establishing a *Label Switched Path (LSP)* for the packets that are to be routed and delivered and the QoS parameters that must be established for the LSP. QoS parameters include the queuing and discarding policy for each LSR along the path and the resources that need to be committed to the path. The process of establishing the LSP and its QoS parameters results in the creation of the FEC; this is illustrated in (1) in Figure 45.6. Once the FEC is created, labels can be assigned to the packets for the FEC.

Packets enter a MPLS switching domain through ingress LSR at the edge of the MPLS network. The ingress LSR processes the packet, determines the QoS services that it requires, and assigns the packet to a FEC and LSP. It then appends the appropriate label and forwards the packet to the next LSR along the LSP. This is illustrated in (2) in Figure 45.6. With the MPLS network, each LSR along the LSP receives the labeled packet and forwards it to the next LSR along the LSP, see (3) in Figure 45.6. When the packet arrives at the egress LSR at the edge of the network closest to the packet's destination, the edge LSR strips the label from the packet, reads its IP packet header, and forwards to packet to its final destination. In the example illustrated in (4) in Figure 45.6, the final destination is a server.

As may be observed in Figure 45.7, an MPLS label is a 32 bit field that includes the following elements:

- Label value: A 20 bit label that has local significance
- Traffic class: A three bit label that signifies QoS priority and explicit network congestion
- Bottom of stack bit: If this is set to 1, it indicates that the current label is the last in the stack
- Time to live: 8 bits are used to encode a hop count or time to live value. This is included to avoid looping or having the packet remain too long in the network because of faulty routing

FIGURE 45.7 MPLS label format.

In short, with MPLS, the first time the packet enters the network, it is assigned to a specific FEC that is indicated in the label that is assigned. Because each router in the network has a table indicating how to handle packets of a specific FEC type, the MPLS network can consistently handle packets with particular characteristics (such as coming from particular ports or carrying traffic of particular application types). Assigning packets to FECs means that packets carrying real-time traffic, such as voice or video, can be mapped to low-latency routes across the network. A key point is that the labels provide a way to attach additional information to each packet that facilitates traffic engineering in ways that are difficult to achieve in IP-networks and other WAN services.

45.3.4 Wide-Area Ethernet

Wide-area Ethernet (WAE) is the delivery of WAN services using Ethernet connectivity. It is a high-speed alternative to traditional WAN services such as frame relay, leased lined, ATM, or T-1 services. WAE maintains the simplicity, high bandwidth, and flat network design of layer 2 Ethernet. To WAE subscribers, connected sites look like one single logical network. WAE is essentially a VPN service for linking remote locations.

FIGURE 45.8 Wide-Area ethernet.

Most WAE implementations use virtual private LAN services (VPLS) to interconnect network endpoints. VPLS allows carriers to define QoS levels for wide area connections and commit resources, such as sufficient bandwidth, for applications such as video or audio. VPLS also enables carriers to create logical Ethernet networks from a variety of WAN services including IP or MPLS networks.

WAE services are sometimes called *Ethernet WAN* or *carrier Ethernet*. Carrier Ethernet includes both WAE and metro Ethernet. Carrier Ethernet services are deployed in several ways, including conventional Ethernet, Ethernet over synchronous digital hierarchy and Ethernet over MPLS. Carrier Ethernet services can accommodate a mixture of residential and business subscribers.

The use of carrier Ethernet technologies to create metropolitan-area networks (MANs) is most commonly called metro Ethernet. Metro Ethernet is often used to provide business LANs and residential subscribers with access to the Internet or other WAN services. Government agencies, educational institutions, and corporations are increasingly using metro Ethernet services to create intranets interconnecting branch offices or campuses.

Carrier Ethernet often capitalizes on the existence of optical fiber and dense wavelength division multiplexing infrastructure to provide WAN and MAN services to subscribers. A high-level example of WAE is provided in Figure 45.8.

45.4 LAN Organization

As with WANs, a LAN is a communications network that interconnects a variety of devices and provides a means for information exchange among those devices. There are several key distinctions between LANs and WANs:

1. The scope of the LAN is small, typically a single building or a cluster of buildings. This difference in geographic scope leads to different technical solutions, as we shall see.
2. It is usually the case that the LAN is owned by the same organization that owns the attached devices. For WANs, this is less often the case, or at least a significant fraction of the network assets is not owned. This has two implications. First, care must be taken in the choice of LAN, because there may be a substantial capital investment (compared to dial-up or leased charges for WANs) for both purchase and maintenance. Second, the network management responsibility for a LAN falls solely on the user.
3. The internal data rates of LANs are typically much greater than those of WANs.

LANs come in a number of different configurations. The most common are switched LANs and wireless LANs. The most common switched LAN is a switched Ethernet LAN, which may consist of a single switch with a number of attached devices, or a number of interconnected switches. Ethernet has come to dominate the wired LAN market, and so this section is devoted to Ethernet systems.

45.4.1 Traditional Ethernet

The Ethernet LAN standard, developed by the IEEE 802.3 standards committee, was originally designed to work over a bus LAN topology. With the bus topology, all stations attach, through appropriate interfacing hardware, directly to a linear transmission medium or bus. A transmission from any station propagates the length of the medium in both directions and can be received by all other stations. A variation on the bus topology is a star topology, with stations attached to a node in such a way that a transmission from any station attached to the node travels to the node and then to all of the other stations attached to the node.

Transmission is in the form of frames containing addresses and user data. Each station monitors the medium and copies frames addressed to itself. Because all stations share a common transmission link,

only one station can successfully transmit at a time, and some form of medium access control technique is needed to regulate access. The technique used for traditional Ethernet is carrier sense multiple access with collision detection (CSMA/CD). CSMA/CD, and the types of Ethernet configurations it supports, is now obsolete and is not discussed further in this chapter.

45.4.2 100 Mbps Ethernet

As data rates for Ethernet increased, the nodes were replaced by switches that enabled full-duplex transmission and in which the access control function is regulated by the switch. This is the general arrangement of all contemporary Ethernet LANs.

The first major step in the evolution of Ethernet was the introduction of 100 Mbps Ethernet. This standard specifies the same frame format as the 10 Mbps version and many of the same protocol details. This version of Ethernet quickly crowded out competing schemes, such as ring-based LANs and ATM-based LANs. The reasons for this are instructive. From the vendor's point of view, the Ethernet formatting and protocol are well understood and vendors have experience building the hardware, firmware, and software for such systems. Scaling the system up to 100 Mbps, or more, is easier than implementing an alternative protocol and topology. From the customer's point of view, it is relatively easy to integrate older Ethernet systems running at 10 Mbps with newer systems running at higher speeds if all the systems use the same frame format and similar access protocols. In other words, the continued use of Ethernet-style LANs is attractive because Ethernet is already there. This same situation is encountered in other areas of data communications. Vendors and customers do not always, or even in the majority of cases, choose the technically superior solution. Cost, ease of management, and other factors relating to the already-existing base of equipment are often more important factors in the selection of new LAN equipment than technically superior alternatives. This is the reason that Ethernet-style systems continue to dominate the LAN market and show every sign of continuing to do so in the foreseeable future.

45.4.3 Gigabit Ethernet

The strategy for Gigabit Ethernet is the same as that for 100 Mbps Ethernet. While defining a new medium and transmission specification, Gigabit Ethernet retains the CSMA/CD protocol and frame format of its 10 and 100 Mbps predecessors. It is compatible with both 100BASE-T and 10BASE-T, preserving a smooth migration path. Most business organizations have moved to 100BASE-T and many have jumped to Gigabit Ethernet for at least some of their LANs. These LANs are putting huge traffic loads on backbone networks, which further increase demand for Gigabit Ethernet and 10 Gigabit Ethernet.

Figure 45.9 shows a typical application of Gigabit Ethernet. A 1/10 Gbps LAN switch provides backbone connectivity for central servers and high-speed workgroup switches. Each workgroup LAN switch supports both 1 Gbps links, to connect to the backbone LAN switch and to support high-performance workgroup servers, and 100 Mbps links, to support high-performance workstations, servers, and 100/1000 Mbps LAN switches.

The current 1 Gbps specification for IEEE 802.3 includes the following physical layer alternatives:

- *1000BASE-LX*: This long-wavelength option supports duplex links of up to 550 m of 62.5 μm or 50 μm multimode fiber or up to 5 km of 10 μm single-mode fiber. Wavelengths are in the range of 1270–1355 nm.
- *1000BASE-SX*: This short-wavelength option supports duplex links of up to 275 m using 62.5 μm multimode or up to 550 m using 50 μm multimode fiber. Wavelengths are in the range of 770–860 nm.

FIGURE 45.9 Example Gigabit ethernet configuration.

- *1000BASE-CX*: This option supports 1 Gbps links among devices located within a single room or equipment rack, using copper jumpers (specialized shielded twisted pair cable that spans no more than 25 m). Each link is composed of a separate shielded twisted pair running in each direction.
- *1000BASE-T*: This option makes use of four pairs of Category 5 unshielded twisted pair to support devices over a range of up to 100 m.

45.4.4 10 Gbps Ethernet

In recent years, 10 Gbps Ethernet switches have made considerable inroads in the LAN market. The principal driving requirement for 10 Gigabit Ethernet is the increase in Internet and intranet traffic. A number of factors contribute to the explosive growth in both Internet and intranet traffic:

- An increase in the number of network connections
- An increase in the connection speed of each end-station (e.g., 10 Mbps users moving to 100 Mbps, analog 56 kbps users moving to DSL and cable modems)
- An increase in the deployment of bandwidth-intensive applications such as high-quality video
- An increase in Web hosting and application hosting traffic

Initially, network managers are using 10 Gbps Ethernet to provide high-speed, local backbone interconnection between large-capacity switches. As the demand for bandwidth increases, 10 Gbps Ethernet will be deployed throughout the entire network and will include server farm, backbone, and

campuswide connectivity. This technology enables Internet service providers (ISPs) and network service providers to create very high-speed links at a low cost, between co-located, carrier-class switches and routers.

The technology also allows the construction of MANs and WANs that connect geographically dispersed LANs between campuses or points of presence. Thus, Ethernet begins to compete with ATM and other wide area transmission/networking technologies. Carrier Ethernet, metro Ethernet, and WAE services are increasingly common components of enterprise networks. In most cases where the primary form of business communications traffic is data and TCP/IP is the preferred mode of transport, 10 Gbps Ethernet provides substantial value over ATM transport for both network end users and service providers:

- No expensive, bandwidth-consuming conversion between Ethernet packets and ATM cells is required; the network is Ethernet, end to end.
- The combination of IP and Ethernet offers quality of service and traffic policing capabilities that approach those provided by ATM, so that advanced traffic engineering technologies are available to users and providers.
- A wide variety of standard optical interfaces (wavelengths and link distances) have been specified for 10 Gbps Ethernet, optimizing its operation and cost for LAN, MAN, or WAN applications.

Maximum link distances for 10 Gbps Ethernet ranges from 300 m to 40 km. The links operate in full-duplex mode only, using a variety of optical fiber physical media. Four physical layer options are defined for 10 Gbps Ethernet:

- *10GBASE-S (short)*: Designed for 850 nm transmission on multimode fiber. This medium can achieve distances up to 300 m.
- *10GBASE-L (long)*: Designed for 1310 nm transmission on single-mode fiber. This medium can achieve distances up to 10 km.
- *10GBASE-E (extended)*: Designed for 1550 nm transmission on single-mode fiber. This medium can achieve distances up to 40 km.
- *10GBASE-LX4*: Designed for 1310 nm transmission on single-mode or multimode fiber. This medium can achieve distances up to 10 km. This medium uses wavelength-division multiplexing to multiplex the bit stream across four light waves.

45.4.5 100 Gbps Ethernet

Ethernet is widely deployed and is the preferred technology for wired local-area networking. Ethernet dominates enterprise LANs, broadband access, data center networking, and has also become popular for communication across metropolitan and even WANs. Furthermore, it is now the preferred carrier wire line vehicle for bridging wireless technologies, such as Wi-Fi and WiMAX, into local Ethernet networks.

This popularity of Ethernet technology is due to the availability of cost-effective, reliable, and interoperable networking products from a variety of vendors. Over the years, a number of industry consortiums have participated in the development of ever-faster versions of Ethernet, including the Fast Ethernet Alliance (100 Mbps), the Gigabit Ethernet Alliance, the 10 Gigabit Ethernet alliance, the Ethernet Alliance, and the Road to 100G alliance. As a testament to the continuing evolution of Ethernet, the first three of the alliances just mentioned no longer exist. The Ethernet Alliance is devoted to promoting the development of Ethernet, whatever the speed. The Road to 100G Alliance is focused on the development of standards and technologies for 100 Gbps ethernet.

As this alliance evolution reflects, the development of converged and unified communications, the evolution of massive server farms, and the continuing expansion of VoIP, TVoIP, and Web 2.0

applications have driven the need for ever faster Ethernet switches. The following are market drivers for 100 Gbps Ethernet:

- *Data center/Internet media providers:* To support the growth of Internet multimedia content and Web applications, content providers have been expanding data centers, pushing 10 Gbps Ethernet to its limits. These providers are likely to be high-volume early adopters of 100 Gbps Ethernet.
- *Metro-video/service providers:* Video on demand has been driving a new generation of 10 Gbps Ethernet metropolitan/core network buildouts. These providers are likely to be high-volume adopters in the medium term.
- *Enterprise LANs:* Continuing growth in convergence of voice/video/data and in unified communications is driving up network switch demands. However, most enterprises still rely on 1 Gbps or a mix of 1 and 10 Gbps Ethernet, and adoption of 100 Gbps Ethernet is likely to be slow.
- *Internet exchanges/ISP (ISP) core routing:* With the massive amount of traffic flowing through these nodes, these installations are likely to be early adopters of 100 Gbps Ethernet.

In 2007, the IEEE 802.3 working group authorized the *IEEE P802.3ba 40 Gb/s and 100 Gb/s Ethernet Task Force*. Table 13.4 indicates the physical layer objectives for this task force. As can be seen, these high-speed switches will be standardized to operate at distances from 1 m to 40 km over a variety of physical media.

An example of the application of 100 Gbps Ethernet is shown in Figure 45.10. The trend at large data centers, with substantial banks of blade servers, is the deployment of 10 Gbps ports on individual servers to handle the massive multimedia traffic provided by these servers. Such arrangements are stressing the on-site switches needed to interconnect large numbers of servers. A 100 GbE rate was proposed to provide the bandwidth required to handle the increased traffic load. It is expected that 100 GbE will be deployed in switch uplinks inside the data center as well as providing interbuilding, intercampus, MAN, and WAN connections for enterprise networks.

The success of fast Ethernet, Gigabit Ethernet, and 10 Gbps Ethernet highlights the importance of network management concerns in choosing a network technology. Both ATM and fiber channel, explored subsequently, may be technically superior choices for a high-speed backbone, because of their flexibility

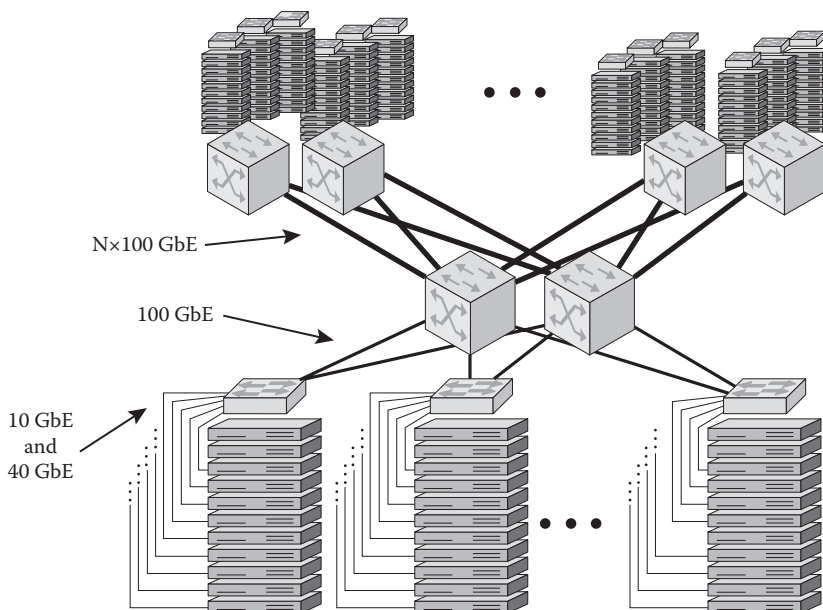

FIGURE 45.10 Example 100-Gbps Ethernet configuration for massive blade server site.

and scalability. However, the Ethernet alternatives offer compatibility with existing installed LANs, network management software, and applications. This compatibility has accounted for the survival of 30-year-old technology in today's fast-evolving network environment.

Key Terms

Asynchronous transfer mode (ATM): A form of packet transmission using fixed-size packets, called cells. Unlike X.25, ATM does not provide error control and flow control mechanisms.

Circuit switching: A method of communicating in which a dedicated communications path is established between two devices through one or more intermediate switching nodes. Unlike packet switching, digital data are sent as a continuous stream of bits. Bandwidth is guaranteed, and delay is essentially limited to propagation time. The telephone system uses circuit switching.

Frame relay: A form of packet switching based on the use of variable-length link-layer frames. There is no network layer and many of the basic functions have been streamlined or eliminated to provide for greater throughput.

Local-area network (LAN): A communication network that provides interconnection of a variety of data communicating devices within a small area.

Packet switching: A method of transmitting messages through a communication network, in which long messages are subdivided into short packets. The packets are then transmitted as in message switching.

Wide-area network (WAN): A communication network that provides interconnection of a variety of communicating devices over a large area, such as a metropolitan area or larger.

46.1 Introduction

The purpose of this chapter is not as a reference on the details of particular implementations but to understand the variety of routing algorithms and the trade-offs between them.

Computer networking can be a very confusing field. Terms such as network, subnetwork, domain, *local area network (LAN)*, internetwork, *bridge*, *router*, and *switch* are often ill-defined. In the original ISO model of network layering, layer 2, the *data-link layer*, was intended to deliver a packet of information to a neighboring machine, and layer 3, the *network layer*, was intended to relay a packet through a series of switches in order to move data from source to destination, and it was intended to be the job of layer 4, the *transport layer* (a protocol between the source and destination), to recover from lost, duplicated, and out-of-order packets. Although this conceptual model of network layers is a great way to learn about networks, in reality, things have gotten extremely complicated. Ethernet, intended to be a layer 2 technology, includes routing. Various other technologies consider it the task of layer 3 to assure no packet loss or misordering. To make it even more difficult to understand this area, various concepts are reinvented in different standards, usually with different terminology, and little available information about how different technologies relate to each other than marketing hype. In this chapter, we discuss various conceptual techniques for moving data throughout a network, and rather than focusing on the details of a particular standard or deployed technology, we focus on the concepts. We also avoid philosophical questions such as which layer something is.

FIGURE 46.1 A multiaccess link and a packet with two headers.

A network consists of several nodes interconnected with various types of links. One type is a *point-to-point link*, which connects exactly two machines. It can either be a dedicated link (e.g., a wire connecting the two machines) or a dial-on-demand link, which can be connected when needed (e.g., when there is traffic to send over the link). Another category of link is a *multiaccess link*. Examples are wireless links, wired LANs, or entire networks that machines can talk to each other across. When one protocol uses a network as a link, it is referred to as a *tunnel*. In such a case, the underlying network can be used to create a point-to-point link between two machines, or a multiaccess link between more than two machines. The underlying network could be something generally assumed to be layer 2 (such as Ethernet) or it could be something generally assumed to be layer 3 (such as IP). A tunneled link presents special challenges to the routing protocol because it has two headers with addressing information. One header (which for simplicity we call the layer 3 header) gives the addresses of the ultimate source and destination. The other header (which for simplicity we call the layer 2 header) gives the addresses of the transmitter and receiver on that particular link (see Figure 46.1, which shows a path incorporating a multiaccess link and a packet with two headers). The terminology cannot be taken too seriously. It is not uncommon to tunnel IP over IP; for example, for an employee to connect to the corporate firewall across the Internet, using an encrypted connection (usually referred to as a “virtual Private Network”). Although the “data link” in that case is an entire network, from the point of view of the protocols using it as a link, it can be considered just a data link.

We define a *switch* to be a device that receives a data packet from the network, uses information in the data packet (e.g., the destination address in the header), plus instructions that are in the switch’s *forwarding table*, and then follows those instructions, for example, forwarding the packet onto the indicated output port. We use the term *switch* to include devices that are known as bridges, routers, gateways, and perhaps other names in this chapter. In this chapter, we describe various possibilities, and their implications, for

- Information in the packet, for example, size of address
- How to find instructions for a particular packet in the forwarding table
- How the forwarding table is computed

46.2 Forwarding Table

When a switch receives a packet, it finds relevant information in the packet, and consults its forwarding table, to determine the proper output port onto which to forward the packet. The forwarding table might indicate a single output port, or a set of output ports, any of which are reasonable for the switch to use for forwarding this packet.

46.2.1 Keeping Packets in Order

If the forwarding table gives several output ports rather than a single answer, any of those ports will deliver the packet to the destination; however, many applications that run over a network have come to depend on the network trying really hard to deliver packets for a particular flow in the same order

in which they were transmitted. As network protocols are generally taught, it is assumed that layer 3 is allowed to send packets in any order, and it is up to layer 4, the *transport layer* (e.g., the TCP protocol) to put packets back into order. However, applications (including many implementations of TCP) perform badly if the network is allowed to reorder packets within a flow. Therefore, switches tend to be careful to keep packets in order. There are several ways of doing this:

1. If the forwarding table gives just a single output port for a particular destination, then all packets for a flow will travel on the same path, so they will not get out of order. If it is desired that packets to the same destination exploit parallel paths (“load splitting” or “path splitting”), then the destination is given multiple addresses, and occupies two entries in the forwarding table. This is the approach generally used in InfiniBand.
2. If the forwarding table gives a set of output ports, then the switch parses the packet to look at additional information beyond the information in the switch’s layer and hashes that information in order to always choose the same output port for a given flow. For instance, if the switch is an IP router, the switch looks beyond the IP header to other information, such as the TCP ports, and hashes fields such as (IP source address, TCP source port, and TCP destination port), and if the forwarding table has indicated, say, five different equally good output ports to get to the destination, the switch might compute the hash mod 5 of those fields. In theory, the switch could choose whichever port was most convenient when it first sees a packet for a given flow and remember that choice, but the hashing procedure allows the switch to accomplish the same thing without keeping state.
3. The packet might contain an “entropy” field, which is specifically for the purpose of choosing a port from a set of ports. There are two reasons for the entropy field instead of doing the hash of fields such as (source IP and TCP ports):
 - a. It saves work for the switch, since it can use the single entropy field, right in the header that the switch is supposed to look at, rather than having to parse through other layers to find enough information to allow path diversity between flows.
 - b. It allows a single source to exploit path diversity to the same destination, in the case where the application does not require packets to stay in order, or if certain subflows of information between the source–destination pair might need to be in order, but independently of the other subflows. If the source sets the entropy field differently for different subflows, it is likely that at least some switches along the path will make different forwarding choices for the different subflows.

46.2.2 Distributed vs. Centralized Forwarding Table Computation

The forwarding table might be computed with a distributed routing protocol (which we will describe later in this chapter) or by a central node that computes tables for each of the switches and programs the switches. It might be computed only after a topology change (e.g., a link or switch failing or recovering) or each time a new flow of information is initiated between a source S and destination D. We will discuss the tradeoffs between these approaches.

The advantages of a distributed algorithm are as follows:

- A distributed algorithm will react more quickly to topology changes; with a distributed algorithm (as we will discuss later in this chapter), information about the link change travels as quickly as physically possible, from the event, and each switch then adjusts its own forwarding table. With a centralized algorithm, news of the topology change must be conveyed to the central node (somehow—the topology change could affect a switch’s configured path to the central node), the central node has to compute new forwarding tables for the switches, and then configure each switch with the new forwarding table.
- There is no central point of failure or bottleneck (as there would be with a centralized algorithm if the central node fails, or is a performance bottleneck).

The reasons some give for a centralized algorithm are as follows:

- It might make the switches simpler because they do not need to implement a routing algorithm. However, a routing algorithm does not make a switch expensive; rather, it is the specialized hardware necessary to move packets quickly through the ports, which needs to be done; however, the forwarding table was computed.
- A centralized algorithm might enable more careful engineering of flows, given other knowledge like which flows will exist and what their bandwidth requirements are. Such things could also be done with a distributed algorithm by changing link costs or creating some paths with reserved bandwidth, but it might be easier with a centralized algorithm.

Most networks today (e.g., the IP-based Internet and Ethernet) use distributed algorithms for computing the forwarding table. Telephony networks of old and InfiniBand (www.infinibandta.org) tend to use a centralized algorithm.

46.2.3 On-Demand vs. Proactive Computation of Paths

The other issue is whether paths should be created “on demand,” that is, when a flow starts or whether the switches should always be prepared for any type of packet. Computing the forwarding tables when a new flow starts causes a delay before packets can flow, which, in most cases, will be unacceptable.

In the case of telephony networks of old (e.g., ATM and X.25), the assumptions that made on-demand computation of a path a reasonable choice were as follows:

- The total number of destinations was far greater than the number of actively communicating pairs at any time, so a value in the header indicating the flow, assigned at the time the flow started, could be a smaller field than a field that indicated a destination address.
- It was acceptable to have a delay when a flow started up for the call to be dialed.
- It was acceptable to indicate, for instance, using a “fast busy signal,” that there are temporarily no resources to set up the call.

These assumptions are not valid in a data center or the Internet.

46.3 Information in Data Packet

When a switch receives a data packet, what information in that packet does it use to make its forwarding decision? There are various possibilities, and we will discuss the tradeoffs:

- *Flat destination address*: A destination address that is “flat,” meaning that the location of a node has no relation to its address; there must be a separate entry for each destination address in the forwarding table.
- *Hierarchical destination address*: A destination address that is hierarchical, meaning that portions of the network can be summarized with a block of addresses, and appear as a single entry in the forwarding table.
- *Path Label*: A path identifier (ID) of significance only on a link; (e.g., as used in X.25, ATM, and MPLS). At each hop, a switch looks up (input port and label 1) and is told by the forwarding table (output port and label 2). The switch not only forwards onto the indicated output port but also replaces label 1 (in the received packet) with label 2.
- *Flow*: The forwarding table gives instructions more specific than simply a destination address (e.g., source address, destination address, source TCP port, destination TCP port, and protocol type).

46.3.1 Flat Destination Address

The forwarding table consists of a set of entries {destination, port(s)}. Each destination occupies a table entry. If a node moves, its address does not change, but the forwarding entry for that node in any particular switch will likely change to be a different port.

Flat addresses are convenient, especially in a data center with virtual machines that might move from one server to another; a virtual machine can move without changing its address. However, the problem with flat addresses is that the forwarding table needs an entry for each destination, so there is a limit to the size of a network that can be created with flat addresses.

For this reason, large networks are based on hierarchical addresses.

46.3.2 Hierarchical Destination Address

Hierarchical addresses are assigned in such a way that a set of addresses can be summarized with a prefix, as in “all addresses that start with 372 are in this circle.”

Figure 46.2 shows hierarchical addresses, with multiple levels of hierarchy. The forwarding table of a switch outside the large circle needs only a single forwarding entry for all the nodes inside the circle; the prefix “372.” A switch inside the large circle but outside the circle labeled 37279* needs a single forwarding entry for the nodes in the circle 37279*, and likewise, if it is outside the 3725* circle, it only needs a single entry for those nodes.

Hierarchical addresses compress the forwarding table but sometimes lead to suboptimal paths, because forwarding tables will not distinguish the best point to enter a circle.

An address prefix summarizes a set of addresses. The shorter the prefix, the more addresses are in the summary. In other words, the prefix 2* contains more addresses than the prefix 245*.

When a forwarding table contains prefixes, there might be several prefixes that match the destination address, for instance, for a destination 123456789, the prefixes 12345*, 123*, and * all match. Usually, a forwarding table will contain the zero length prefix, which matches anything. The switch needs to find the most specific match, that is, the longest prefix that matches the destination. There are at least two algorithms for doing this, which are described in detail in Perlman (1999). Although these algorithms are certainly implementable, they are more work, and slower, for a switch, than doing a hash of the

FIGURE 46.2 Hierarchical addressing.

destination address to find the entry (as would be done with, say, a 6 byte Ethernet address) or doing a direct lookup (if the destination is few enough bits so that the switch can have a table directly indexed by the destination address).

46.3.3 Path Label

A path label is a field in a packet that is only significant within the scope of a link. A switch's forwarding table maps (input port and label) to (output port and label). An entry $((p1,x); (p2,y))$ means that if a packet is received on port $p1$ with label x , the switch should forward it onto port $p2$ and replace the label with y .

A path label represents a source–destination pair. Therefore, if all nodes can talk to all other nodes, the forwarding tables using path labels would have n^2 entries, whereas with destination-based forwarding, the table would only need to have $O(n)$ entries.

The path label approach was invented for telephony networks such as X.25 and ATM. The concept was based on the following three assumptions:

- The total number of addressable nodes attached to the network is much greater than the number of active connections between nodes.
- It is acceptable to incur a delay while a path is set up, before two nodes can communicate.
- It is acceptable if there is currently no available labels on a link, or other state required at a switch to support a particular flow, to allow the connection to fail, with some signal to “try again later.” In the U.S. telephone network, this was signaled to the person making a call with a fast busy signal.

A commonly used protocol in the Internet, in backbone ISPs, is MPLS. It uses path labels. A path across the ISP is used for many conversations, and the actual end points are identifiable because the MPLS label encapsulates an IP header. MPLS grew out of a concept known as “tag switching,” in which a switch $S1$ requested that its neighbor $S2$ put a “label” on a packet for a particular destination, to save $S1$ from having to do a longest prefix match for that destination. Today, MPLS is primarily used for “traffic engineering,” which means configuring a path. The concept of encapsulating an IP (or other) packet with a header that is easier to parse (i.e., not needing to do longest prefix match) is a good one, but MPLS would have been more scalable if it had been based on destinations rather than path labels.

46.3.4 Flow

This approach envisions a forwarding table entry for every conversation; not just a source–destination pair, but using TCP port numbers to distinguish different conversations from the same communicating node pair. The thinking behind this approach is to choose different paths for different flows in order to spread the traffic among a lot of links.

However, this approach obviously makes the forwarding table much larger; even worse, in fact, than the path label approach, since the path label approach can have many connections share the same path, but the flow approach requires a separate forwarding table for each flow.

And if the desire is to spread traffic among many links, it is far better to use a destination-based approach where the forwarding table gives the switch a set of ports to choose between. A switch is in a better position to know which ports are congested at this moment in time.

In some rare cases, flows might be high enough bandwidth, and sufficiently long-lived, that it might be worth creating paths with reservations for those flows, but most flows will be bursty, and the amount of congestion at a port will be constantly varying, so that the best place to make the decision is at the switch.

If a switch must keep packets in order, it can still re-hash which packets should travel on which ports, if some ports are getting too much use.

46.4 Distributed Routing Protocols

There are two basic types of distributed routing protocol:

- Distance vector
- Link state

In both cases, switches communicate with other switches to exchange information, and based on this information, each switch computes its own forwarding table.

An example of a distance vector protocol is RIP (Hedrick, 1988). The spanning tree algorithm used in Ethernet, which will be described later in this chapter, can arguably be called a variant of distance vector as can the Border Gateway protocol (BGP) (Rekhter et al., 2006), which is sometimes called a “path vector” protocol, and which will also be described later in this chapter. EIGRP (http://www.cisco.com/en/US/tech/tk365/technologies_tech_note09186a0080093f07.shtml) is a Cisco proprietary distance vector protocol.

The two best-known link state protocols are IS-IS (Oran, 1990) and OSPF (Moy, 1998).

46.4.1 Distance Vector

The idea behind this class of algorithm is that each router is responsible for keeping a table (known as a distance vector) of distances from itself to each destination. It computes this table based on receipt of distance vectors from its neighbors. For each destination D, router R computes its distance to D as follows:

- 0, if R = D.
- The configured cost, if D is directly connected to R.
- The minimum cost through each of the reported paths through the neighbors.

For example, suppose R has four ports, a, b, c, and d. Suppose also that the cost of each of the links is, respectively, 2, 4, 3, and 5. On port a, R has received the report that D is reachable at a cost of 7. The other (port and cost) pairs R has heard are (b, 6), (c, 10), and (d, 2). Then, the cost to D through port a will be 2 (cost to traverse that link) + 7, that is, 9. The cost through b will be 4 + 6, that is, 10. The cost through c will be 3 + 10, that is, 13. The cost through d will be 5 + 2, that is, 7. So the best path to D is through port d, and R will report that it can reach D at a cost of 7 (see Figure 46.3).

The spanning tree algorithm is similar to a distance vector protocol in which each bridge is only computing its cost and path to a single destination, the root. But the spanning tree algorithm does not suffer from the count-to-infinity behavior that distance vector protocols are prone to (see next section).

FIGURE 46.3 Example: distance vector protocol.

FIGURE 46.4 Example: the count-to-infinity problem.

46.4.1.1 Count to Infinity

One of the problems with distance vector protocols is known as the count-to-infinity problem. Imagine a network with three nodes, A, B, and C (see Figure 46.4).

Let us discuss everyone's distance to C. Node C will be 0 from itself, B will be 1 from C, and A will be 2 from C. When C crashes, B unfortunately does not conclude that C is unreachable, but instead goes to its next best path, which is via neighbor A, who claims to be able to reach C at a cost of 2. So now B concludes it is 3 from C and that it should forward packets for C through A. When B tells A its new distance vector, A does not get too upset. It merely concludes its path (still through B) has gotten a little worse, and now A is 4 from C. Node A will report this to B, which will update its cost to C as 5, and A and B will continue this until they count to infinity. Infinity, in this case, is mercifully not the mathematical definition of infinity, but is instead a parameter (with a definite finite value such as 16). Routers conclude if the cost to a node is greater than this parameter, that node must be unreachable.

A common enhancement that makes the behavior a little better is known as *split horizon*. The split horizon rule is usually implemented as follows: if router R uses neighbor N as its best path to destination D, R should not tell N that R can reach D. This eliminates loops of two routers. For instance, in Figure 46.4, node A would not have told B that A could reach C. Thus, when C crashed, B would conclude B could not reach C at all; and when B reported infinity to A, node A would conclude that A could not reach C either, and everything would work as we would hope it would.

Unfortunately, split horizon does not fix loops of three or more routers. Referring to Figure 46.5, and looking at distances to D, when D crashes, C will conclude C cannot reach D (because of the split horizon rule, A and B are not reporting to C that they can reach D).

Node C will inform A and B that C can no longer reach D. Unfortunately, each of them thinks they have a next-best path through the other. Say A acts first, decides its best path is through B, and that A is now 3 from D. Node A will report infinity to B (because of split horizon), and report 3 to C. B will now (for a moment) think it cannot reach D. It will report infinity to A, but it is too late; A has already reported a finite cost to C. Node C will now report 4 to B, which will now conclude it is 5 from D.

Although split horizon does not solve the problem, it is a simple enhancement, never does any harm, does not add overhead, and helps in many cases.

The simplest distance vector protocols (e.g., RIP) are very slow to converge after a topology change. The idea is that routing information is periodically transmitted quite frequently (on the order of 30 s). Information is discarded if it has not been heard recently (on the order of 2 min). Most implementations only store the best path; and when that path fails, they need to wait for their neighbors' periodic

FIGURE 46.5 Example: loops with three or more routers.

transmissions in order to hear about the second best path. Some implementations query their neighbors (“do you know how to reach D?”) when the path to D is discarded. In some implementations when R discards its route to D (for instance, it times out), R lets its neighbors know that R has discarded the route, by telling the neighbors R’s cost to D is now infinity. In other implementations, after R times out the route, R will merely stop advertising the route, so R’s neighbors will need to time out the route (starting from when R timed out the route).

Distance vector protocols need not be periodic. The distance vector protocol used for DECnet Phases 3 and 4 transmits routing information reliably and only sends information that has changed. Information on a LAN is sent periodically (rather than collecting acknowledgments (ack’s) from all router neighbors), but the purpose of sending it periodically is solely as an alternative to sending ack’s. Distance vector information is not timed out in DECnet, as it is in a RIP-like protocol. Instead, there is a separate protocol in which “Hello” messages are broadcast on the LAN to detect a dead router. If a “Hello” is not received in time, the neighbor router is assumed dead and its distance vector is discarded.

Another variation from the RIP-family of distance vectors is to store the entire received distance vector from each neighbor, rather than only keeping the best report for each destination. Then, when information must be discarded (e.g., due to having that neighbor report infinity for some destination or due to that neighbor being declared dead) information for finding an alternative path is available immediately.

There are variations proposed to solve the count-to-infinity behavior. One variation has been implemented in BGP. Instead of just reporting a cost to destination D, a router reports the entire path from itself to D. This eliminates loops but has high overhead. Another variation proposed by Garcia-Luna-Aceves (1989) and implemented in the proprietary protocol EIGRP involves sending a message in the opposite direction of D, when the path to D gets worse, and not switching over to a next-best path until ack’s are received indicating that the information has been received by the downstream subtree. These variations may improve convergence to be comparable to link state protocols, but they also erode the chief advantage of distance vector protocols, which is their simplicity.

46.4.2 Link State Protocols

The idea behind a link state protocol is that each router R is responsible for the following:

- Identifying its neighbors
- Constructing a special packet known as a *link state packet* (LSP) that identifies R and lists R’s neighbors (and the cost to each neighbor)
- Cooperating with all of the routers to reliably broadcast LSPs to all the routers
- Keeping a database of the most recently generated LSP from each other router
- Using the LSP database to calculate routes

Identifying neighbors and constructing an LSP is straightforward. Calculating routes using the LSP database is also straightforward. Most implementations use a variation of the shortest path algorithm attributed to Dijkstra. The tricky part is reliably broadcasting the LSP. The original link state algorithm was implemented in the ARPANET. Its LSP distribution mechanism had the unfortunate property that if LSPs from the same source, but with three different sequence numbers, were injected into the network, these LSPs would turn into a virus. Every time a router processed one of them, it would generate more copies, and so the harder the routers worked, the more copies of the LSP would exist in the system. The problem was analyzed and a stable distribution scheme was proposed in Perlman (1983). The protocol was further refined for the IS-IS routing protocol and copied in OSPF (see next section).

One advantage of link state protocols is that they converge quickly. As soon as a router notices one of its links has changed (going up or down), it broadcasts an updated LSP, which propagates in a straight line outwards (in contrast to a distance vector protocol where information might sometimes be ping-ponged back and forth before proceeding further or where propagation of the information is delayed waiting for news from downstream nodes that the current path’s demise has been received by all nodes).

Link state protocols have other advantages as well. The LSP database gives complete information, which is useful for managing the network, mapping the network, or constructing custom routes for complex policy reasons (Clark, 1989) or for sabotage-proof routing (Perlman, 1988).

46.4.2.1 Reliable Distribution of LSPs

Each LSP contains

- Identity of the node that generated the LSP
- A sequence number large enough to never wrap around except if errors occur (e.g., 64 bits)
- An age field, estimating time since source generated the LSP
- Other information

Each router keeps a database of the LSP with the largest sequence number seen thus far from each source. The purpose of the age field is to eventually eliminate a LSP from a source that does not exist anymore or that has been down for a very long time. It also serves to get rid of an LSP that is corrupted or for which the sequence number has reached the largest value.

For each LSP, a router R has a table, for each of R's neighbors, as to whether R and the neighbor N are *in sync* with respect to that LSP. The possibilities are as follows:

- R and N are in sync. R does not need to send anything to N about this LSP.
- R thinks N has not yet seen this LSP. R needs to periodically retransmit this LSP to N until N acknowledges it.
- R thinks N does not know R has the LSP. R needs to send N an ack for this LSP.

Router R goes through the list of LSPs round-robin, for each link, and transmits LSPs or acks as indicated. If R sends an ack to N, R changes the state of that LSP for N to be in sync.

The state of an LSP gets set as follows:

- If R receives a new LSP from neighbor N, R overwrites the one in memory (if any) with smaller sequence number, sets send ack for N, and sets send LSP for each of R's other neighbors.
- If R receives an ack for an LSP from neighbor N, R sets the flag for that LSP to be in sync.
- If R receives a duplicate LSP or older LSP from neighbor N, R sets the flag for the LSP in memory (the one with higher sequence number) to send LSP.
- After R transmits an ack for an LSP to N, R changes the state of that LSP to in sync.

If an LSP's age expires, it is important that all of the routers purge the LSP at about the same time. The age is a field that is set to some value by the source and is counted down. In this way, the source can control how long it will last. If R decides that an LSP's age has expired, R refloods it to R's neighbors (by setting the state to send LSP). If R receives an LSP with the same sequence number as one stored, but the received one has zero age, R sets the LSP's age to 0 and floods it to its neighbors. If R does not have an LSP in memory and receives one with zero age, R acks it but does not store it or reflood it.

46.4.2.2 Calculating Routes Based on Link State Information

Given an LSP database, the most popular method of computing routes is to use some variant of an algorithm attributed to Dijkstra. The algorithm involves having each router compute a tree of shortest paths from itself to each destination. Each node on the tree has a value associated with it which is the cost from the root to that node. The algorithm is as follows:

- Step 0: put yourself, with cost 0, on the tree as root.
- Step 1: examine the LSP of the node X just put on the tree. For each neighbor N listed in X's LSP, add X's cost in the LSP to the cost to X to get some number c. If c is smaller than any path to N found so far, place N tentatively in the tree, with cost c.
- Step 2: find the node tentatively in the tree with smallest associated cost c. Place that node permanently in the tree. Go to step 1.

46.5 Evolution of Ethernet from Carrier Sense Multiple Access with Collision Detect to TRansparent Interconnection of Lots of Links

Originally routing was supposed to be done at layer 3; but today, “Ethernet” is a network with multiple links and switches that forward packets along a path. The only way to understand why this is, is to understand the history.

Indeed, originally routing was done at layer 3, and layer 2 was for getting a piece of information from a node to an immediate neighbor. Ethernet was intended to be a single shared link, using a contention protocol known as carrier sense multiple access with collision detect (CSMA/CD). Layer 3 should have been used to interconnect different links.

Unfortunately, many people started implementing protocols directly on Ethernet, omitting layer 3. That meant their protocol could not work beyond the scalability of the original CSMA/CD Ethernet.

This was short-sighted. Indeed, it was desired for those protocols to work beyond a single link. But rather than changing all of the Ethernet endnodes, Digital Equipment Corporation designed (and IEEE eventually adopted) the concept of the “transparent bridge.” The goal was to be able to interconnect links without needing to change the endnodes. And there was a fixed maximum size of an Ethernet packet, so nothing could be modified in an Ethernet packet. The transparent bridge concept can work on any sort of link, even though usually today the links are Ethernet.

The basic idea of a transparent bridge is that on each port, the bridge listens promiscuously to all packets, stores them, and forwards each packet onto each other port when given permission by the LAN protocol on that port (e.g., if it were a token ring, when the port received the token, or if it were an Ethernet, when the link was idle). An enhancement is to have the bridge learn, based on addresses in the LAN header of packets received by the bridge, where the stations reside, so that the bridge does not unnecessarily forward packets (see Figure 46.6, where a bridge has learned some of the station addresses). The bridge learns from the source field in the LAN header and forwards based on the destination address. For example, in Figure 46.6, when S transmits a packet with destination address D, the bridge learns which interface S resides on, and then looks to see if it has already learned where D resides. If the bridge does not know where D is, then the bridge forwards the packet onto all interfaces (except the one from which the packet was received). If the bridge does know where D is, then the bridge forwards it only onto the interface where D resides, or if the packet arrived from that interface, the bridge discards the packet.

This created the need for the spanning tree algorithm (Perlman, 1985).

46.5.1 Transparent Bridging

The goal of transparent bridging was to invent a box that would interconnect LANs even though the stations were designed with protocols that only worked on a LAN; that is, they lacked a network layer able to cooperate with routers, devices that were designed for forwarding packets.

FIGURE 46.6 A bridge learning station addresses.

The basic idea of a transparent bridge is something that is attached to two or more LANs. On each LAN, the bridge listens promiscuously to all packets, stores them, and forwards each packet onto each other LAN when given permission by the LAN protocol on that LAN. An enhancement is to have the bridge learn, based on addresses in the LAN header, of packets received by the bridge, where the stations reside, so that the bridge does not unnecessarily forward packets (see Figure 46.6, where a bridge has learned some of the station addresses). The bridge learns from the source field in the LAN header and forwards based on the destination address. For example, in Figure 46.6, when S transmits a packet with destination address D, the bridge learns which interface S resides on, and then looks to see if it has already learned where D resides. If the bridge does not know where D is, then the bridge forwards the packet onto all interfaces (except the one from which the packet was received). If the bridge does know where D is, then the bridge forwards it only onto the interface where D resides, or if the packet arrived from that interface, the bridge discards the packet.

46.5.1.1 Spanning Tree Algorithm

The spanning tree algorithm is a very simple variant on distance vector, where all bridges calculate their path to a single destination; the root bridge. The tree of shortest paths from that root bridge to each LAN and each bridge is the calculated spanning tree.

46.5.1.1.1 Finding the Tree

How do the bridges decide on the root? Each bridge comes, at manufacture time, with a globally unique 48-bit *IEEE 802 address*, usually one per interface. A bridge chooses one of the 48-bit addresses that it owns as its ID. Because each bridge has a unique number, it is a simple matter to choose the one with the smallest number. However, because some network managers like to easily influence which bridge will be chosen, there is a configurable priority value that acts as a more significant field tacked onto the ID. The concatenated number consisting of priority and ID is used in the election, and the bridge with the smallest value is chosen as the root. The way in which the election proceeds is that each bridge assumes itself to be the root unless it hears, through spanning tree configuration messages, of a bridge with a smaller value for priority/ID. News of other bridges is learned through receipt of spanning tree configuration messages, which we describe shortly.

The next step is for a bridge to determine its best path to the root bridge and its own cost to the root. This information is also discovered through receipt of spanning tree configuration messages.

A spanning tree configuration message contains the following, among other information:

- Priority/ID of best known root
- Cost from transmitting bridge to root
- Priority/ID of transmitting bridge

A bridge keeps the best configuration message received on each of its interfaces. The fields in the message are concatenated together, from most significant to least significant, as root's priority/ID to cost to root to priority/ID of transmitting bridge. This concatenated quantity is used to compare messages. The one with the smaller quantity is considered better. In other words, only information about the best-known root is relevant. Then, information from the bridge closest to that root is considered, and then the priority/ID of the transmitting bridge is used to break ties.

Given a best received message on each interface, B chooses the root as follows:

- Itself, if its own priority/ID beats any of the received value, else
- The smallest received priority/ID value B chooses its path to the root as follows:
 - Itself, if it considers itself to be the root, else
 - The minimum cost through each of its interfaces to the best-known root

Each interface has a cost associated with it, either as a default or configured. The bridge adds the interface cost to the cost in the received configuration message to determine its cost through that interface.

B chooses its own cost to the root as follows:

- 0, if it considers itself to be the root, else
- The cost of the minimum cost path chosen in the previous step

Node B now knows what it would transmit as a configuration message, because it knows the root's priority/ID, its own cost to that root, and its own priority/ID. If B's configuration message is better than any of the received configuration messages on an interface, then B considers itself the *designated bridge* on that interface and transmits configuration messages on that interface. If B is not the designated bridge on an interface, then B will not transmit configuration messages on that interface.

Each bridge determines which of its interfaces are in the spanning tree. The interfaces in the spanning tree are as follows:

- The bridge's path to the root: if more than one interface gives the same minimal cost, then exactly one is chosen. Furthermore, if this bridge is the root, then there is no such interface.
- Any interfaces for which the bridge is designated bridge are in the spanning tree.

If an interface is not in the spanning tree, the bridge continues running the spanning tree algorithm but does not transmit any data messages (messages other than spanning tree protocol messages) to that interface and ignores any data messages received on that interface.

If the topology is considered a graph with two types of nodes, bridges, and LANs, the following is the reasoning behind why this yields a tree:

- The root bridge is the root of the tree.
- The unique parent of a LAN is the designated bridge.
- The unique parent of a bridge is the interface that is the best path from that bridge to the root.

46.5.1.1.2 Dealing with Failures

The root bridge periodically transmits configuration messages (with a configurable timer on the order of 1 s). Each bridge transmits a configuration message on each interface for which it is designated, after receiving one on the interface which is that bridge's path to the root. If some time elapses (a configurable value with default on the order of 15 s) in which a bridge does not receive a configuration message on an interface, the configuration message learned on that interface is discarded.

In this way, roughly 15 s after the root or the path to the root has failed, a bridge will discard all information about that root, assume itself to be the root, and the spanning algorithm will compute a new tree.

46.5.1.1.3 Avoiding Temporary Loops

In a routing algorithm, the nodes learn information at different times. During the time after a topology change and before all nodes have adapted to the new topology, there are temporary loops or temporary partitions (no way to get from some place to some other place). Because temporary loops are so disastrous with bridges (because of the packet proliferation problem), bridges are conservative about bringing an interface into the spanning tree. There is a timer (on the order of 30 s, but configurable). If an interface was not in the spanning tree, but new events convince the bridge that the interface should be in the spanning tree, the bridge waits for this timer to expire before forwarding data messages to and from the interface.

IEEE has replaced the timer mechanism of avoiding temporary loops with a complex interlock mechanism of coordinating with neighbors before turning on ports, which allows faster failover. This variant of spanning tree is known as rapid spanning tree protocol.

46.5.2 TRansparent Interconnection of Lots of Links

Once everyone fixed the mistake of omitting layer 3 from network stacks, and having most protocols run directly on top of layer 3, and given that everyone has agreed on a single layer 3 protocol (IPv4, atleast for now), why have not transparent bridges been replaced by IP routers?

A true layer 3 protocol has advantages over spanning tree:

- Spanning tree does not yield shortest paths between any two nodes. For instance, if the topology is a big circle, spanning tree must refrain from using some links. Nodes on either side of that link have to take a long path between each other.
- Not all links can be utilized, so traffic is concentrated on links in the tree and other links are idle.
- For subtle reasons, if spanning tree switches do not have the computational capacity to process every incoming packet, loops can form, which are disastrous because of the lack of a hop count to detect infinitely circulating packets.

However, IP as a layer 3 protocol has disadvantages. In IP, each link has its own block of addresses. If you have a block of IP addresses and want to use them for a network, you have to carve up the address space to make a unique prefix for each link, you have to configure all the routers to know which address blocks are on which of their ports; and if a node moves to a different link, it must change its IP address.

Layer 3 does not need to work that way. In particular, ISO's version of IP, known as ConnectionLess Network Protocol (CLNP), had a 20 byte address. The top 14 bytes were the prefix for an entire cloud of links. The bottom six bytes indicated the node within that cloud.

Routing between clouds was similar to IP, in that the top 14 bytes could be used hierarchically, with routing to the longest prefix match. Within a cloud, endnodes announced their presence to their local router, which announced its endnodes to the other routers in the cloud. If a packet's 14 byte prefix indicated "this cloud," then routers in the cloud routed to the specific endnode.

So with CLNP, there was a large cloud with a flat address space. Routers within a cloud need not be configured; someone in the cloud needed to know the cloud's 14 byte prefix and inform the rest of the routers. Nodes could move within the cloud without changing their address.

But unfortunately, the world does not have CLNP, and instead has IP. Even if the world does migrate to IPv6, with a 16-byte address, IPv6 behaves the same as IPv4, in that each link is intended to have its own prefix.

Therefore, people would like to create large flat Ethernet clouds, with self-configuring switches inside the cloud, and the ability for nodes to migrate within the cloud without changing their address.

TRansparent Interconnection of Lots of Links (TRILL) (RFC 6325; Perlman et al., 2011) accomplishes this, and it does it in an evolutionary way. Within an existing spanning tree-based Ethernet, any subset of the switches can be replaced by TRILL switches; and the more you replace, the better the bandwidth utilization and the more stable the Ethernet appears. Existing endnodes see no change other than that the Ethernet is performing better.

Two TRILL switches are neighbors if they are directly connected (on the same link) or through spanning tree switches. TRILL switches find their neighbors (by sending multicast messages that are not forwarded by TRILL switches) and form a network using a variant of the IS-IS routing protocol, to create forwarding table entries for reaching all the other TRILL switches (but not the endnodes).

Edge TRILL switches (those that are attached to endnodes), create an additional table of (MAC and egress TRILL switch), which is either configured or learned when receiving data packets. Core TRILL switches do not need to have such a table; a core TRILL switch forwards to the last TRILL switch.

The first TRILL switch (the "ingress switch") adds an extra header to an Ethernet packet. This header contains the fields

- Ingress switch
- Egress switch
- Hop count (to detect and discard looping packets)

TRILL switches dynamically acquire 2 byte nicknames. This is done by having TRILL switch T1 choose a nickname N and claim it in T1's LSP. Switch T1 examines all other TRILL switches' LSPs, and if some

other TRILL switch T2 has chosen nickname N, then based on priority, one of them gets to keep N and the other chooses a different nickname (one not already claimed in another switch's LSP).

Edge switches learn (or are configured) with an endnode table consisting of Ethernet address of endnode and attached TRILL switch nickname. When an ingress switch S receives an Ethernet packet, S looks up the destination Ethernet address in S's table, finds the proper egress TRILL nickname E, and S adds a TRILL header with TRILL ingress switch nickname = S and TRILL egress switch nickname = E.

The core switches need only look at the TRILL header.

The advantages of the extra TRILL header are as follows:

- Core switches can forward based on an easy lookup in the forwarding table, since a 16-bit switch nickname can be a direct index into the forwarding table.
- Core switches only need a forwarding table, which is as big as the number of TRILL switches; not the number of endnodes.
- There is a hop count in the TRILL header, so it is routable just like layer 3, with all the techniques that are usually associated with layer 3, such as shortest paths, multipathing, etc.

Key Terms

Bridge: A box that forwards information from one link to another but only looks at information in layer 2.

Cloud: An informal representation of a multiaccess link. The purpose of representing it as a cloud is that what goes on inside is irrelevant to what is being discussed. When a system is connected to the cloud, it can communicate with any other system attached to the cloud.

Data-link layer: The layer that gets information from one machine to a neighbor machine (a machine on the same link).

IEEE 802 address: The 48-bit address defined by the IEEE 802 committee as the standard address on 802 LANs.

Hops: The number of times a packet is forwarded by a router.

Local area network (LAN): A multiaccess link with multicast capability.

MAC address: Synonym for IEEE 802 address.

Medium access control (MAC): The layer defined by the IEEE 802 committee that deals with the specifics of each type of LAN (for instance, token passing protocols on token passing LANs).

Multiaccess link: A link on which more than two nodes can reside.

Multicast: The ability to transmit a single packet that is received by multiple recipients.

Network layer: The layer that traditionally forms a path by concatenation of several links.

Router: A box that forwards packets at layer 3.

Switch: Any device that forwards packets (including bridges or routers).

47.1 Introduction

An important requirement of any information management system is to protect information against improper disclosure or modification (known as *confidentiality* and *integrity*, respectively). *Access control* is a fundamental technology to achieve this goal (e.g., [22,26]). It controls every access request to a system and determines whether the access request should be granted or denied. In access control systems, a distinction is generally made among *policies*, *models*, and *mechanisms*. Policies are high level guidelines that determine how accesses are controlled and access decisions determined. A policy is then formalized through a security model and is enforced by access control mechanisms. The access control mechanism works as a *reference monitor* that mediates every attempted access by a user (or program executing on behalf of that user) to objects in the system. The reference monitor consults an *authorization database* to determine if the user attempting to do an operation is actually authorized to perform that operation. Authorizations in this database are usually defined with respect to the identity of the users. This implies that access control requires *authentication* as a prerequisite, meaning that the identity of the requesting user has to be correctly verified (e.g., [8,19,25,31]). The reader is surely familiar with the process of signing on to a computer system by providing an identifier and a password. This authentication establishes the identity of a human user to a computer. More generally, authentication can be computer-to-computer or process-to-process and mutual in both directions. Access control is then concerned with limiting the activity of legitimate users who have been successfully authenticated. The set of authorizations are administered and maintained by a security administrator. The administrator sets the authorizations on the basis of the security policy of the organization. Users may also be able to modify some portion of the authorization database, for example, to set permissions for their personal files. The effectiveness

of the access control rests on a proper user identification and on the correctness of the authorizations governing the reference monitor.

The variety and complexity of the protection requirements that may need to be imposed in today's systems make the definition of access control policies a far from trivial process. For instance, many services do not need to know the real identity of a user but they may need to know some characteristics/properties of the requesting users (e.g., a user can access a service only if she works in an European country), or different systems may need to collaborate while preserving their autonomy in controlling access to their resources [23,24,26]. The goal of this chapter is therefore to provide an overview of the access control evolution. This overview begins with a discussion on the classical discretionary, mandatory, and role-based access control policies and models (Sections 47.2 through 47.4), and then continues with an illustration of the administration policies (Section 47.5) that determine who can modify the accesses allowed by such policies. We then discuss the most recent advances in access control, focusing on attribute and credential-based access control (Section 47.6). Finally, we present our conclusions in Section 47.7.

47.2 Discretionary Access Control (DAC)

Discretionary access control policies govern the access of users to the information/resources on the basis of the users' identities and authorizations (or rules) that specify, for each user (or group of users) and each object in the system, the access modes the user is allowed on the object. Each request of a user to access an object is checked against the specified authorizations. If there exists an authorization stating that the user can access the object in the specific mode, the access is granted; it is denied, otherwise. In the following, we first describe the access matrix model, which is useful to understand the basic principles behind discretionary access control models and policies, and discuss implementation alternatives. We then illustrate how discretionary policies have been further expanded.

47.2.1 The Access Matrix Model and Its Implementation

A first step in the definition of an access control model is the identification of the set of *objects* to be protected, the set of *subjects* who request access to objects, and the set of *access modes* that can be executed on objects. While subjects typically correspond to users (or groups thereof), objects and access modes may differ depending on the specific system or application. For instance, objects may be files and access modes may be Read, Write, Execute, and Own. The meaning of the first three of these access modes is self evident. Ownership is concerned with controlling who can change the access permissions for the file. An object such as a bank account may have access modes Inquiry, Credit, and Debit corresponding to the basic operations that can be performed on an account. These operations would be implemented by application programs, whereas for a file the operations would typically be provided by the operating system.

A subtle point that is often overlooked is that subjects can themselves be objects. A subject can create additional subjects to accomplish its task. The children subjects may be executing on various computers in a network. The parent subject will usually be able to suspend or terminate its children as appropriate. The fact that subjects can be objects corresponds to the observation that the initiator of one operation can be the target of another. (In network parlance, subjects are often called initiators, and objects called targets.)

The access matrix is a conceptual model which specifies the rights that each subject possesses for each object. There is a row in the matrix for each subject, and a column for each object. Each cell of the matrix specifies the access authorized for the subject in the row to the object in the column. The task of access control is to ensure that only those operations authorized by the access matrix actually get executed. This is achieved by means of a *reference monitor*, which is responsible for mediating all attempted operations by subjects on objects.

TABLE 47.1 An Example of Access Matrix

	File1	File2	File3	File4	Account1	Account2
John	Own R W		Own R W		Inquiry Credit	
Alice	R	Own R W	W	R	Inquiry Debit	Inquiry Credit
Bob	R W	R		Own R W		Inquiry Debit

Table 47.1 shows an example of access matrix where the access modes R and W denote read and write, respectively, and the other access modes are as discussed previously. The subjects shown here are John, Alice, and Bob. There are four files and two accounts. This matrix specifies that, for example, John is the owner of File1 and can read and write that file, but John has no access to File2 and File4. The precise meaning of ownership varies from one system to another. Usually the owner of a file is authorized to grant other users access to the file, as well as revoke access. Since John owns File1, he can give Alice the R right and Bob the R and W rights as shown in Table 47.1. John can later revoke one or more of these rights at his discretion.

The access modes for the accounts illustrate how access can be controlled in terms of abstract operations implemented by application programs. The Inquiry operation is similar to read since it retrieves information but does not change it. Both the Credit and Debit operations will involve reading the previous account balance, adjusting it as appropriate and writing it back. The programs which implement these operations require read and write access to the account data. Users, however, are not allowed to read and write the account object directly. They can manipulate account objects only indirectly via application programs which implement the Debit and Credit operations. Also, note that there is no own right for accounts. Objects such as bank accounts do not really have an owner who can determine the access of other subjects to the account. Clearly, the user who establishes the account at the bank should not be the one to decide who can access the account. Within the bank different officials can access the account depending on their job functions in the organization.

In a large system the access matrix will be enormous in size, and most of its cells are likely to be empty. Accordingly, the access matrix is very rarely implemented as a matrix. We now discuss some common approaches for implementing the access matrix in practical systems.

Access control lists: Each object is associated with an access control list (ACL), indicating for each subject in the system the accesses the subject is authorized to execute on the object. This approach corresponds to storing the matrix by columns. ACLs corresponding to the access matrix of Table 47.1 are shown in Figure 47.1. Essentially the access matrix column for File1 is stored in association with File1, and so on.

By looking at an object's ACL, it is easy to determine which access modes subjects are currently authorized for that object. In other words, ACLs provide for convenient access review with respect to an object. It is also easy to revoke all accesses to an object by replacing the existing ACL with an empty one. On the other hand, determining all the accesses that a subject has is difficult in an ACL-based system. It is necessary to examine the ACL of every object in the system to do access review with respect to a subject. Similarly, if all accesses of a subject need to be revoked, all ACLs must be visited one by one. (In practice revocation of all accesses of a subject is often done by deleting the user account corresponding to that subject. This is acceptable if a user is leaving an organization. However, if a user is reassigned within the organization it would be more convenient to retain the account and change its privileges to reflect the changed assignment of the user.)

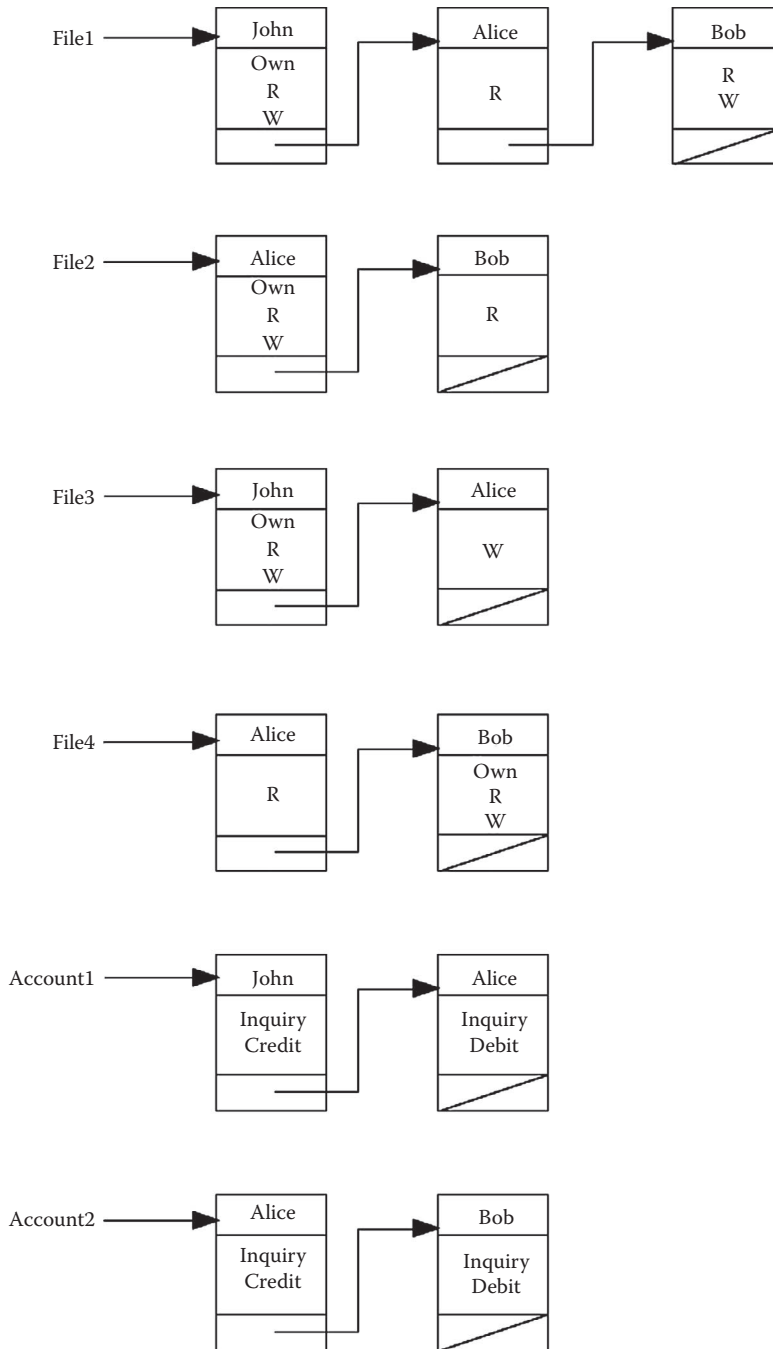

FIGURE 47.1 Access control lists corresponding to the access matrix in Table 47.1.

Many systems allow group names to occur in ACLs (see Section 47.2.2). For instance, an entry such as (ISSE, R) can authorize all members of the ISSE group to read a file. Several popular operating systems (e.g., Unix) implement an abbreviated form of ACLs in which a small number, often only one or two, group names can occur in the ACL. Individual subject names are not allowed. With this approach the ACL has a small fixed size so it can be stored using a few bits associated with the file.

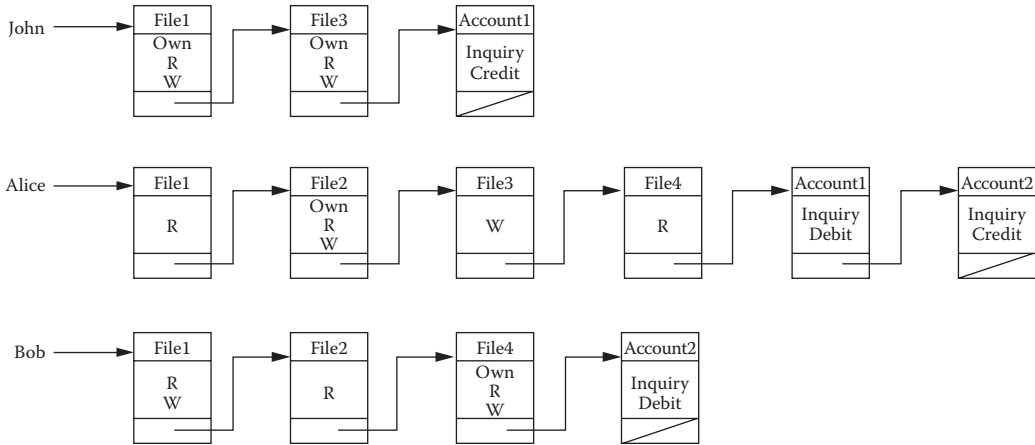

FIGURE 47.2 Capability lists corresponding to the access matrix in Table 47.1.

Capabilities: Capabilities are a dual approach to ACLs. Each subject is associated with a list, called capability list, indicating for each object in the system, the accesses the subject is authorized to execute on the object. This approach corresponds to storing the access matrix by rows. Figure 47.2 shows the capability lists corresponding to the access matrix in Table 47.1. In a capability list approach it is easy to review all accesses that a subject is authorized to perform by simply examining the subject’s capability list. However, determination of all subjects who can access a particular object requires examination of each and every subject’s capability list. A number of capability-based computer systems were developed in the 1970s, but did not prove to be commercially successful. Modern operating systems typically take the ACL-based approach.

It is possible to combine ACLs and capabilities. Possession of a capability is sufficient for a subject to obtain access authorized by that capability. In a distributed system this approach has the advantage that repeated authentication of the subject is not required. This allows a subject to be authenticated once, obtain its capabilities and then present these capabilities to obtain services from various servers in the system. Each server may further use ACLs to provide finer-grained access control.

Authorization relations: We have seen that ACL- and capability-based approaches have dual advantages and disadvantages with respect to access review. There are representations of the access matrix which do not favor one aspect of access review over the other. For instance, the access matrix can be represented by an authorization relation (or table) as shown in Table 47.2. Each row, or tuple, of this table specifies one access right of a subject to an object. Thus, John’s accesses to File1 require three rows. If this table is sorted by subject, we get the effect of capability lists. If it is sorted by object, we get the effect of ACLs. Relational database management systems typically use such a representation.

47.2.2 Expanding Authorizations

Although the access matrix still remains a framework for reasoning about accesses permitted by a discretionary policy, discretionary policies have been developed considerably since the access matrix was proposed. In particular, early approaches to authorization specifications allowed *conditions* to be associated with authorizations to restrict their validity [33]. Conditions may involve some system predicates, and may specify restrictions based on the content of objects or on accesses previously executed. Another important feature supported by current discretionary policies is the definition of abstractions on users and objects. Both users and objects can therefore be hierarchically organized, thus introducing *user groups* and *classes of objects*. Figure 47.3a and b illustrate an example of user group hierarchy and object hierarchy, respectively. The definition of groups of users

TABLE 47.2 Authorization Relation
Corresponding to the Access Matrix in Table 47.1

Subject	Access Mode	Object

Bob	Inquiry	Account2
Bob	Debit	Account2

FIGURE 47.3 An example of (a) user group and (b) object hierarchy.

(and classes of objects) requires a technique to easily handle exceptions. For instance, suppose that all users belonging to a group can access a specific object but user *u*. In this case, it is necessary to explicitly associate an authorization with each user in the group but *u*, which is clearly a solution that does not take advantage from the definition of user groups. This observation has been the driving factor supporting the development of access control models that combine *positive* and *negative* authorizations (e.g., [10]). In this way, the previous exception can be easily modeled by the definition of two authorizations: a positive authorization for the group and a negative authorization for user *u*. Hierarchies can also simplify the definition of authorizations because authorizations specified on an abstraction can be propagated to all its members. The propagation of authorizations over a hierarchy may follow different *propagation policies* (e.g., [35,52]). For instance, authorizations associated with

an element in the hierarchy may not be propagated, may be propagated to all its descendants, or may be propagated to its descendants if not overridden.

The use of both positive and negative authorizations introduces two problems: (1) *inconsistency*, which happens when for an access there are both a negative and a positive authorization; and (2) *incompleteness*, which happens when some accesses are neither authorized nor denied (i.e., no authorization exists for them). The inconsistency problem is solved by applying a *conflict resolution policy*. There are several conflict resolution policies [35,45] such as: *no conflict*, the presence of a conflict is considered an error; *denials take precedence*, negative authorizations take precedence; *permissions take precedence*, positive authorizations take precedence; *nothing takes precedence*, neither positive nor negative authorizations take precedence and conflicts remain unsolved; *most specific takes precedence*, the authorization that is more specific with respect to a hierarchy wins (e.g., consider the user group hierarchy in Figure 47.3a, the effect on John of a positive authorization for the Admin group to read File1, and a negative authorization for reading the same file for Personnel is that he is allowed to read File1 since Admin is more specific than Personnel); and *most specific along a path takes precedence*, the authorization that is more specific with respect to a hierarchy wins only on the paths passing through it (e.g., consider the user group hierarchy in Figure 47.3a, the effect on John of a positive authorization for the Admin group to read File1, and a negative authorization for reading the same file for Personnel is that there is a conflict for managing John's access to File1 since the negative authorization wins along path ⟨Personnel, Purchase, John⟩ and the positive authorization wins along path ⟨Personnel, Admin, John⟩). The incompleteness problem can be solved by adopting a *decision policy*, that is, an *open policy* or a *closed policy*. Open policies are based on explicitly specified authorizations and the default decision of the reference monitor is denial. Open policies are based on the specification of denials instead of permissions. In this case, for each user and each object in the system, the access modes the user is forbidden on the object are specified. Each access request by a user is checked against the specified (negative) authorizations and granted only if no authorization denying the access exists. The combination of a propagation policy, a conflict resolution policy, and a decision policy guarantees a complete and consistent policy for the system.

47.3 Mandatory Access Control (MAC)

The flexibility of discretionary policies makes them suitable for a variety of systems and applications, especially in the commercial and industrial environments. However, discretionary access control policies have the drawback that they do not provide real assurance on the flow of information in a system. It is easy to bypass the access restrictions stated through the authorizations. For instance, a user who is authorized to read data can pass them to other users not authorized to read them without the cognizance of the owner. The reason is that discretionary policies do not impose any restriction on the usage of information by a user once the user has got it (i.e., dissemination of information is not controlled). By contrast, dissemination of information is controlled in mandatory systems by preventing flow of information from high-level objects to low-level objects. Mandatory policies govern access on the basis of a classification of subjects and objects in the system. Note that the concept of subject in discretionary policies is different from the concept of subject in mandatory policies. In fact, authorization subjects correspond to users (or groups thereof) while in mandatory policies users are human beings who can access the system, and subjects are processes operating on behalf of users.

Each subject and each object in a mandatory system is assigned an *access class*. The set of access classes is a partially ordered set and in most cases an access class is composed by a *security level* and a set of *categories*. The security level is an element of a hierarchical ordered set. In the military and civilian government arenas, the hierarchical set generally consists of top secret (TS), secret (S), confidential (C), and unclassified (U), where $TS > S > C > U$. Each security level is said to dominate itself and all others below it in this hierarchy. The set of categories is a subset of an unordered set, whose elements reflect functional, or competence, areas (e.g., financial, demographic, medical). Given two access

classes c_1 and c_2 , we say that c_1 dominates c_2 , denoted $c_1 \geq c_2$, iff the security level of c_1 is greater than or equal to that of c_2 and the categories of c_1 include those of c_2 .

The semantics and use of the access classes assigned to objects and subjects within the application of a multilevel mandatory policy depends on whether the access class is intended for a secrecy or an integrity policy. In the following, we illustrate secrecy-based and integrity-based mandatory policies.

47.3.1 Secrecy-Based Model

The main goal of a secrecy-based mandatory policy is to protect the confidentiality of information. In this case, the security level associated with an object reflects the sensitivity of the information contained in the object, that is, the potential damage which could result from unauthorized disclosure of the information. The security level associated with a user, also called *clearance*, reflects the user's trustworthiness not to disclose sensitive information to users not cleared to see it. The set of categories associated with a user reflects the specific areas in which the user operates. The set of categories associated with an object reflects the area to which information contained in the object is referred. Categories enforce restrictions on the basis of the need-to-know principle (i.e., a subject should be only given those accesses which are required to carry out the subject's responsibilities). Users can connect to the system at any access class dominated by their clearance. A user connecting to the system at a given access class originates a subject at that access class.

Access to an object by a subject is granted only if some relationship (depending on the type of access) is satisfied between the access classes associated with the two. In particular, the following two principles are required to hold.

Read-down A subject's access class must dominate the access class of the object being read.

Write-up A subject's access class must be dominated by the access class of the object being written.

Satisfaction of these principles prevents information in high level objects (i.e., more sensitive) to flow to objects at lower levels. Figure 47.4 illustrates the effect of these rules. Here, for simplicity, accesses classes are only composed of a security level. In such a system, information can only flow upwards or within the same security class.

To better understand the rationale behind the read-down and write-up rules, it is important to analyze the relationship between users and subjects in this context. Suppose that the human user Jane is cleared to S (again, for simplicity, access classes are only composed of a security level), and assume she always signs on to the system as an S subject (i.e., a subject with clearance S). Jane's subjects are

FIGURE 47.4 Controlling information flow for secrecy.

prevented from reading TS objects by the read-down rule. The write-up rule, however, has two aspects that seem at first sight contrary to expectation.

- First, Jane’s S subjects can write a TS object (even though they cannot read it). In particular, they can overwrite existing TS data and therefore destroy them. Due to this integrity concern, many systems for mandatory access control do not allow write-up but limit writing to the same level as the subject. At the same time write-up does allow Jane’s S subjects to send electronic mail to TS subjects, and can have its benefits.
- Second, Jane’s S subjects cannot write C or U data. This means, for example, that Jane can never send electronic mail to C or U users. This is contrary to what happens in the paper world, where S users can write memos to C and U users. This seeming contradiction is easily eliminated by allowing Jane to sign to the system as a C, or U, subject as appropriate. During these sessions she can send electronic mail to C or, U and C, subjects, respectively.

The write-up rule prevents malicious software from leaking secrets downward from S to U. Users are trusted not to leak such information, but the programs they execute do not merit the same degree of trust. For instance, when Jane signs onto the system at U level her subjects cannot read S objects, and thereby cannot leak data from S to U. The write-up rule also prevents users from inadvertently leaking information from high to low.

47.3.2 Integrity-Based Model

Mandatory access control can also be applied for the protection of information integrity. The integrity level associated with an object reflects the degree of trust that can be placed in the information stored in the object, and the potential damage that could result from unauthorized modification of the information. The integrity level associated with a user reflects the user’s trustworthiness for inserting, modifying or deleting data and programs at that level. Again, categories define the area of competence of users and data. Principles similar to those stated for secrecy are required to hold, as follows.

Read-up A subject’s integrity class must be dominated by the integrity class of the object being read.

Write-down A subject’s integrity class must dominate the integrity class of the object being written.

Satisfaction of these principles safeguard integrity by preventing information stored in low objects (and therefore less reliable) to flow to high objects. This is illustrated in Figure 47.5, where, for simplicity, integrity classes are only composed of integrity levels, which can be crucial (C), important (I),

FIGURE 47.5 Controlling information flow for integrity.

and unknown (U) with $C > I > U$. Controlling information flow in this manner is only one aspect of achieving integrity. Integrity in general requires additional mechanisms, as discussed in [16,53].

Note that the only difference between Figures 47.4 and 47.5 is the direction of information flow, being bottom to top in the former case and top to bottom in the latter. In other words, both cases are concerned with one-directional information flow. The essence of classical mandatory controls is one-directional information flow in a lattice of security classes. For further discussion on this topic see [52].

47.4 Role-Based Access Control (RBAC)

Role-based policies regulate the access of users to the information on the basis of the activities the users execute in the system. Role-based policies require the identification of roles in the system. A role can be defined as a set of actions and responsibilities associated with a particular working activity. Then, instead of specifying all the accesses each user is allowed to execute, access authorizations on objects are specified for roles. Users are given authorizations to play roles. This greatly simplifies the authorization management task. For instance, suppose a user's responsibilities change, say, due to a promotion. The user's current roles can be taken away and new roles assigned as appropriate for the new responsibilities. Another advantage of RBAC is that roles allow a user to sign on with the least privilege required for the particular task at hand. Users authorized to powerful roles do not need to exercise them until those privileges are actually needed. This minimizes the danger of damage due to inadvertent errors or by intruders masquerading as legitimate users. Note that, in general, a user can take on different roles on different occasions. Also, the same role can be played by several users, perhaps simultaneously. Some proposals for role-based access control allow a user to exercise multiple roles at the same time. Other proposals limit the user to only one role at a time, or recognize that some roles can be jointly exercised while others must be adopted in exclusion to one another. In the remainder of this section, we briefly describe the standard RBAC model and then illustrate an extension of RBAC.

47.4.1 Basic RBAC Model

In 2004, the National Institute of Standards and Technology (NIST) proposed a US national standard for role-based access control through the International Committee for Information Technology Standards (ANSI/INCITS) [3,28]. The standard RBAC model is organized in four components, which are briefly described in the following.

Core RBAC: Core RBAC includes five basic elements, that is, users, roles, objects, operations, and permissions. Users are assigned to roles, and permissions (i.e., the association between an object and an operation executable on the object) are assigned to roles. The permission-to-role and user-to-role assignments are both many-to-many, thus providing greater flexibility. In addition, Core RBAC includes the concept of session, where each session is a mapping between a user and a set of activated roles, which are a subset of the roles assigned to the user. The permissions available to a user during a session are therefore all the permissions associated with the roles activated by the user in the session.

Hierarchical RBAC: This model introduces the concept of role hierarchy. In many applications there is a natural hierarchy of roles, based on the familiar principles of generalization and specialization. For instance, the Medical Staff role may be specialized into Doctor and Nurse (see Figure 47.6).

FIGURE 47.6 An example of role hierarchy.

The role hierarchy has implication on role activation and access privileges: a specialized role inherits the authorizations of its generalizations; also, users authorized to activate a role inherit the authorization to activate the generalizations of the role. For instance, with reference to Figure 47.6, role `Nurse` inherits all authorizations of role `Medical Staff`. Also, users authorized to activate role `Nurse` will also be allowed to activate role `Medical Staff`. A role hierarchy can be an arbitrary partial order or it may be possible to impose some restrictions on the type of hierarchy. For instance, it is possible to require that a role hierarchy has to be a tree, meaning that each role may have only one single direct parent.

Static separation of duty: The RBAC model can be enriched by adding separation of duty constraints. Intuitively, static separation of duty imposes restrictions on the assignments of users to roles. For instance, a user assigned to the `Nurse` role may not be assigned to the `Doctor` role. A separation of duty constraint is defined as a pair where the first element is a set rs of roles and the second element is an integer n greater than or equal to two denoting the number of roles that would constitute a violation. For instance, $\{\{\text{Doctor}, \text{Nurse}\}, 2\}$ states that a user may be assigned to one out of the two roles mentioned in the constraint. Since static separation of duty constraints can be also defined in the presence of a role hierarchy, it is important to ensure that role inheritance does not violate the static separation of duty constraints.

Dynamic separation of duty: In the dynamic separation of duty, constraints are enforced at run-time: users can activate any role to which they are assigned but the activation of some roles during a session will rule out their ability to activate another role which is in a separation of duty constraint with the activated roles. An example of dynamic separation of duty is the two-person rule. The first user who executes a two-person operation can be any authorized user, whereas the second user can be any authorized user different from the first. The dynamic separation of duty constraints are still defined as pairs composed by a set rs of roles and an integer n greater than or equal to two and their enforcement requires that no user is assigned to n or more roles from rs in a single session.

In addition to the four components described above, the NIST RBAC standard defines administrative functions related to the creation and management of the basic elements and relations of RBAC, and permission review functions.

47.4.2 Expanding RBAC

The RBAC model has been adopted in a variety of commercial systems (e.g., DB2, Oracle), and has been the subject of many research proposals aimed at extending and enriching the model to support particular domain specific security policies (e.g., web services, social networks), administration models, and delegation. Some proposals are also aimed at integrating RBAC with other technologies such as cryptography, trust mechanisms, and XML-based access control languages (e.g., [1,30]). Given the huge amount of work on RBAC, it is clearly not feasible to provide a comprehensive summary of the extensions proposed in the literature. A notable example is the *usage control model* (UCON_{ABC}) [51], a framework that encompasses access control, trust management, and digital right management. This proposal is interesting since it supports DAC, MAC, and RBAC and is based on attributes characterizing subjects and objects that are used for specifying authorizations (see Section 47.6 for more details about attribute-based access control). In particular, the UCON_{ABC} model integrates authorizations, obligations, and conditions within a unique framework, and includes the following eight components.

Subjects, objects, and rights: Subjects, objects, and rights have the same meaning of the corresponding concepts also used within the DAC, MAC, and RBAC access control models. A subject is therefore an individual who holds some rights on objects.

Subject and object attributes: Each subject and object in the system is characterized by a set of attributes that can be used for verifying whether an access request can be granted. Examples of subject

attributes include identities, group names, and roles while examples of object attributes include ownerships, security labels, and so on. A peculiarity of the $U\text{CON}_{ABC}$ model is that subject and object attributes can be mutable, meaning that their values may change due to an access.

Authorizations: Authorizations are evaluated for usage decision and return whether a subject can perform the required right on an object. Authorizations are based on subject and object attributes, and are distinguished between pre-authorizations and ongoing-authorizations. A pre-authorization is performed before the execution of the requested right while an ongoing-authorization is performed during the access.

Obligations: An obligation is a requirement that a user has to perform before (pre) or during (ongoing) access. For instance, a pre-obligation may require a user to provide her date of birth before accessing a service. The execution of obligations may change the value of mutable attributes and therefore they may affect current or future usage decisions.

Conditions: Conditions evaluate current environmental or system status. Examples are time of the day and system workload. The evaluation of these conditions cannot change the value of any subject or object attributes.

A family of $U\text{CON}_{ABC}$ core models is defined according to three criteria: the decision factor, which may be authorizations, obligations, and conditions; the continuity of decision, which may be either pre or ongoing; and the mutability, which can allow changes on subject or object attributes at different times. According to these criteria, the authors in [51] define 16 basic $U\text{CON}_{ABC}$ models and show how these models can support traditional DAC, MAC, and RBAC.

47.5 Administration of Authorizations

Administrative policies determine who is authorized to modify the allowed accesses. This is one of the most important, and least understood, aspects of access control.

In mandatory access control the allowed accesses are determined entirely on the basis of the access class of subjects and objects. Access classes are assigned to users by the security administrator. Access classes of objects are determined by the system on the basis of the access classes of the subjects creating them. The security administrator is typically the only one who can change access classes of subjects or objects. The administrative policy is therefore very simple.

Discretionary access control permits a wide range of administrative policies. Some of these are described as follows:

- *Centralized:* A single authorizer (or group) is allowed to grant and revoke authorizations to the users.
- *Hierarchical:* A central authorizer is responsible for assigning administrative responsibilities to other administrators. The administrators can then grant and revoke access authorizations to the users of the system. Hierarchical administration can be applied, for example, according to the organization chart.
- *Cooperative:* Special authorizations on given resources cannot be granted by a single authorizer but need cooperation of several authorizers.
- *Ownership:* A user is considered the owner of the objects he/she creates. The owner can grant and revoke access rights for other users to that object.
- *Decentralized:* In decentralized administration the owner of an object can also grant other users the privilege of administering authorizations on the object.

Within each of these there are many possible variations [52].

Role-based access control has a similar wide range of possible administrative policies. In this case roles can also be used to manage and control the administrative mechanisms.

Delegation of administrative authority is an important aspect in the administration of authorizations. In large distributed systems, centralized administration of access rights is infeasible. Some existing systems allow administrative authority for a specified subset of the objects to be delegated by the central security administrator to other security administrators. For instance, authority to administer objects in a particular region can be granted to the regional security administrator. This allows delegation of administrative authority in a selective piecemeal manner. However, there is a dimension of selectivity that is largely ignored in existing systems. For instance, it may be desirable that the regional security administrator be limited to granting access to these objects only to employees who work in that region. Control over the regional administrators can be centrally administered, but they can have considerable autonomy within their regions. This process of delegation can be repeated within each region to set up sub-regions and so on.

47.6 Attribute and Credential-Based Access Control

Emerging distributed scenarios (e.g., cloud computing and data outsourcing) are typically characterized by several independent servers offering services to anyone who needs them (e.g., [21]). In such a context, traditional assumptions for enforcing access control do not hold anymore. As a matter of fact, an access request may come from unknown users and therefore access control policies based on the identity of the requester cannot be applied. Alternative solutions that have been largely investigated in the last 20 years consist in adopting *attribute-based access control* that uses the attributes associated with the resources/services and requesters to determine whether the access should be granted (e.g., [5]). The basic idea is that not all access control decisions are identity-based. For instance, information about a user's current role (e.g., doctor) or a user's date of birth may be more important than the user's identity for deciding whether an access request should be granted.

In the remainder of this section, we first review the basic concepts about attribute and credential-based access control and then describe some solutions based on such a model.

47.6.1 Basic Elements of the Model

Attribute-based access control differs from traditional discretionary access control since both the subject and the object appearing in an authorization are replaced by a set of *attributes* associated with them. Such attributes may correspond to an identity or a non-identifying characteristic of a user (e.g., date of birth, nationality) and to metadata associated with an object that provide additional context information (e.g., data of creation). In particular, the attributes associated with a user may be specified by the user herself (*declarations*), or may be substantiated by *digital certificates* or *credentials* (e.g., [12,57]). Metadata associated with resources/services can be in different form (e.g., textual or semistructured data). By analyzing previous works in the area, we identify the following main concepts captured by attribute/credential-based access control models.

Authority: An authority is an entity responsible for producing and signing certificates. A party may accept certificates issued by an authority that it trusts or that has been (directly or indirectly) delegated by an authority that it trusts.

Certificate: A certificate is a statement certified by an authority trusted for making such a statement. Each certificate is characterized by the identity of the issuer, the identity of the user for which the certificate has been issued, a validity period, a signature of the issuing authority, and a set of certified attributes. Certificates can be classified according to different dimensions. Since we focus on the use of certificates in access control, we distinguish between *atomic* and *non-atomic* certificates [7]. Atomic certificates (e.g., X.509) can only be released as a whole, meaning that all attributes in a certificate are disclosed. These certificates are the most common type of certificates used today in distributed systems. Although these certificates can only be released as a whole, there is usually the possibility

FIGURE 47.7 An example of certificate abstractions.

to refer to specific attributes within a certificate for querying purpose. Given a certificate c including a set $\{a_1, \dots, a_m\}$ of attributes, we can use the dot notation to refer to a given attribute in c . For instance, given credential `Passport` certifying attributes `name`, `dob`, and `country`, `Passport.name` denotes attribute `name` certified by the `Passport` credential. Non-atomic certificates (e.g., Idemix [15]) allow the selective release of the attributes certified by them. Non-atomic certificates are based on technologies that also permit to certify the possession of a given certificate without disclosing the attributes within it. Abstractions can be defined within the domain of certificates. Figure 47.7 illustrates an example of certificate abstractions. The use of abstractions in the policy specification provides a compact and easy way to refer to complex concepts. For instance, the specification of abstraction `Passport` in a policy states that any kind of passport (diplomatic or regular) can be accepted. Abstractions can be formally modeled through a hierarchy $\mathcal{H} = (\mathcal{C}, <)$, with \mathcal{C} a set of certificate abstractions and $<$ a partial order relationship over \mathcal{C} . Given two certificate abstractions c_i and c_j , $c_i < c_j$ if c_j is an abstraction of c_i .

An important concept captured by several credential-based access control models is *delegation*. The delegation is the ability of an authority to produce credentials on behalf of the delegator. Delegation increases flexibility and permits the inexpensive creation of credentials, particularly in an open environment. A *delegation certificate* issued by an authority states that it trusts another authority for issuing certificates that include specific attributes. An authority can delegate other authorities only on given attributes (e.g., a hospital can issue a certificate delegating physicians to certify specific properties of patients) or can give unrestricted delegation to other authorities.

Low-level issues related to the certificate creation, retrieval, validation, and revocation are all usually assumed to be managed by an underlying implementation of the certificate management system (e.g., [38,41,44]) and are therefore outside the scope of this chapter.

Policy: A policy defines the rules (authorizations) regulating access to resources. Such authorizations model access restrictions based on generic properties associated with subjects and objects. In general, these restrictions can refer to attributes within specific credentials or can refer to certificate abstractions. In this latter case, a restriction involving a certificate abstraction applies also to its specialized abstractions/credentials. For instance, with respect to the certificate abstractions in Figure 47.7, `ID.dob` represents attribute `dob` certified by a credential of type `ID`. From an analysis of the current attribute and credential-based access control policies, it is easy to see that at an abstract level the main elements of an authorization that are common to many proposals are the following:

- *Subject expression:* A subject expression identifies a set of subjects having specific attributes. A subject expression can be seen as a boolean formula of basic conditions defined on attributes. Attributes appearing in basic conditions must be certified or can be declared by a user. For instance, expression `ID.dob>01-05-1971` denotes all users with a certificate of type `ID` certifying that the date of birth of the users is after January 05, 1971.
- *Object expression:* An object expression identifies the resources/services to be protected. Like for subject expressions, also an object expression can be seen as a boolean formula of basic conditions defined on the metadata associated with resources/services. For instance, assume that `producer` is a metadata attribute associated with objects. Then, expression `producer="EU"` denotes all objects made in an European country.
- *Action:* An action denotes the operation (or group thereof) to which the authorization refers.

Different languages have been developed for the specification of policies, and each of them supports different features. In the remainder of this section, we first describe the policy communication problem (Section 47.6.2), which is a specific problem of the attribute-based access control systems, and then we present some policy languages (Section 47.6.3). In particular, we present logic-based languages, which are expressive but turn out to be not applicable in practice, and then XACML-based languages, which are easy to use and consistent with consolidated technology.

47.6.2 Policy Communication

A peculiarity of access control systems based on attributes is that the server offering resources/services evaluates the policies without a complete knowledge of users and their properties. The server has then to communicate to users the policies that they should satisfy to have their requests possibly permitted. For instance, consider a service accessible to all people older than 18 and working in an European country. In this case, the server has to communicate to the user that she has to provide her date of birth and the place where she works before accessing the service. This policy communication problem has been under the attention of the research and development communities for more than a decade and several solutions have been proposed, each addressing different issues (e.g., [29,38]). A simple policy communication strategy consists in giving the user a list with all the possible sets of certificate that would allow the access. This solution is not always applicable due to the large number of possible alternatives (e.g., with compound credential requests such as “a passport and one membership certificate from a federated association,” there may be a combinatorial explosion of alternatives). Automated trust negotiation strategies have been therefore proposed (e.g., [38,55,56,59,60,61,62]), which are based on the assumption that parties may be unknown a-priori and a multi-step trust negotiation process is necessary for communicating policies and for releasing certificates, which are both considered sensitive. The goal of a trust negotiation process is to gradually establish trust among parties by disclosing credentials and requests for credentials. In successful trust negotiations, credentials eventually are exchanged so that the policy regulating access to the required resource/service is satisfied. In [55] two different strategies are described: *eager* and *parsimonious* credential release strategies. Parties applying the first strategy communicate all their credentials if the release policy for them is satisfied, without waiting for the credentials to be requested. Parsimonious parties only release credentials upon explicit request by the server (avoiding unnecessary releases). In [60] the *PRUdent NEgotiation Strategy* (PRUNES) strategy ensures that a user communicates her credentials to the server only if the access will be granted and the set of certificates communicated to the server is the minimal necessary for granting it. Each party defines a set of credential policies that regulates how and under what conditions the party releases its credentials. The negotiation consists of a series of requests for credentials and counter-requests on the basis of the parties' credential policies. In [61] the authors present a family of trust negotiation strategies, called *disclosure tree strategy* (DTS) family, and show that if two parties use different strategies from the DTS family, they are able to establish a negotiation process. In [59] the authors present a *unified schema for resource protection* (UniPro) for protecting resources and policies in trust negotiation. UniPro gives (opaque) names to policies and allows any named policy P_1 to have its own policy P_2 regulating to what parties policy P_1 can be disclosed. TrustBuilder [62] is a prototype developed to incorporate trust negotiation into standard network technologies. Traust [38] is a third-party authorization service that is based on the TrustBuilder framework for trust negotiation. The Traust service provides a negotiation-based mechanism that allows qualified users to obtain the credentials necessary to access resources provided by the involved server. In [56] the authors introduce a formal framework for automated trust negotiation, and formally define the concept of correct enforcement of policies during a trust negotiation process. In [6] the authors present an expressive and flexible approach for enabling servers to specify, when defining their access control policies, if and how the policy should be communicated to the client. Intuitively, an access control policy is represented through its expression tree and each node of the tree is associated with a disclosure policy (modeled with three colors, namely green, yellow, or

red), ensuring a fine-grained support and providing expressiveness and flexibility in establishing disclosure regulations. The disclosure policies state whether an element in the policy can be released as it is or whether it has to be obfuscated. The authors also illustrate how to determine the user's view on the policy (i.e., the policy to be communicated to the user requesting access) according to the specified disclosure policies.

47.6.3 Languages for Access Control

Languages for access control aim to support the expression and the enforcement of policies [52]. Several access control languages have been developed, and most of them rely on concepts and techniques from logic and logic programming (e.g., [13,27,35,36,39,40,42]). Logic languages are particularly attractive due to their clean and unambiguous semantics, suitable for implementation validation, as well as formal policy verification. Logic languages can be expressive enough to formulate all the policies introduced in the literature, and their declarative nature yields a good compromise between expressiveness and simplicity. Nevertheless, many logic-based proposals, while appealing for their expressiveness, are not applicable in practice, where simplicity, efficiency, and consistency with consolidated technology are crucial. Effectively tackling these issues is probably the main motivation for the success of the eXtensible Access Control Markup Language (XACML) [50]. XACML is an OASIS standard that proposes an XML-based language for specifying and exchanging access control policies over the Web. The language can support the most common security policy representation mechanisms and has already found significant support by many players. Moreover, it includes standard extension points for the definition of new functions, data types, and policy combination methods, which provide a great potential for the management of access control requirements in emerging and future scenarios.

In the following, we survey some logic-based access control languages, and then describe the XACML language along with some extensions aiming at including the possibility of using credentials in the XACML policy specification.

47.6.3.1 Logic-Based Languages

The first work investigating logic languages for the specification of authorizations is the work by Woo and Lam [58]. They shown how flexibility and extensibility in access specifications can be achieved by abstracting from the low level authorization triples and adopting a high level authorization language. Their language is a many-sorted first-order language with a rule construct, useful to express authorization derivations and therefore model authorization implications and default decisions (e.g., closed or open policy). Their work has been subsequently refined by several authors (e.g., [35]).

Several logic-based languages have been developed for formulating, for example, dynamic policies, inheritance and overriding, policy composition, and credential-based authorizations (e.g., [9,11,12,35]). In particular, specific solutions have addressed the problem of constraining the validity of authorizations through periodic expressions and appropriate temporal operators. For instance, the proposal in [9] shows a temporal authorization model that supports periodic access authorizations and periodic rules, and allows the derivation of new authorizations based on the presence or absence of other authorizations in specific periods of time. Other logic-based access control languages support inheritance mechanisms and conflict resolution policies. Jajodia et al. [35] present a proposal for a logic-based language that allows the representation of different policies and protection requirements, while at the same time providing understandable specifications, clear semantics (guaranteeing therefore the behavior of the specifications), and bearable data complexity. Authorizations are specified in terms of a locally stratified rule base logic. Such a solution allows the representation of different propagation policies (i.e., policies that specify how to obtain derived authorizations from the explicit authorizations), conflict resolution policies, and decision policies that a security system officer might want to use.

The fact that in open environments there is the need for combining access control restrictions independently stated by different parties motivates the development of solutions specifically targeted to the

composition of policies (e.g., [11,54]). These solutions typically do not make any assumption on the language adopted for specifying the given policies and define a set of policy operators used for combining different policies. In particular, in [12] a policy is defined as a set of triples of the form (s, o, a) , where s is a constant in (or a variable over) the set of subjects \mathcal{S} , o is a constant in (or a variable over) the set of objects \mathcal{O} , and a is a constant in (or a variable over) the set of actions \mathcal{A} . Here, complex policies can then be obtained by combining policies via specific algebra operators.

Logic-based approaches have been also used for specifying, reasoning about, and communicating protection requirements. In particular, several proposals have addressed the problem of defining and enforcing credential-based authorization policies and trust management (e.g., [12,34,43,48,62]). In particular, in [12] the authors present a framework that includes an access control model, a language for expressing access and release policies, and a policy-filtering mechanism to identify the relevant policies for a negotiation. Access regulations are specified by logical rules, where some predicates are explicitly identified. The system is composed of two entities: the *client* that requests access, and the *server* that exposes a set of services. Abstractions can be defined on services, grouping them in sets, called *classes*. Servers and clients interact via a *negotiation process*, defined as the set of messages exchanges between them. Clients and servers have a *portfolio*, which is a collection of credentials (certified statements) and declarations (unsigned statements). Credentials are modeled as *credential expressions* of the form $credential_name(attribute_list)$, where *credential_name* is the credential name and *attribute_list* is a possibly empty list of elements of the form $attribute_name=value_term$, where *value_term* is either a ground value or a variable. The proposed framework allows a client to communicate the minimal set of certificates to a server, and the server to release the minimal set of conditions required for granting access. For this purpose, the server defines a set of *service accessibility rules*, representing the necessary and sufficient conditions for granting access to a resource. More precisely, this proposal distinguishes two kinds of service accessibility rules: *prerequisites* and *requisites*. Prerequisites are conditions that must be satisfied for a service request to be taken into consideration (they do not guarantee that it will be granted); requisites are conditions that allow the service request to be successfully granted. The basic motivation for this separation is to avoid unnecessary disclosure of information from both parties. Therefore, the server will not disclose a requisite rule until after the client satisfies a corresponding prerequisite rule. Also, both clients and servers can specify a set of *portfolio disclosure rules*, used to define the conditions that govern the release of credentials and declarations.

The rules both in the service accessibility and portfolio disclosure sets are defined through a logic language that includes a set of predicates whose meaning is expressed on the basis of the current *state*. The state indicates the parties' characteristics and the status of the current negotiation process, that is, the certificates already exchanged, the requests made by the two parties, and so on. Predicates evaluate both information stored at the site (persistent state) and acquired during the negotiation (negotiation state). Information related to a specific negotiation is deleted when the negotiation terminates. In contrast, persistent state includes information that spans different negotiations, such as user profiles maintained at web sites.

Since there may exist different policy combinations that may bring the access request to satisfaction, the communication of credentials and/or declarations could be an expensive task. To overcome this issue, the *abbreviation* predicates are used to abbreviate requests. Besides the necessity of abbreviations, it is also necessary for the server, before releasing rules to the client, to evaluate state predicates that involve private information. For instance, the client is not expected to be asked many times the same information during the same session and if the server has to evaluate if the client is considered not trusted, it cannot communicate this request to the client itself.

Communication of requisites to be satisfied by the requester is then based on a filtering and renaming process applied on the server's policy, which exploits partial evaluation techniques in logic programs [12,47]. Access is granted whenever a user satisfies the requirements specified by the filtering rules calculated by means of the original policy and the already released information.

47.6.3.2 XML-Based Languages

With the increasing number of applications that either use XML as their data model, or export relational data as XML data, it becomes critical to investigate the problem of access control for XML. To this purpose, many XML-based access control languages have been proposed (e.g., [14,20,37,50]). As already mentioned, the eXtensible Access Control Markup Language (XACML) is the most relevant XML-based access control language. XACML version 1.0 [49] has been an OASIS standard since 2003. Improvements have been made to the language and incorporated in version 3.0 [50].

XACML supports the definition of policies based on attributes associated with subjects and resources other than their identities. The attributes are assumed to be known during the evaluation time and stored in the XACML evaluation context, or presented by the requester together with the request. While XACML acknowledges that properties can be presented by means of certificates, and in fact, it has been designed to be integrated with the Security Assertion Markup Language (SAML) [2] for exchanging various types of security assertions and for providing protocol mechanisms, it does not provide a real support for expressing and reasoning about digital certificates in the specification of the authorization policies. Intuitively, XACML supports attribute-based access control but does not really support credential-based access control (see Section 47.6.3.3). XACML also supports policies independently specified by multiple authorities on the same resources. When an access request on that resource is submitted, the system has to take into consideration all these policies and their outcomes are combined according to a combining algorithm. Policies defined by different parties may be enforced at different enforcement points. XACML provides a method for specifying some actions, called *obligations*, that must be fulfilled in conjunction with the policy enforcement. Figure 47.8 illustrates the XACML data-flow that consists of the following steps:

- The requestor sends an access request to the *Policy Evaluation Point* (PEP) module, which has to enforce the access decision taken by the decision point.
- The PEP module sends the access request to the *Context Handler* that translates the original request in a canonical format, called *XACML request context*, and sends it to the *Policy Decision Point* (PDP).
- The PDP module requests any additional *subject, resource, action, and environment* attributes from the Context Handler.
- The Context Handler requests the attributes required by the PDP module to the *Policy Information Point* (PIP) module. To this purpose, PIP interacts with the *Subjects, Resource, and Environment* modules. The *Environment* module provides a set of attributes that are relevant to take an authorization decision and are independent of a particular *subject, resource, and action*.
- The Context Handler sends the required attributes (and possibly the resource) to the PDP module.
- The PDP then evaluates the policies made available by the *Policy Administration Point* (PAP) and returns the *XACML response context* to the Context Handler. The context handler translates the XACML response context to the native format of the PEP and returns it to the PEP together with an optional set of obligations.
- The PEP fulfills the obligations and, if the access is permitted, it performs the access. Otherwise, the PEP denies access.

The main concepts of interest in the XACML policy language are *rule, policy, and policy set*. Each XACML policy has a root element that can be either a `Policy` or a `PolicySet`. A `PolicySet` is a collection of `Policy` or `PolicySet`. A XACML policy consists of a *target*, a set of *rules*, an optional set of *obligations*, an optional set of *advices*, and a *rule combining algorithm*. We now describe these components more in details.

- *Target*: It consists of a simplified set of conditions for the *subject, resource, and action* that must be satisfied for a policy to be applicable to a given request. Note that the definition of the subjects, resources, and actions in a target are based on attributes. For instance, a physician at an hospital may have the attribute of being a researcher, a specialist in some field, or many other job roles. According to these

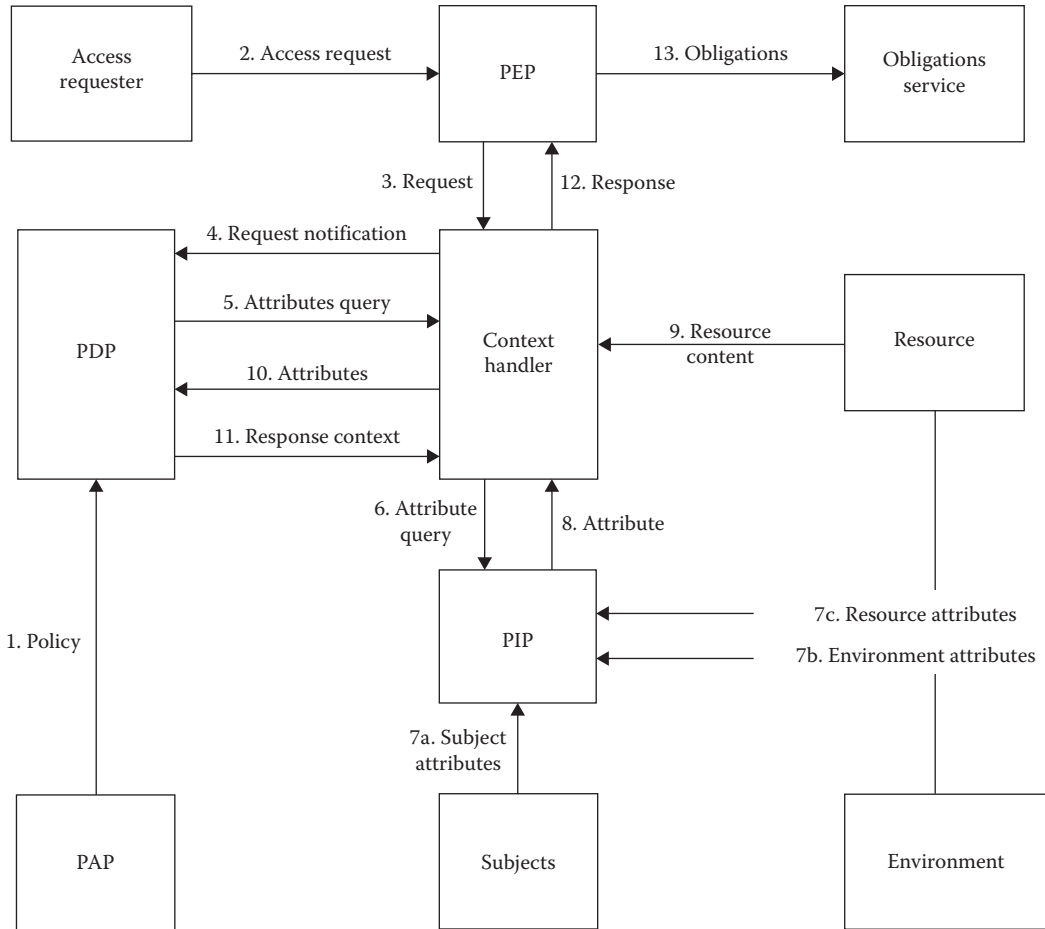

FIGURE 47.8 XACML overview. (From OASIS, *extensible Access Control Markup Language (XACML) Version 3.0*, 2010. <http://www.oasis-open.org/committees/xacml>.)

attributes, the physician can be able to perform different functions within the hospital. If all the conditions of a `Target` are satisfied, its associated `Policy` (or `Policyset`) applies to the request. If a policy applies to all entities of a given type, that is, all subjects, actions, or resources, an empty element, named `AnySubject`, `AnyAction`, `AnyResource`, respectively, is used.

- **Rule:** The components of a rule are a *target*, an *effect*, a *condition*, *obligation expressions*, and *advice expressions*. The target defines the set of resources, subjects, and actions to which the rule applies. The effect of the rule can be `permit` or `deny`. The condition represents a boolean expression that may further refine the applicability of the rule. Note that the `target` element is an optional element: a rule with no target applies to all possible requests. Obligation and advice expressions are evaluated and they can be returned to the PEP in the response context. Note that while obligations cannot be ignored, advices can be safely ignored by the PEP.
- **Obligation:** An obligation is an operation that has to be performed in conjunction with the enforcement of an authorization decision. For instance, an obligation can state that all accesses on medical data have to be logged. Obligations are returned by the PDP to the PEP along with the response. Note that, only policies that are evaluated and have returned a response of `permit` or `deny` can return obligations. This means that if a policy evaluates to `indeterminate` or `not applicable`, the associated obligations are not returned to the PEP.

- *Advice*: An advice is a supplementary piece of information that is returned to the PEP with the decision of the PDP.
- *Rule combining algorithm*: Each policy is associated with a rule combining algorithm used for reconciling the decisions each rule make. The final decision value, called *authorization decision*, inserted in the XACML context by the PDP is the value of the policy as defined by the rule combining algorithm. XACML defines eight different combining algorithms: *deny overrides*, *ordered-deny-overrides*, *permit overrides*, *ordered-permit-overrides*, *deny-unless-permit*, *permit-unless-deny*, *first applicable*, and *only-one-applicable* (see [50] for more details about the meaning of these combining algorithms). If no rule applies, the result is `not applicable`. If only one policy applies, the result coincides with the result of evaluating that rule. According to the selected combining algorithm, the authorization decision returned to the PEP can be `permit`, `deny`, `not applicable` (when no applicable policies or rules could be found), or `indeterminate` (when some errors occurred during the access control process). In particular, XACML 3.0 defines an extended set of indeterminate values, which includes: `indeterminate{D}` when a policy (rule) could have evaluated to `deny` but not `permit`; `indeterminate{P}` when a policy (rule) could have evaluated to `permit` but not `deny`; `indeterminate{DP}` when a policy (rule) could have evaluated to `deny` or `permit`.

XACML also defines a standard format for expressing requests and responses. The original request submitted by the PEP is translated through the Context Handler in a canonical form, and then forwarded to the PDP to be evaluated. For instance, an application can provide a SAML [2] message that includes a set of attributes characterizing the subject making the access request. This message has to be converted to the XACML canonical form and, analogously, the XACML decision has then to be converted to the SAML format. A request contains attributes for the subject, resource, action, and, optionally, for the environment. Each request includes exactly one set of attributes for the resource and action and at most one set of environment attributes. There may be multiple sets of subject attributes each of which is identified by a category URI. A response element contains one or more results corresponding to an evaluation. Each result contains six elements: `Decision` specifies the authorization decision (i.e., `permit`, `deny`, `indeterminate`, `not applicable`); `Status` indicates if some error occurred during the evaluation process; `Obligations` states the obligations that the PEP must fulfill; `AssociatedAdvice` is optional and reports a list of advices that provide additional information to the PEP; `Attributes` is optional and contains a list of attributes that were part of the request; `PolicyIdentifierList` is optional and corresponds to a list of policy or policy set identifiers that have been applied to a request.

47.6.3.3 Expanding XACML with Credentials

Although designed to be integrated with the Security Assertion Markup Language (SAML) [2] for exchanging security assertions and providing protocol mechanisms, XACML lacks a real support for considering, reasoning, and expressing conditions on certified properties. Recent proposals have tried to overcome this and other limitations that make XACML not yet suitable for open Web-based systems. In particular, the novel features that should be supported by a practical access control language can be summarized as follows [4]:

- *Certified information*: The attributes used in the XACML policies are assumed to be known during the evaluation time and stored within the XACML context or presented by the user together with the access request. To represent and manage credentials in XACML it is then necessary to express the fact that some attributes should be presented through given certificates, possibly imposing conditions on the value of these attributes and on the certificates themselves.
- *Abstractions*: Intuitively, abstractions represent a shorthand by which a single concept is introduced to represent a more complex one (e.g., a set, a disjunction, or a conjunction of concepts). For instance, `ID` (abstraction head) can be defined as an abstraction for any element in set

{Passport, DriverLicense} of credentials (abstraction tail). A policy specifying that an access requester must provide an ID can then be satisfied by presenting any of the two credentials above.

- *Recursive conditions*: The support for recursive reasoning allows the specification of policies based on chains of credentials and of conditions on data with a recursive structure.
- *Dialog*: The introduction of dialog between the involved parties has the advantages that the server can communicate which information is needed to evaluate an access control policy, and a user can release only the necessary credentials instead of releasing the whole set. A further advantage is that it permits to tackle the issue of the privacy trade-off between providing the whole set of credentials (on the access requester side) and disclosing the whole access control policy (on the server side). The proposal in [4] obtains this result by attaching a disclosure attribute to each condition in an access control policy. This attribute indicates what type of disclosure policy is associated with the condition, and it is enforced by hiding from the access requester the information that cannot be released according to such a disclosure policy. The more (less) of an access control policy is disclosed, the smaller (bigger) is the quantity of information in terms of released credentials that will have to be provided by the user.

The proposal in [4] illustrates how certified information, abstractions, recursive reasoning, and dialog management can be deployed in XACML. In particular, it shows that the integration of XACML with XQuery can be adopted for supporting abstractions and recursive conditions. Credentials and dialog management require a minimal change in the XACML language that consists in the addition of appropriate elements and attributes. Other proposals (e.g., [17,18,32,46]) provide XACML extensions to support trust negotiation.

47.7 Conclusions

In this chapter we introduced the most important concepts related to access control. We first described the discretionary, mandatory, and role-based access control policies, and then we illustrated recent proposals in the area of access control models and languages. In particular, we described novel approaches based on digital certificates, which are more suitable for open scenarios where servers offering services and users requesting such services do not know each other. We also provided an overview of logic-based and XML-based access control languages.

Key Terms

Access control: A process that controls every request to a system and determining, based on specified authorizations, whether the request should be granted or denied.

Access matrix: A matrix representing the set of authorizations defined at a given time in the system.

ACL: Access Control List.

Administrative policy: A policy regulating who can modify the allowed accesses.

Authorization: The right granted to a user to exercise an action (e.g., read, write, create, delete, and execute) on certain objects.

Certificate: A statement certified by an authority trusted for making such a statement.

DAC: Discretionary Access Control.

MAC: Mandatory Access Control.

Obligation: An action that must be performed sometime to allow the execution of a given action.

PDP: Policy Decision Point.

PEP: Policy Evaluation Point.

PIP: Policy Information Point.

RBAC: Role Based Access Control.

Role: A job function within an organization that describes the authority and responsibility related to the execution of an activity.

Security mechanism: Low-level software and/or hardware functions that implement security policies.

Security policy: High-level guidelines establishing rules that regulate access to resources.

XACML: eXtensible Access Control Markup Language.

48.1 Introduction

Data compression involves generating a compact description of information from a representation that may contain redundancies either of exposition or of interpretation. The process of generating a compact description involves understanding how information is organized in data. One way this can be done is by understanding the statistical characteristics of the data. If the data sequence is independent, we could treat the data as a sequence of independent, identically distributed (*iid*) random variables with a particular probability distribution. If the data are correlated, we can develop models for how redundancies could have been introduced into a nonredundant information stream. The study of data compression involves ways to characterize the structure present in the data and then use the characterization to develop algorithms for their compact representation. We will look at a number of different ways in which commonly used sources of data, such as text, speech, images, audio, and video, can be modeled and the compression algorithms that result from these models.

If the reconstruction of the data exactly matches the original data, the compression algorithm is called a *lossless* compression algorithm. If the reconstruction is inexact, the compression algorithm is called a *lossy* compression algorithm. In our study of compression algorithms, we will make use of this natural division to organize the subject.

Before we examine the various approaches to compression, we briefly look at ways of quantifying information. We then look at some of the basic theories behind lossless and lossy compression. We begin our study of compression techniques by describing lossless and lossy compression techniques that assume the source to be from an *iid* distribution. We then examine different ways of modeling structures within the data and the algorithms that are a consequence of the different models. Finally, we conclude with some suggestions for further reading.

48.2 Entropy and Kolmogorov Complexity

In order to realize compression, the code generated by an encoding process must be shorter than the original sequence, something possible only when the original data can be described more concisely than in its original form. Fortunately, many sequences of interest can be described more concisely than with their original representations. What permits this concise description is the organization on different levels within the data. Data compression is generally applied to anthropic or scientific (that could also be considered anthropic) data that are the output of complex systems. Text data are records of natural languages, driven by grammar rules, and containing repetitive structures as a result. Still images usually capture structured objects as observed in the visible band of the electromagnetic spectrum. Motion pictures have a similar configuration as well as containing structured objects moving with bounded velocities. Computer graphics, in general, are generated by rules defined by specific programs. Audio streams are gathered from the instances of acoustic processes. Scientific data sampled from observed physical processes are governed by the laws of physics. When attempting to compress data, it is assumed that the input is not obtained from randomly unorganized media. Clearly, the more structured the data are, the higher the compression the coding system can achieve when given prior knowledge of data organization.

Let's consider the coding problem with two example sequences. Assume two binary sequences S_B and S_π are given as

$$S_B = 10101010100001101111100110000011001011101001110101 \quad (48.1)$$

$$S_\pi = 00100100001111110110101010001000100001011010001100 \quad (48.2)$$

The first sequence S_B is the first 50 outcomes of a Bernoulli trial or the results of a sequence of coin flips where the coin is fair. The second sequence is the first 50 fractional digits of the number π . To describe the first sequence, we do not have many options other than transmitting the entire sequence. However, there is more room for maneuvering when coding the second sequence. We can actually generate the first digits of π with a simple program implementing a series expansion. If $l(S_B)$ is the number of bits needed to describe S_B and $l(S_\pi)$ is the number of bits needed to describe S_π , the description length of these sequences would be

$$l(S_B) = O(n) \quad (48.3)$$

$$l(S_\pi) = l_p + \lceil \log_2 n \rceil \quad (48.4)$$

The sequence S_B is a random sequence and requires around n bits to describe. The sequence S_π can be described using a series expansion program, which can be represented using l_p bits, followed by $\lceil \log_2 n \rceil$ bits to encode the integer n . Clearly, the coding length can differ significantly based on the complexity of a sequence.

Out of all possible descriptions, the one with the shortest length is called the Kolmogorov complexity $K_U(x)$ [1] of a sequence:

$$K_U(x) = \min_{p:U(p)=x} l(p) \quad (48.5)$$

Here, U represents a universal Turing machine; and the output is x when the halting program p is executed.

By definition, a sequence x cannot be compressed to less than $K_U(x)$ bits; therefore, the Kolmogorov complexity determines the theoretical lower bound of data compression. However, there is no guarantee that the Kolmogorov complexity is computable; and even estimating $K_U(x)$ may take infinite time. The estimation of $K_U(x)$ requires a perfect understanding of the system generating a sequence, which is usually not available. Therefore, instead of a physical-model-driven (top-down) description, we use a probabilistic description (bottom-up) to obtain the lower bound for the description length. According to the probabilistic approach, a sequence is a realization of a stationary random process. Therefore, we can model it in terms of the probability distribution of the elements of the sequence. In a landmark paper in 1948 [2], Claude Shannon connected the ideas of information and randomness. Given an event A and its probability of occurrence $p(A)$, he defined the information associated with the occurrence of the event A as *self-information* that is given by

$$i(A) = \log_b \frac{1}{p(A)}$$

where the units of the information depend on the base b of the logarithm. If $b = 10$, the unit is Hartley, after the famous American electrical engineer who laid some of the foundations for what was to become information theory. If $b = e$, the base of the natural logarithm, the unit of information is *nat*. The most common base used in this context is 2; when the base 2 logarithm is used, the unit of information is *bit*.

If we treat each element of a sequence X_1, X_2, \dots as the independent outcome of an experiment where the possible outcomes come from a set \mathcal{A} , then we can define the *average information* as the expected value of the self-information. Shannon called this average information *entropy* and denoted it by H . Thus, if S is a *source* that emits the sequence X_1, X_2, \dots , the entropy of the source is given by

$$H(S) = \sum_{X_i \in \mathcal{A}} p(X_i) \log_2 \frac{1}{p(X_i)}$$

We can show [3] that

$$\frac{1}{n} E\{K_U(X)\} \rightarrow \sum_{X_i \in \mathcal{A}} p(X_i) \log_2 \frac{1}{p(X_i)} \quad (48.6)$$

Thus, if we accept the conceit that a given sequence is a realization of a random process, we can see that the lower bound on the number of bits used to represent the sequence is given by the entropy.

We can see from the equation earlier that the expected value of the self-information for an *iid* source is the entropy. For a more general source that emits a sequence of n symbols X_i with a joint probability density function $p(X_1, X_2, \dots, X_n)$, we can define an entropy per n -tuple as

$$H_n = - \sum_n p(X_1, X_2, \dots, X_n) \log p(X_1, X_2, \dots, X_n)$$

The entropy of this general source is defined as the limiting value of the entropy per n -tuple:

$$H(S) = \lim_{n \rightarrow \infty} \frac{1}{n} H_n$$

48.2.1 Lossless Compression

Lossless compression refers to a compression process in which the recovered data are identical copies of the input. Erroneous decoding of certain types of data is not tolerable. Transmitting incorrect text to the receiver might result in serious semantic mistakes. Similarly, conveying scientific data with errors might impact the conclusion inferred from the data, such as inferring mutations for DNA or protein sequences that do not actually exist. Because of the need for absolute fidelity in a wide variety of applications, lossless compression algorithms form a significant part of the data compression field.

Data compression involves data processing performed on computers and data transmission via digital communication systems. Therefore, both the data to be encoded and the compressed streams are discrete signals with quantized values. Within this framework, it is possible to view the data to be compressed as a sequence of symbols from a finite set. The set of possible symbols A is called the *alphabet* of the source S , and elements of this set are referred to as *letters*. Alphabets vary according to data types. For text documents with ASCII characters, the alphabet consists of 128 letters (the printable ASCII characters). Grayscale images encoded using 8 bits/pixel have an alphabet size of 256, the values 0–255. A sequence $\{X_1, X_2, \dots\}$, $X_i \in A$ is generated by the source S . During the encoding process, a sequence is mapped to a binary string called the *code*. Binary strings corresponding to the mapping of each letter in the alphabet are referred to as *codewords*.

Lossless compression is achieved by an invertible coding process bijectively mapping the input sequence to a more compact code stream. Bijective coding imposes the requirement that the encoder generate a unique code for each sequence. In order to attain compression, the code has to have a length shorter than the input sequence. This performance of the compression algorithm is usually measured by the *compression ratio* and the *rate*. The compression ratio is the ratio of the number of bits used to represent the original sequence to the the number of bits used for the compressed representation. For example, if a grayscale image of 800×600 pixels, which is encoded using an alphabet of size 256, is stored as a 240,000 byte file, we say that the corresponding compression ratio is 2:1. The rate of the compression algorithm is usually defined as the number of bits per symbol. For the image example described earlier, the average number of bits required to represent a pixel is 4 bits. In other words, the rate is 4 bits/symbol.

48.2.2 Lossy Compression

Lossless compression involves an invertible mapping of data to a shorter compressed string. While this is an essential requirement when information loss cannot be tolerated, a majority of data compression applications do not require perfect reconstruction. The compression techniques where the reconstruction is an approximation of the original data are called *lossy compression* algorithms.

Preference of lossy compression over lossless compression generally depends on the application. One, and perhaps the most significant, motivation for lossy compression is the limited and inferential nature of human perception. Compressing natural images or audio sequences does not require perfect representation of these sequences because they are to be perceived by the limited capabilities of human visual or auditory systems. The human visual system is known to be able to perceive an electromagnetic frequency band between red and violet frequencies. It has higher sensitivity to the intensity of light than to its color components. Moreover, spatial details are usually filtered out; and more attention is paid to the smoother variations. Image and video coding systems are designed to take advantage of all these aspects of human perception, allowing us to discard “unnecessary” data components, focusing resources on those aspects that are important for perception. Similarly, our auditory system can hear the frequency band of 20 Hz–20 kHz. The response in this band is nonlinear, with a greater sensitivity to higher frequencies. Other effects, such as masking frequencies, also play a role in hearing. Using the same rationale as for still or motion picture coding, various “unnecessary” audio components can be discarded.

Beyond that natural reduction that is generally imperceptible, perceptible loss may also need to be tolerated due to economic or physical constraints. Data compression is needed for either storage or

transmission over communication systems. Bandwidth and disk spaces are limited that can result in the need for more compression if the demand for these resources is greater than the supply. An example of this is telephone communication in which lower quality, resulting from the low coding rates, may be satisfactory as long as the message is delivered.

A lossy coding scheme in which each codeword can represent more than one element from the original data enables coding at rates lower than the source entropy. The price is the difference between the original data and the reconstructed sequence generally referred to as *distortion*. Obviously, a trade-off between the quality and the rate occurs. However, *quality* is subjective; and it is difficult to define a distortion measure that quantifies the approximations of data based on their quality. On the other hand, simple mathematical definitions of distortion can be useful for studying the limits and opportunities provided by the quality-rate trade-off. *Rate distortion theory* describes the theoretical limits of achievable rates for a given amount of distortion.

48.3 Modeling Data as an *iid* Sequence

We begin with the simplest of models where the data are assumed to be *iid* and are described by a probability model. There has been considerable effort spent on developing compression schemes based on such models. The reason for this is twofold. There are, at times, data that really are *iid* and are well compressed by these algorithms. When the data sequence is not *iid* and can only be modeled by a complex model, it is convenient to use the model to obtain a transformation resulting in a *transformed* or *residual* sequence that is *iid* and then compress the *iid* sequence. In fact most compression systems can be seen as consisting of two stages: (1) a stage of redundancy removal or transformation resulting in the generation of an *iid* sequence followed by (2) a coding of the *iid* sequence thus generated. We look at how to most efficiently represent *iid* sequences both in the case of lossless compression and in the case of lossy compression.

48.3.1 Lossless Compression of *iid* Sequences

We would like to design lossless compression algorithms that promise rates close to the entropy. However, the rate is not the only criterion that needs to be considered. First, a code generated by an encoder must be *uniquely decodable*, so that the decoder will not reconstruct an erroneous sequence. It seems this requirement could be satisfied if every letter in an alphabet was mapped to a unique codeword. However, this is not the case. For example, consider a code in which the letters $\{a, b, c, d\}$ are coded with the codewords $\{0, 100, 01, 00\}$, respectively. Each letter has a unique codeword associated with it; however, a code 0100 could be interpreted as either ab or cd as the sequence of codewords is not uniquely decodable. Mitigation of this problem requires that the code should have only one parsing. One way in which we can guarantee that we have a unique parsing is to make sure that no codeword is a prefix of another codeword. We can check to see if a codeword is a prefix of another codeword by representing the code in the form of a tree. For a code in which no codeword is a prefix of another codeword, called a *prefix code*, the codewords are always assigned to the leaves of the code tree. In Figure 48.1, we show two four-letter codes: $\{0, 100, 01, 00\}$ and $\{00, 01, 100, 101\}$, where the filled-in circles denote codewords. For the first code, we can see that the codeword 0 is a prefix to the codewords 01 and 00. In the case of the second code, all codewords are assigned to the leaves of the tree; and hence, no codeword is a prefix to another codeword. In decoding a sequence encoded using the prefix code, we decode a letter whenever we reach a leaf of the code tree. Clearly, a prefix code will give us a uniquely decodable code. However, while the fact that a code is a prefix code guarantees that the code is uniquely decodable, it is not a necessary condition. Consider the code $\{0, 01, 11\}$. This is not a prefix code; however, we can show that this code is uniquely decodable [4]. We are faced with what seems to be a conundrum. If we restrict our search for codes to prefix codes, we can guarantee that the code will be uniquely decodable. However, could we find lower-rate codes if we did not restrict ourselves to prefix code? Happily, the answer is no.

FIGURE 48.1 Code trees for two different codes. The tree on the right corresponds to a prefix code.

To show this, we will use the Kraft–McMillan inequality [4]. Consider a code over an alphabet of m letters, with codeword lengths l_1, l_2, \dots, l_m . If the code is uniquely decodable, the following inequality holds:

$$\sum_i 2^{-l_i} \leq 1 \tag{48.7}$$

Furthermore, we can show that given a set of integers l_1, l_2, \dots, l_m that satisfy this inequality, we can always build a prefix code with codeword lengths l_1, l_2, \dots, l_m . Hence, if a code is uniquely decodable, the lengths of the codewords satisfy the Kraft–McMillan inequality; and if the lengths satisfy the Kraft–McMillan inequality, we can generate a prefix code with those lengths. Thus, for every uniquely decodable code, we can always generate a prefix code with the same average length. This being the case, restricting ourselves to prefix codes does not cost us anything in terms of the average length of the code.

The Kraft–McMillan inequality is also useful for determining bounds on the length of uniquely decodable codes. If the probability of observing the letter i is p_i , then the average codeword length is

$$L = \sum_i p_i l_i \tag{48.8}$$

We want to pick $\{l_i\}$ that minimize L while satisfying the Kraft–McMillan inequality. We can do that by finding l_1, l_2, \dots, l_m that minimize the Lagrangian

$$J = \sum_i p_i l_i + \lambda \sum_i 2^{-l_i} \tag{48.9}$$

Taking the derivative of J with respect to l_i and setting it equal to 0, we obtain

$$p_i = \lambda 2^{-l_i} \ln 2 \tag{48.10}$$

Substituting this expression in the Kraft–McMillan inequality, we can solve for l_i and get

$$l_i = \log_2 \frac{1}{p_i} \tag{48.11}$$

This length is not restricted to be an integer. If we want integer codeword lengths, we can simply use the ceiling function

$$l_i = \left\lceil \log_2 \frac{1}{p_i} \right\rceil \tag{48.12}$$

(Note that we use the ceiling rather than the floor function in order not to violate the Kraft–McMillan inequality.) Using these codeword lengths, we can find the upper and lower bounds on the average length L :

$$L = \sum_i p_i \left\lceil \log_2 \frac{1}{p_i} \right\rceil \quad (48.13)$$

$$\geq \sum_i p_i \log_2 \frac{1}{p_i} \quad (48.14)$$

$$= H \quad (48.15)$$

Thus, the average length is always greater than or equal to the entropy. We can also obtain an upper bound on the average length:

$$L = \sum_i p_i \left\lceil \log_2 \frac{1}{p_i} \right\rceil \quad (48.16)$$

$$\leq \sum_i p_i \left(\log_2 \frac{1}{p_i} + 1 \right) \quad (48.17)$$

$$= H + 1 \quad (48.18)$$

Therefore, the expected rate of an optimal prefix code is in the 1-bit neighborhood of the source entropy, while it cannot get better than the entropy.

48.3.1.1 Huffman Coding

We have seen that prefix codes can achieve rates close to entropy, in cases where the codeword selection is arranged optimally (i.e., with length close to $-\lfloor \log_2 p_i \rfloor$). A constructive way of building optimal prefix codes is the Huffman coding algorithm [5,6]. This algorithm is based on two observations. First, an optimal code should have longer codewords for less probable symbols. This is a direct result of our previous discussion. Second, the codewords for the two least frequent symbols should have the same length. We can see why this is required by showing the contradictory case. Consider that in an optimal prefix code, the least probable symbol had a longer codeword than the second least probable one. If we deleted the least significant bit of the longer codeword, this shortened codeword would not conflict with another codeword (because no codeword is the prefix of another). Therefore, we obtain another uniquely decodable code with a shorter average codeword length. This is in contradiction with the initial assumption that this prefix code was optimal. Thus, the least probable two codewords must have the same length.

Huffman added a third requirement that, while not necessary, made it easier to obtain the code. The requirement was that the codewords of the two least probable symbols should only differ in the last bit. We can easily show that this requirement does not in any way reduce the optimality of the code.

The Huffman algorithm is a hierarchical codeword construction scheme, starting from the least significant bits of the least probable two codewords, building up adding more probable codewords and significant bits. We can summarize the procedure as follows:

1. Sort the symbol probabilities.
2. Halt if only one symbol exists.
3. Push bits 1 and 0 to the least probable two codewords.
4. Combine the least probable two symbols into one. GOTO 1.

Following this procedure, we allocate bits giving higher priority to the least significant symbols. This is in the spirit of the first property of optimal codes. Since we combine the least probable symbols, they will be treated together in a bit assignment step in any future iteration. As a result, they will have the same length satisfying the second property. Note that combining the symbols that differ in the last bits will not let any codeword be the prefix of another, complying with the definition of prefix codes. Let's perform Huffman coding on an example.

We design a Huffman code for a five-letter alphabet $\mathcal{A} = \{a_1, a_2, a_3, a_4, a_5\}$ with probabilities $\{.3, .1, .2, .25, .15\}$. The two letters with the lowest probabilities are a_5 and a_2 . We assign a zero as the least significant bit for a_5 and a one as the least significant bit for a_2 . We then combine these two letters giving us a letter with a combined probability of .25. We can re-sort this reduced set in one of two ways, $\{a_1, a_4, [a_5a_2], a_3\}$ or $\{a_1, [a_5a_2], a_4, a_3\}$. Depending on which sorting we use, we will get a different code; however, both sortings will result in a code with minimum length, in other words, a Huffman code. In this example, we will use the latter sorting. At this point, the two lowest probability elements in our set are a_3 with a probability of 0.2 and a_4 with the probability of 0.25. We push a zero into the least significant bit for a_4 and a one into the least significant bit for a_3 and continue. The complete process can be represented as in Figure 48.2. Working from the root to the leaves, we obtain the following code:

a_1	10
a_2	111
a_3	01
a_4	00
a_5	110

We have seen that Huffman coding is optimal given the alphabet and the source distribution. However, the Huffman code is not unique. The Huffman coding algorithm finds one of multiple optimal assignments. It is easy to see that Huffman coding is not unique, since other optimal codes can be obtained by inverting bits or swapping the codes of the least probable symbols.

The Huffman coding algorithm requires that the alphabet distribution be known. In practice, the distribution for a source may not be available *a priori* unless the operations are performed offline. For such applications, the algorithm can be made adaptive by using a binary tree update procedure [7]. The leaves represent the codewords and are weighted according to the observing frequency of a symbol, so that the algorithm can keep track of the distribution statistics. The decoder follows the same procedure as the encoder, so that at any instance both the transmitter and the receiver have the same codewords.

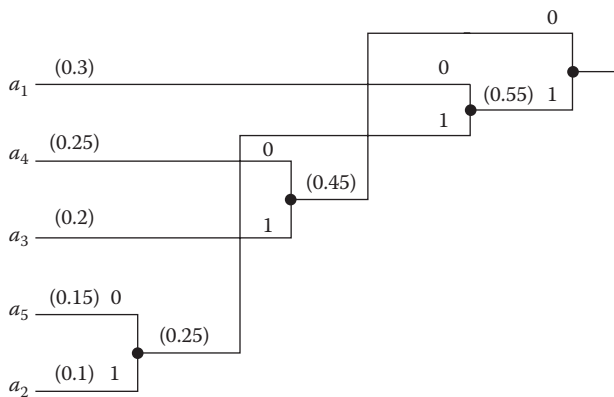

FIGURE 48.2 Construction of a Huffman code tree.

A rate bound tighter than the bound derived for optimal codes can be derived for Huffman codes. It can be shown that the upper rate bound for a Huffman code is $H(X) + \arg \max_i P(X_i) + 0.086$ [7]. This guarantees rates closer to the source entropy for an alphabet distribution in which all letters have small probabilities. However, the code might be inefficient when the probability distribution is highly skewed and the maximum probability is large. This is the case for binary sources such as bilevel documents. Extending the alphabet to blocks of symbols is one way of mitigating this dominant symbol problem. Instead of encoding the source output one symbol at a time, we group the output into blocks and treat the blocks as letters from a larger alphabet. If we block n symbols together, the upper bound on the number of bits needed to encode a block of n symbols is given by $H(X_1, X_2, \dots, X_n) + \max P(X_1, X_2, \dots, X_n) + 0.86$. However, for an *iid* sequence,

$$H(X_1, X_2, \dots, X_n) = nH(X) \quad (48.19)$$

and

$$\max P(X_1, X_2, \dots, X_n) = \max_i P(X_i)^n \quad (48.20)$$

Therefore, the upper bound on the average number of bits needed to encode a single symbol becomes $H(X) + \max_i P(X_i)^n / n + 0.086/n$. The cost is an increase in the number of codewords required. If the alphabet of the source is of size M , the alphabet of the block of n symbols is M^n . This exponential increase in the number of codewords required makes the approach infeasible in terms of Huffman coding for all but the smallest alphabet sizes. However, if we do not need to generate all the codewords and only need to generate the codeword of the sequence being encoded, this cost is no longer a cost. This is precisely the case for the next coding technique we discuss, namely, arithmetic coding.

48.3.1.2 Arithmetic Coding

The result that a better code (with a rate closer to the source entropy) might be available by extending the alphabet to the blocks of symbols is very promising. This result is especially significant when the source alphabet is small (e.g., bilevel images with binary alphabet). The upper bound of the rate asymptotically converges to the source entropy as the block size increases. Obviously, the best case would be where the block size is equal to the sequence length. However, in practice, this will cause the problem of an exponentially growing alphabet size. Note that the Huffman coding procedure assigns optimal codewords to each letter in the alphabet, whereas in the case of the block length being equal to the sequence length, only one of them, the codeword corresponding to the sequence itself, is observed.

Arithmetic coding offers a solution to the problem of exponentially increasing alphabet size by generating a code only for the observed sequence. In order for this code to be optimal, two fundamental aspects of optimal codes must be preserved. First, the length of the code must be inversely proportional to the observed probability of the symbol (or sequence in this case). This length should be an integer close to $-\log_2 p(S_i)$ where $p(S_i)$ is the probability of observing the sequence. Second, the code must be uniquely decodable. In cases where the entire sequence is mapped into a single codeword, this means different sequences should not be mapped onto the same codeword.

The fundamental idea of arithmetic coding is that every sequence can be mapped to an arbitrary interval on the real number line. The binary code for the sequence is the binary representation of a number in the interval to which the sequence is mapped. In practice, we take this interval to be $[0,1)$. Without loss of generality, we can consider the case of finite sequences of the same length. The number of possible sequences of length n generated from a source with the alphabet A is $m = |A|^n$. All of these sequences can be represented by m nonoverlapping intervals drawn from $[0,1)$. Each interval can be tagged with the binary fractional part of a rational number drawn from it. Therefore, each sequence is tagged by a distinct code; and this satisfies the property of unique decodability. In order to satisfy the optimal

coding requirement, a careful allocation of these intervals into the unit interval is needed. Assigning larger intervals to more probable sequences allows them to be represented with shorter codes, because it would take a fewer number of significant bits to locate a rational number in a larger interval. k bits are required to represent an interval of size $(1/2)^k$. Assume we pick the size of the interval to be the probability of the sequence S_i assigned to it. This interval can be tagged with k bits, where k is the smallest integer satisfying $p(S_i) > (1/2)^k$. Therefore, the number of bits required to tag a sequence with probability $p(S_i)$ is

$$k = \lceil -\log_2 p(S_i) \rceil \quad (48.21)$$

which satisfies the optimal code requirement.

Two observations on allocating the intervals representing sequences are important for the arithmetic coding algorithm. First, the nonoverlapping intervals adjacently tile the unit interval. Therefore, since $\sum_i p(S_i) = 1$, the boundaries of these intervals can be determined by the cumulative distribution function (*cdf*). Second, since the symbols are *iid*, the probability of a sequence is equal to the product of the probabilities of the individual elements of the sequence. As the sequence grows, the probability of the sequence decreases because each time a new element is added to the sequence, the probability of the sequence is multiplied by a number less than one. It can be shown that if the sequences are assigned to intervals by lexicographical ordering, each symbol read in shrinks the representative interval to the subset of the corresponding prefix. As a result, the binary codeword corresponding to the sequence can be found by recursively zooming in to the subintervals determined by the *cdf* of symbols. This separability is very useful in practice because it allows the use of an iterative algorithm to generate the code as the symbols are read in, regardless of the length of a sequence.

In practice, we keep track of the upper and lower limits of the interval corresponding to the sequence being encoded. If the upper and lower limits corresponding to the sequence when it consists of k elements are given by $u^{(k)}$ and $l^{(k)}$, then we can show that the recursion equations that generate the upper and lower limits are given by

$$l^{(k)} = l^{(k-1)} + (u^{(k-1)} - l^{(k-1)})F(X_i^{(k)} - 1) \quad (48.22)$$

$$u^{(k)} = l^{(k-1)} + (u^{(k-1)} - l^{(k-1)})F(X_i^{(k)}) \quad (48.23)$$

where

$F(X_i^{(k)})$ is the *cdf* evaluated for the letter that is the k th element of the sequence S_i

$F(X_i^{(k)} - 1)$ is the *cdf* evaluated for the letter lexicographically preceding the letter that is the k th element of the sequence S_i

Note that after processing the first symbol, the length of the interval is $p(X_i^{(1)})$. With the introduction of the second symbol, the length shrinks to $u^{(2)} - l^{(2)} = (u^{(1)} - l^{(1)})p(X_i^{(2)}) = p(X_i^{(1)})p(X_i^{(2)})$ and for the k th symbol to $u^{(k)} - l^{(k)} = \prod_{j=1}^k p(X_i^{(j)})$. Therefore, the number of bits required to represent a number in the final interval for a sequence of length N is given by

$$\left\lceil -\log_2 \prod_{k=1}^N p(X_i^{(k)}) + 1 \right\rceil \cong NH(X) + 2 \quad (48.24)$$

Although determining the tag using $l^{(N)}$ and $u^{(N)}$ is sufficient for generating the code, some practical issues need to be considered for implementing the algorithm. First, we want to send the bits as we read

through the sequence without waiting for the termination of the sequence. More importantly, as we keep multiplying by numbers less than one, the size of the interval becomes smaller and smaller until it falls below the machine precision level. Two strategies are used to provide incremental coding and prevent the upper and lower levels from converging. The first strategy is used when the interval corresponding to the sequence is wholly contained in either the upper or the lower half of the unit interval. In this case, the most significant bit (MSB) of the upper and lower limits is the same, as are the most significant bits of any number in the interval. We can, therefore, release this bit to the communication channel. We can also shift this bit out from the registers holding upper and lower limits and shift in a 1 for the upper and a 0 into the registers holding the upper and lower limits, respectively. By doing this, we effectively double the size of the interval.

When the interval is contained in the middle half of the unit interval, $[0.25, 0.75)$, with the lower limit in $[0.25, 0.5)$ and the upper limit in $[0.5, 0.75)$, we cannot use this strategy. However, we know that in the future, if the interval is contained in either the upper or the lower half of the unit interval there, the size of the interval will be less than 0.25. If this interval is entirely contained in the lower half of the unit interval, the most significant bit of the upper and lower limits, and, hence, all numbers in the interval, will be 0 and the second most significant bit will be 1. Similarly, if the interval is entirely contained in the upper half of the unit interval, the most significant bit of all numbers in the interval will be 1 and the second most significant bit will be 0. This knowledge of the future is used by the algorithm by doubling the interval at the current time without releasing any bits into the communication channel. Instead, a counter, *scale3*, keeps track of the number of times the interval is scaled; and when in the future the upper and lower limits end up with the same most significant bit, the encoder releases that bit followed by *scale3* bits, which are the complement of the most significant bit. The scaling of the interval is performed by shifting out the most significant bit, complementing the next most significant bit, and shifting in a 1 or a 0 for the upper and lower limits, respectively.

The algorithm for encoding can be summarized as follows:

1. Read the first symbol and initialize l and u and $scale3 = 0$.
2. IF l and u have the same MSB, send MSB and the complement of MSB $scale3$ times; shift-left l , u , reset $scale3 = 0$.
3. IF l and u are in the middle half shift-left & complement MSB of l , u ; increment $scale3$.
4. IF u and l are in the lower, middle, or upper half of the unit interval, GOTO 2.
5. Update l and u using the next symbol.
6. IF end of sequence send l ; terminate, ELSE GOTO 2.

The encoding algorithm can be implemented using integer buffers containing l and u as described. Floating numbers with corresponding scaling operations can also be employed. The decoder mimics the scaling operations of the encoder. However, instead of sending the MSB, it pushes the new LSB from the code to a tag buffer t . Searching for the *cdf* interval, including the current tag, and representing the corresponding symbol are also performed in the update phase. The updates of l , u , and t are done using the detected interval. Therefore, the sequence can be decoded online as the code is retrieved. The first symbol is decoded after the first m bits are fed into the buffers, where m is determined by the smallest *cdf* interval.

Let's go through the encoding procedure with an example. Assume a sequence drawn from a three-letter alphabet $\mathcal{A} = \{a_1, a_2, a_3\}$ with probabilities $\{0.7, 0.2, 0.1\}$. We encode the sequence $a_1 a_3 a_2 a_2$. The corresponding *cdf* is $F(1) = 0.7$, $F(2) = 0.9$, $F(3) = 1$. Reading the first symbol a_1 , we initialize $l^{(1)} = 0$ and $u^{(1)} = 0.7$. With the second symbol a_3 , the updates are performed by Equation 48.22, giving $l^{(2)} = 0.63$ and $u^{(2)} = 0.7$. The MSB of $l^{(2)}$ and $u^{(2)}$ are both 1. Scaling using Step 2 of the algorithm $l^{(2)} = 0.26$ and $u^{(2)} = 0.4$, and 1 is sent to the receiver. The MSB for both are now 0. We can send 0 and scale again using Step 2 once more. Now $l^{(2)} = 0.52$ and $u^{(2)} = 0.8$. One more scaling with Step 2 sends 1 and scales $l^{(2)} = 0.04$ and $u^{(2)} = 0.6$. Now $l^{(2)}$ and $u^{(2)}$ cover more than half of the unit interval. So we proceed to Step 5 and read the third symbol, a_2 , and update $l^{(3)} = 0.432$ and $u^{(3)} = 0.5832$. The condition of Step 3 holds, so we increment *scale3* and scale

FIGURE 48.3 Example of the arithmetic encoding procedure.

$l^{(3)} = 0.364$ and $u^{(3)} = 0.6664$. Once more $l^{(3)}$ and $u^{(3)}$ lie in the middle half, so repeating Step 3, $scale3 = 2$, $l^{(3)} = 0.228$ and $u^{(3)} = 0.8328$. The interval is greater than half the unit interval, so we read the fourth symbol a_2 and update the interval using Step 5, $l^{(4)} = 0.6514$ and $u^{(4)} = 0.8147$. The MSB are both 1, so we send 1 followed by 2 ($scale3$) 0s, and scale $l^{(4)} = 0.3027$ and $u^{(4)} = 0.6293$. The interval is in the middle half, so we follow Step 3, resulting in $l^{(4)} = 0.1054$ and $u^{(4)} = 0.7586$. This is the terminating symbol. So we transmit $l^{(4)}$ using the scaling of Step 2 (it lies in the lower half); a 0 followed by a 1 is transmitted. Finally, the code generated is 10110001. The encoding process can be seen in Figure 48.3.

For unknown distributions, the arithmetic coding algorithm can easily be made adaptive. In this case, initially, equal intervals represent each symbol in the alphabet. As a new symbol is encoded (decoded), the frequency count of the symbol coded is incremented. As the symbols are coded (decoded), the cdf is updated accordingly. The compression performance is similar to arithmetic coding with known distributions for large sequences. Since this operation can be performed simultaneously at the encoder and the decoder, no side information needs to be sent.

The performances of Huffman coding and arithmetic coding can be seen on an example of image coding. A 512×512 grayscale Lena image is shown in Figure 48.4. Each pixel is coded to 256 levels (8 bits), and the estimated entropy of the image is 7.4455 bits/symbol. Coding the image using a 256-letter alphabet results in a rate of 7.4682 bits/symbol for Huffman coding. The same image can be coded with a rate of 7.4456 bits/symbol by arithmetic coding. While both algorithms behave close to the source entropy, arithmetic coding is even closer since it uses block coding rather than symbol-by-symbol encoding.

48.3.2 Lossy Compression of iid Sequences

Lossy compression allows for distortion in the reconstruction hence, the input alphabet and the reconstruction alphabet can have different cardinalities. Lossy compression can be viewed as a mapping from an input space \mathfrak{N} with a large, possibly infinite, alphabet onto a finite output space $\hat{\mathfrak{N}}$. In the most

FIGURE 48.4 Lena image. Original size: 262,144 bytes. Entropy: 7.4455 bits/pixel. Huffman coding rate: 7.4682 bits/symbol. Arithmetic coding rate: 7.4456 bits/symbol.

general setting, this map is called *quantization*. Given a distortion measure, which is a function defined on the source and reconstruction alphabet pairs $d: \mathfrak{X} \times \hat{\mathfrak{X}} \rightarrow \mathfrak{R}^+$, a quantization method attempts to assign a reconstruction value to the input that results in the smallest possible distortion between the original and reconstruction values. Conversely, given a certain acceptable distortion value, the quantization process picks the particular mapping from the set of acceptable mappings that will result in the minimum rate.

Given a distortion function d , the expected distortion due to quantization is defined as

$$D = \sum_{x, \hat{x}} p(x, \hat{x}) d(x, \hat{x}) \quad (48.25)$$

$$= \sum_{x, \hat{x}} p(x) p(\hat{x}|x) d(x, \hat{x}) \quad (48.26)$$

Unlike entropy, the distortion depends not only on the source distribution but also on the conditional distribution of the output.

The rate distortion theorem [8,9] states that for an *iid* source, the distortion D for which the minimum rate is achieved is bounded by the average mutual information between the source and the output:

$$R_{\min} = \min I(X; \hat{X}) \quad (48.27)$$

such that

$$= \sum_{x, \hat{x}} p(x) p(\hat{x}|x) d(x, \hat{x}) \leq D \quad (48.28)$$

where $I(X; \hat{X}) = H(X) + H(\hat{X}) - H(X; \hat{X})$ is a measure of the shared information between the source and the output distributions. This theorem provides the theoretical limit on the performance of lossy compression. In this sense, it serves a role similar to the one played by entropy in lossless compression.

48.3.2.1 Scalar Quantization

Scalar quantization maps each symbol of a sequence to a codeword from a finite alphabet. This is a many-to-one mapping and, therefore, not invertible. The goal in quantizer design is to come up with a mapping and a representation set that results in a reconstruction with the minimum average distortion. The input alphabet is partitioned into sets that are each represented by a codeword from the quantizer output alphabet. The design of the partition and the representative codewords turns out to be a Voronoi partition problem. Given a set of reconstruction values, we want to partition the input alphabet such that each partition is represented by the reconstruction value that results in minimum distortion. Furthermore, given a partition of the input alphabet, we want to find the set of reconstruction values, one for each partition, which can be used to represent the input alphabet with the least distortion. For an R bit quantizer, the problem will turn out to be

$$\min_{\hat{x}} \sum_{i=1}^{2^R} \sum_{x \in v_i} p(x) d(x, \hat{x}_i) \tag{48.29}$$

such that

$$v_i = \{x : d(x, \hat{x}_i) < d(x, \hat{x}_j), \forall j \neq i\}$$

where \hat{x} represents the reconstruction points. The inner summation changes to an integration for continuous alphabets, and the distribution $p(x)$ turns out to be the *pdf* of the source. This problem is hard even for tractable distortion measures such as the mean squared distance measure. An approximate solution for general distributions is as follows. Starting from a set of arbitrary reconstruction points, the partitions v_i are found by assigning each letter from the input alphabet to the closest letter from the reconstruction; then the new reconstruction points are estimated as the mean of each partition v_i . This procedure is iteratively repeated. The distortion in each iteration can be shown to be nonincreasing, and the total distortion is expected to converge to a local minimum. This algorithm is known as Lloyd's algorithm [10].

The input-output maps for different configurations of a scalar quantizer are shown in Figure 48.5. If the quantization intervals Δ_i are the same for all except the outermost intervals, the quantizer is called

FIGURE 48.5 Two scalar quantizer input-output maps. The one on the left is called a midrise quantizer, while the one on the right is called a midtread quantizer.

a *uniform quantizer*. If not, it is called a *nonuniform quantizer*. One popular implementation of the uniform quantizer is where the quantizer output label l is generated by a division

$$l = \left\lfloor \frac{x}{\Delta} + 0.5 \right\rfloor$$

The reconstruction is given by

$$\hat{x} = l\Delta$$

This results in a quantizer whose innermost interval (corresponding to an output value of zero) is twice the size of the other quantization intervals.

A popular method, widely used in the telecommunication industry, for implementing nonuniform quantizers is the use of companding. Here, the input is passed through a logarithmic compressor function prior to uniform quantization. The reconstruction is obtained by taking the uniform quantizer reconstruction level and mapping it through an expanding function. The companding characteristic used in the United States and Japan is called the μ -law and is given by

$$c(x) = x_{\max} \frac{\ln\left(1 + \mu \frac{|x|}{x_{\max}}\right)}{\ln(1 + \mu)} \operatorname{sgn}(x) \quad (48.30)$$

$$c^{-1}(x) = \frac{x_{\max}}{\mu} \left[(1 + \mu)^{\frac{|x|}{x_{\max}}} - 1 \right] \operatorname{sgn}(x) \quad (48.31)$$

where $\mu = 255$. The companding characteristic used in most of the rest of the world is called the A -law and is given by

$$c(x) = \begin{cases} \frac{A|x|}{1 + \ln A} \operatorname{sgn}(x) & 0 \leq \frac{|x|}{x_{\max}} \leq \frac{1}{A} \\ x_{\max} \frac{1 + \ln \frac{A|x|}{x_{\max}}}{1 + \ln A} \operatorname{sgn}(x) & \frac{1}{A} \leq \frac{|x|}{x_{\max}} \leq 1 \end{cases} \quad (48.32)$$

$$c^{-1}(x) = \begin{cases} \frac{|x|}{A} (1 + \ln A) & 0 \leq \frac{|x|}{x_{\max}} \leq \frac{1}{1 + \ln A} \\ \frac{x_{\max}}{A} \exp\left[\frac{|x|}{x_{\max}} (1 + \ln A) - 1\right] & \frac{1}{1 + \ln A} \leq \frac{|x|}{x_{\max}} \leq 1 \end{cases} \quad (48.33)$$

where $A = 87.6$.

48.3.2.2 Vector Quantization

Recall that employing lossless compression by coding blocks of symbols can result in better performance than symbol-by-symbol encoding even in the case of *iid* sequences. An analogous situation applies for lossy coding. Quantizing blocks of symbols results in better rates for a given distortion

for sources with a nonuniform distribution. Using the rate distortion theorem, it is possible to show that for an *iid* source, the achievable rate to quantize blocks of length n with a 2^{nR} level quantizer satisfies

$$nR(D) \leq nR \quad (48.34)$$

where nR is the number of bits allocated for R bit scalar quantizers achieving the same distortion D . Quantizing blocks of input sequences is called *vector quantization* (VQ).

The geometry of multidimensional distributions plays a role in the design of vector quantizers. One class of quantizers indexes the reconstruction points that are distributed regularly, taking the geometry of the distribution into consideration. This class of vector quantizers is called the *lattice quantizers* [11–13].

The vector quantizers can be extended to general distributions by generalizing Lloyd's algorithm for the multidimensional case. If the same procedure is applied for vectors of symbols instead of single symbols, an approximate solution to the VQ problem is provided. This procedure is known as the Linde–Buzo–Gray (LBG) algorithm [14].

48.4 Modeling Data Organization

The rates achieved by entropy coding techniques, such as Huffman coding or arithmetic coding, are close to the first-order entropy of the source. This is only optimal under the assumption that the source is *iid*. However, in general, the data organization cannot be captured only by the alphabet distribution. This organization can stem from various aspects specific to different data sources. For example, in a natural language text, certain words and phrases could be used more frequently than others. Consider the words *dour* and *ordu*. Using entropy coding, the total length of the code allocated for each word would be the same, the sum of the length of the codewords of the letters composing the word. However, *dour* is a much more probable word in English than *ordu* (the reverse is true in Turkish). Therefore, if we knew that the text we were compressing was English, information theory says that we should use fewer bits to encode *dour* than we would use to encode *ordu*. However, such a coding would only be possible if we discarded the assumption that the text sequence was made up of *iid* symbols. The argument against using an *iid* assumption is also true for other types of data. In digital images, the same blocks of pixels can be repeated several times. In motion pictures, adjacent frames have significant parts that remain unchanged, etc. These structures are formed by higher-order organizations that cannot be captured by entropy coding. This structure, if captured, can be used to achieve rates lower than entropy coding of the raw sequence alone can provide.

Similar arguments apply for lossy compression. The quantization schemes assume *iid* distribution of the source. However, correlations in data result in nonzero mutual information between symbols, that is, not utilized by *iid* quantizers. Therefore, it makes sense to first use knowledge of the source model to generate a decorrelated sequence that can then be quantized.

Instead of monolithic coding schemes, a modular approach of modeling and coding is generally adopted for data compression. Since entropy coding is the final phase of compression, the output of the modeling phase should be a sequence with a low first-order entropy. Therefore, we can view the modeling as a data processing step that transforms the data from its original domain to a sequence with uncorrelated elements. Although models can have different objectives, describing data with uncorrelated features is the aim of all models. We can roughly categorize the modeling techniques into three main groups based on their approach to exploring the organization of data.

The first group of algorithms assumes the data are composed of building blocks that are repeatedly used in a sequence. They attempt to parse the data to isolate these building blocks and encode them as units. This can be done by organizing the repeated building blocks into a lookup table or *dictionary*.

The second group attempts to explore the correlations in a sequence by generating a model and encoding the model parameters and the uncorrelated residual. The last group uses the natural structure associated with the physical dynamics of the process generating the data to process the data sequence.

48.4.1 Modeling Building Blocks: Dictionary Methods

In general, a compression algorithm should assign shorter codewords to frequently recurring elements while assigning long codewords to rarely expected elements. Consider a converse approach. Instead of designing variable-length codewords for fixed-size items, we encode frequently occurring variable-length blocks with fixed-size codes. Given an alphabet A , we define a group of letters forming a sequence to be a *word*. A lookup table of words with indices is called a *dictionary*, and compression methods using dictionaries for coding are called *dictionary techniques*.

If the dictionary consists of frequently occurring words within a sequence, which are the building blocks of the corresponding data, the dictionary technique can provide significant compression. It is not difficult to find examples of sequences with recurring items. Texts of natural languages consist of frequent words and phrases. Similarly, computer-generated images have repetitive blocks of the same pixel values. There are many types of data that have similar repetitive structures, which is why dictionary coding techniques are frequently used in general purpose archiving programs.

48.4.1.1 Lempel–Ziv Methods

The most well-known class of dictionary techniques are based on two algorithms proposed by Lempel and Ziv in 1977 [15] and 1978 [16], referred to as the LZ77 and LZ78 algorithms. The LZ77 and LZ78 algorithms and their variations work on the premise that sequences are constructed of repeatedly used building blocks. Therefore, these algorithms attempt to identify and index these blocks. Encoded sequences are streams of indices pointing to entries corresponding to these blocks in a dictionary that is constructed adaptively.

The LZ77 algorithm attempts to represent a variable-sized block of input by an exact match in the history. Starting from the current symbol to be encoded, a variable-sized block is grown one symbol at a time, until the point where the addition of a symbol will result in a pattern that has not been previously encountered. The pointers coding the position and the length of that block in the previously coded sequence and the code for the symbol that terminated the search form the code for the current block. Assume that we are encoding “that_is_the_block_that_is_repeated”, and we are at the point where we have encoded “that_is_the_block_”. In the remaining string “that_is_repeated”, we can grow the block up to the substring “that_is_” that can be found in the previously coded sequence. The code for this block is the triplet (18, 7, code[r]). Where 18 is the offset from the beginning of the block “that_is_” and its previous occurrence in the sequence, 7 is the length of the block to be copied and code[r] is the code for the symbol r . The decoder will interpret this as “go back 18 symbols, copy 7 symbols, and insert the 7 symbols at the end of the decoded sequence followed by the symbol r .” There are numerous variations of this basic algorithm. Most use a variable-length code to encode the various indices. Most also replace the triplet $\langle \text{offset}, \text{length}, \text{code} \rangle$ with a single-bit flag followed by either the code for a symbol or the double $\langle \text{offset}, \text{length} \rangle$. This latter variation was developed by Storer and Syzanski [17] and hence is referred to as LZSS. Generally, the distance in the history in which to search for a match is limited for computational efficiency or due to memory requirements.

The LZ78 algorithm differs from the LZ77 algorithm in the way it indexes the repeated sequences. Previously encountered unique blocks are recorded in a lookup table. Similar to LZ77, the block to be encoded grows until there is no match in the lookup table. A double consisting of the index of the entry in the dictionary that matches all but the last element in the block and the last symbol in the block (which made the block unique) are encoded, and the new unique block is recorded in the lookup table.

This can be viewed as parsing the sequence into a minimal number of building blocks constructively. The rate behavior of LZ78 is similar to that of LZ77.

As was the case for LZ77, several variations of LZ78 have been proposed. The most widely used is the LZW algorithm [18]. It eliminates the need for encoding the second element of the double—the last symbol in the block—by priming the dictionary with the source alphabet. The encoder only sends the index of the matching block; however, the dictionary is extended by adding the concatenation of this block and the last symbol. It is easiest to see the process with an example. Consider encoding the sequence *ababbbbaa...*. The initial dictionary consists of only two entries:

1	<i>a</i>
2	<i>b</i>

When we parse the sequence, we encode the index for *a* and begin a new entry in the dictionary:

1	<i>a</i>
2	<i>b</i>
3	<i>a...</i>

The next element in the sequence is *b*. If we extended this, we would get the sequence *ba* that is not in the dictionary; so we encode the index for *b* and add this to the incomplete third element in the dictionary. This results in the third item becoming *ab* that is unique in the dictionary. Thus, the third item is complete; and we bring a fourth item with the symbol *b*:

1	<i>a</i>
2	<i>b</i>
3	<i>ab</i>
4	<i>b...</i>

The next symbol to be encoded is *a*. As this exists in the dictionary, we extend this block to include the following symbol; and we get the block *ab*. This also exists in the dictionary so we continue and get the block *abb*. This does not exist in the dictionary so we simply encode the index for *ab*. We now update the dictionary with the symbols that have been encoded. The fourth item in the dictionary is extended to *ba* that is unique so we complete that item and begin the fifth item with *a* followed by *b*. As *ab* exists in the dictionary, this item is incomplete:

1	<i>a</i>
2	<i>b</i>
3	<i>ab</i>
4	<i>ba</i>
5	<i>ab...</i>

As we continue, we will encode the indices 1,2,3,2,4,1 and the dictionary will become as follows:

1	<i>a</i>
2	<i>b</i>
3	<i>ab</i>
4	<i>ba</i>
5	<i>abb</i>
6	<i>bb</i>
7	<i>baa</i>
8	<i>a...</i>

All LZ-based algorithms are causal, so that the dictionaries are built both at the encoder and the decoder. That is why no information about the dictionaries other than the indices needs to be sent.

Algorithms based on the LZ algorithms are used in a large number of compression applications. The LZW variant of LZ78 is used in the Unix *compress* command as well as in the graphics interchange format (GIF). The compression algorithms in both portable network graphics (png) [19] as well as *gzip* [20] are based on LZ77.

48.4.2 Modeling Correlated Structures: Predictive Methods

Dictionary methods are well suited to repetitive data. However, the structure might not result in exact repetitions in various situations. Without exact repetition, the use of lookup tables is not useful. However, it is still possible to exploit this imperfect recurrent structure with models capturing the correlations. There are a great variety of approaches for modeling correlated structures. These include prediction filters using the context of a sample, Markov models, and decorrelating data transformations.

Let's consider a simple case where the adjacent symbols are not statistically independent. The entropy of the extended symbols of doubles would be

$$H(x_i x_{i+1}) = H(x_i) + H(x_{i+1}) - I(x_i; x_{i+1}) = 2H(x) - I(x_i; x_{i+1}) \quad (48.35)$$

where $I(x_i; x_{i+1})$ is defined as the average mutual information between adjacent symbols. Since we know that the adjacent symbols are statistically dependent, the mutual information value is greater than zero. Therefore, the achievable rate of this sequence is smaller than $2H(x)$ if we use an extended alphabet of doubles. This example can be generalized by induction. If correlations exist within a sequence, the entropy, and, consequently, the achievable rate of that sequence, is smaller than first-order approximations may suggest. A similar argument can be proposed for the rate distortion function of correlated sequences.

A general strategy to exploit structural redundancy in data compression is the use of a decorrelation phase prior to entropy coding. A model capturing the correlations in the data is used to remove the correlation leaving behind an uncorrelated residual sequence with a first-order entropy considerably less than the original sequence.

This is a *predictive* strategy, and compression algorithms that use this strategy make up an important body of data compression algorithms. The reason behind their importance is that many sources of data of interest for data compression exhibit various types of correlated structures. One form of this structure originates from the dominance of low-frequency components in nature. For example, in daily records of temperature, a measurement is generally correlated with the previous day's measurement. Therefore, given the recent history of temperatures, the current temperature is not very uncertain. Similar time series behavior can be observed in many forms of data from audio streams to medical signals. Data recorded in image format contain spatial correlations. It is very likely that neighboring pixels correspond to the same morphological object resulting in similar intensity and color values. Correlations in each data type might appear in different ways, but they can all be considered as the effect of the low-frequency nature of signals of interest to humans. Another form of correlation is the result of global structure. These are patterns that are repeated in the data though not necessarily in adjacent temporal or spatial locations. Furthermore, unlike the repeated patterns that are captured using dictionary methods, these repeats may be imperfect or approximate. Obviously, models with a more global view of memory are needed to decorrelate data in this context. We can classify predictive models into two categories: models predicting global structure and models predicting local structure.

The predictive model employed at the encoder has to be repeatable at the decoder in order for the input sequence to be recovered. This requirement imposes the use of a causal context in models predicting local structure. For models predicting global structure, we have the option of either encoding model parameters as side information or using causal adaptive models that can mimic the same prediction operation at the receiver.

48.4.2.1 Predicting Local Structure

Predictive coding techniques exploit the local structure using the context of a symbol to predict the current symbol. Since the prediction is deterministic, the uncertainty to be encoded is contained in the residual sequence. If an accurate model is used to predict the current symbol well, the residual should be a white sequence with a low variance. The low variance indicates a sequence with low complexity that can be coded at low rate. In the following, we look at different prediction approaches that use different prediction models.

48.4.2.2 Prediction with Partial Match

Prediction with partial match (ppm) attempts to model the conditional probability of the current symbol given a context of previous symbols. The implicit model is a collection of Markov processes of different orders. The *ppm* algorithm estimates the distribution of symbols in different contexts in the form of frequency tables based on statistics gathered from previously encoded parts of the sequence. The frequency tables associated with a particular context only include symbols that have occurred in that context. As the encoding progresses, the algorithm updates the frequency tables. This aspect is similar to dictionary methods. However, *ppm* differs from dictionary methods in that unlike dictionary coding *ppm* uses the previously occurring words as contexts for a frequency table that is then used to entropy code the symbol under consideration. Instead of continually growing the size of the context as in LZ78-based approaches, words in *ppm* are limited to a maximal length in order to mitigate memory problems and avoid model overfitting.

A maximum context length ℓ is specified as a parameter of the algorithm. To encode a symbol, the algorithm first looks to see if this symbol has been observed before in the context of the ℓ previous symbols. In case such an event exists in the history, the symbol is encoded based on its conditional distribution given those ℓ previous symbols. If this is the first time this symbol has occurred in this context, the algorithm encodes an escape symbol and repeats the process using the context of $(\ell - 1)$ previous symbols. This process is repeated until a context in which the symbol has previously occurred is encountered. If the symbol has never been previously encountered in any context, it is encoded using the first-order distribution of the symbols. The decoder begins by assuming that a context of size ℓ was used. Whenever an escape symbol is decoded, the decoder downsizes the context to look for a suitable match. Because the escape symbol can occur at any context, its frequency of occurrence is included in each frequency table by default.

Assume that we are currently encoding the last letter of the word *prediction* with the maximum context length of 6. We first check for a context *dictio* followed by *n*. If there is none, the contexts of *ictio*, *ctio*, *tio*, *io*, and *o* are checked until one of these contexts followed by an *n* is found. At each step, either the symbol *n* or an escape symbol is encoded using arithmetic coding with the frequency table of the context. Once a symbol has been encoded, the corresponding frequency tables are updated. This makes *ppm* an adaptive arithmetic coding algorithm with variable context length. Since the frequency tables of each context size can be derived causally from previously coded data, the same operations can be conducted both by the encoder and decoder without any further need of side information.

There are several popular variations on the basic *ppm* theme. The modifications deal mostly with the derivation of the frequency tables, especially the escape symbol frequencies. The algorithm *ppm** [21] provides a very creative approach to determining the maximum context length. The algorithm first looks at the longest matching context that has only one symbol (other than the escape symbol) in its frequency table, the idea being that that single symbol is the same as the symbol being encoded with high probability. If this is not the case, the algorithm encodes an escape symbol and defaults to a maximum context length. The algorithm *ppmz*, which can be found at <http://www.cbloom.com/src/ppmz.htm>, is the best-known variant of the *ppm** approach. Another modification is the disabling of impossible symbols that can be determined by the nonmatches of longer contexts. Assume in encoding *prediction*, we downsized the context to *o*. If the frequency table of context *io* has the symbol *w*, we can discard the symbol *w* in the frequency table of the context *o*, because if the symbol was *w*, an escape would not be encoded.

48.4.2.3 Burrows–Wheeler Transform

The Burrows–Wheeler Transform (BWT) is a powerful technique which is particularly useful when strong correlations between the symbols and their contexts exist. The advantage of this method is that all possible contexts without a size limitation are considered. However, this advantage comes with a cost as it requires an offline phase of BWT.

Given a sequence, the maximal context of each symbol is considered and ordered lexicographically. The sequence of symbols in this order is the BWT. Here, unlike causal methods, the context starts from the next (right-hand) symbol. Since the contexts of the repeated patterns are the same, they are placed adjacent to each other in the transform. For example, the words containing “*predict-*” will be ordered together by the contexts starting with “*redict-*.” Therefore, the corresponding part of the transform is expected to have a run of *p*’s. In a correlated sequence, the resulting BWT sequence consists of long runs of the same letter. This provides the opportunity to use coding schemes like run-length coding with low rates.

In order to obtain all possible contexts, the transform takes the original sequence and generates all possible cyclic shifts of the sequence. All cyclic shifts are then ordered lexicographically. The sequence consisting of the last elements of each of the lexicographically ordered cyclic shifts forms the transform of the original sequence. This transform, along with an index pointing to the location of the original sequence in the lexicographically ordered set, can be used to recover the original sequence. The algorithm is described using an example.

Example

As an example, consider the word GALATASARAY, which is the name of a Turkish soccer team. The circular permutations of the word are

G	A	L	A	T	A	S	A	R	A	Y
A	L	A	T	A	S	A	R	A	Y	G
L	A	T	A	S	A	R	A	Y	G	A
A	T	A	S	A	R	A	Y	G	A	L
T	A	S	A	R	A	Y	G	A	L	A
A	S	A	R	A	Y	G	A	L	A	T
S	A	R	A	Y	G	A	L	A	T	A
A	R	A	Y	G	A	L	A	T	A	S
R	A	Y	G	A	L	A	T	A	S	A
A	Y	G	A	L	A	T	A	S	A	R
Y	G	A	L	A	T	A	S	A	R	A

Lexicographically ordering this we get

A	L	A	T	A	S	A	R	A	Y	G
A	R	A	Y	G	A	L	A	T	A	S
A	S	A	R	A	Y	G	A	L	A	T
A	T	A	S	A	R	A	Y	G	A	L
A	Y	G	A	L	A	T	A	S	A	R
G	A	L	A	T	A	S	A	R	A	Y
L	A	T	A	S	A	R	A	Y	G	A
R	A	Y	G	A	L	A	T	A	S	A
S	A	R	A	Y	G	A	L	A	T	A
T	A	S	A	R	A	Y	G	A	L	A
Y	G	A	L	A	T	A	S	A	R	A

The transformed sequence consists of the last letters of the ordered matrix: GSTLRYAAAAA. Notice how all the A's occur together. This means we can easily get a compact representation for this sequence. We encode the transformed sequence and the location of the original sequence in the ordered matrix. In this case, the original sequence is the sixth row of the ordered matrix. At the decoder, we lexicographically order the transformed sequence to obtain AAAAAGLRSTY. The sixth letter is G; therefore, we know that the first letter of the decoded sequence is G. We look for G in the transformed sequence and find that it occurs in the first position, so the second letter of the decoded sequence is the letter in the first position of the lexicographically ordered sequence, namely, A. Now we look for the first A in the transformed sequence. It is in position 7; therefore, the next decoded letter is the letter in position 7 of the lexicographically ordered sequence, namely, L. Continuing in this fashion, we can decode the entire sequence.

48.4.2.4 Differential Encoding

The predictive coding techniques we have discussed attempt to remove the redundancy in correlated sequences using context-based distributions. An adaptive coding scheme based on skewing the symbol probabilities by conditioning over the neighboring context is suitable for data types such as text documents or archiving applications. However, different paradigms of prediction can be more useful based on the data type considered. For example, data sampled from natural waveforms, such as image or audio data, can be viewed as a sequence of correlated numbers. Thus, numerical prediction that uses the correlation works well for this data type.

Lossless image coding is an application of this type of predictive coding. The basic idea behind lossless image coding is that a pixel to be coded can be predicted using the surrounding texture. The difference between the pixel value and the predicted value, or the residual, generally has much lower first-order entropy than the pixels themselves and can, therefore, be encoded efficiently using arithmetic coding. A three-phase procedure is generally followed: (1) initial prediction of the pixel to be encoded, (2) refinement of the initial prediction using the previous events of the same kind, and (3) entropy coding of the residual sequence.

In order to avoid transmitting a large amount of model parameters as side information, the algorithms are causal, or backwards, conducting the same operations on both the transmitter and receiver ends. Therefore, by the surrounding texture, we refer only to the previously encoded neighborhood of the pixel. The initial prediction is obtained using the neighboring pixel values as well as the horizontal and vertical gradients in this neighborhood. The lossless Joint Photographic Expert Group (JPEG) standard uses one of the immediate neighbors (N, W, NW) or the weighted average of these neighbors as the prediction of the current pixel. In JPEG-LS, the prediction is replaced by the median adaptive prediction of the LOCO-I algorithm [22]. Median adaptive prediction selects one of (N, W, W+N-NW) based on the ranking of the three neighboring pixels. If N or W is the median of the neighbors, it is assigned as the prediction. Otherwise, a third assignment is performed.

As the second phase, LOCO-I refines the predicted value considering the previous errors made with different classes of gradient. Consider the pixel labels in Figure 48.6, two local horizontal (NE-N, N-NW) gradients and a vertical (NW-W) local gradient are quantized based on their magnitude into 365 contexts. A correction factor, which is determined by the errors occurring for the corresponding context, is added to the initial prediction. The correction factor is adaptive and is updated at each pixel prediction. This refinement step introduces global capture of the correlations within an image. Therefore, its

NW	N	NE
W	X	

FIGURE 48.6 Current pixel to be encoded X and surrounding texture of causal neighborhood.

effect is to decorrelate the error sequences utilizing the mutual information within the errors. Further whitening of the residual generally results in a Laplacian-like distribution in the encoded symbols. While adaptive Huffman or arithmetic coding can be applied in the final coding phase for lossless JPEG, the JPEG-LS standard prefers Golomb codes that perform well on geometric sources.

An idea similar to that of the *ppm* algorithm can also be used for generating predictions for lossless image compression. Instead of using similar contexts in the history to obtain the frequency counts, an average value of all pixels that have occurred in that particular context can be used as a prediction for the pixel being encoded [23]. This approach has been used to good effect in the lossless compression of hyperspectral images [24].

In the case of lossless compression, the prediction is performed based on the past history of the sequence. In lossy coding, one has to be a bit more cautious. Unlike the case for lossless compression, the reconstruction at the decoder in lossy compression does not exactly match the original sequence. Therefore, if the prediction at the encoder is obtained using the original sequence, the predictions performed by the encoder and decoder will diverge from each other. This is an error accumulation effect caused by the quantization error. At each prediction step, the receiver predictor adds up the previous quantization error with the current one since the prediction is performed using erroneous inputs. To mitigate this effect, the encoder and the decoder are forced to generate the same predictions by generating the reconstructed sequence at the encoder and using this replica of the reconstructed sequence to generate the prediction. A block diagram of this differential encoding scheme is shown in Figure 48.7. The section of the encoder that mimics the decoder is shown in the dotted box.

Data sampled from continuous waveforms, such as speech signals, contain local correlations that are not limited to the immediate neighbors of the symbols. Therefore, the predictive filters should be of a higher order to remove a greater amount of redundancy. Employing autoregressive filters is a well-known solution that has been used successfully in differential pulse code modulation (DPCM) systems. An autoregressive filter uses the linear regression of the previous N samples with minimum variance:

$$\min_a E \left[\left(x_n - \sum_{i=1}^N a_i x_{n-i} \right)^2 \right] \tag{48.36}$$

where

x_n is the n th symbol in the sequence

a_i is the autoregression coefficient

FIGURE 48.7 A block diagram of the encoder for a lossy predictive coding scheme.

The optimal filter coefficients then satisfy the Wiener–Hopf equation, so

$$\sum_{i=1}^N a_i R_{xx}(i-j) = R_{xx}(j), \quad \forall j \in \{1, 2, \dots, N\} \quad (48.37)$$

In this equation system, R_{xx} denotes the autocorrelation function of the input sequence that can be estimated using the sequence samples.

The sequence to be coded can be of a nonstationary nature; thus, the autocorrelation behavior might change temporally or spatially. To capture local correlation structure, DPCM systems are generally adaptive, updating the filter coefficients as the sequence is coded. Adaptation can be offline, estimating the coefficients over a window and transmitting them as side information. For each window, the receiver uses the predetermined coefficients. Blocks of 8×8 pixels in images or 16 ms time frames in speech signals have been widely used for offline adaptation. The use of side information and time-delay problems in real-time communication systems illustrates the need for adaptive systems operating online. Updating the filter coefficients using the feedback error provides a solution that can be employed without any need of side information or an offline-pass over the input sequence. The filter coefficients are updated using the gradient descent, least mean squared (LMS), algorithm. The LMS algorithm updates the filter coefficients at each time step using the rule

$$a_i^{(n+1)} = a_i^{(n)} + \alpha r_n x_{n-i}, \quad \forall i \in \{1, 2, \dots, N\} \quad (48.38)$$

where

- r_n is the prediction for the n th symbol
- α is the stepsize of the gradient descent

The LMS algorithm can keep track of local correlation structures, which permits the coding system to adapt to nonstationary sources. Quantization, followed by prediction, can also be made adaptive by adjusting the variations in residual range.

48.4.2.5 Predicting Global Structure

Redundancy in data caused by correlated structures may not always be caused by the low variation of symbols within a neighborhood. Similar structures of large context may reoccur due to global organization. An obvious example of this occurs in video sequences. An object captured in a video sequence can exist in different locations in different frames. Although large blocks of pixels corresponding to this object may repeat with some slight variation in the video stream, this redundancy might not be revealed by prediction techniques intended to capture local correlations. So the prediction methods removing global redundancy can be substantially different than the methods of local prediction. We will discuss prediction in video coding in a later section.

The idea of identifying similar blocks to remove redundancy is a primary motivation for the use of VQ for compression. VQ provides better rate distortion performance, even in the case of *iid* sources. Where global correlations within the blocks of data exist, VQ further captures the mutual information between similar blocks by quantizing them to the same codeword. Therefore, correlated contexts can be mapped into the same codeword, decorrelating the sequence to be compressed.

VQ as a joint model of redundancy removal and lossy coding is generally employed as follows. The rate selected determines the number of codewords. That is to say, if a rate of R bits is selected and blocks of M symbols are going to make up the vectors, 2^{MR} binary codewords, which index 2^{MR} reconstruction points, are used. A VQ design algorithm, such as LBG, can train reconstruction points and assign each symbol block to the nearest reconstruction point. The block is coded using MR bits indexing the

reconstruction point. During decoding, a lookup table can reconstruct the blocks using the coded indices. Since the lookup table must be available to the decoder, the model has to be sent as side information. This method has two main drawbacks. First, as the bitrate increases, the codebook grows exponentially. This results in a proportional increase in computational complexity to train the codebook and encode the blocks. Also, memory requirements and side information to be transmitted suffer from the same exponential growth. Therefore, VQ has mostly been used in low-rate applications such as low-rate speech coding or image coding. In low-rate speech coding, the vectors being quantized are generally vectors of model parameters, while in image coding applications, the inputs are generally square blocks of image pixels. Variations on VQ have been used to mitigate the exponential complexity and memory increase to enable it to be used in high-rate applications. Structures, such as tree-based and trellis-based quantizers or divide-and-conquer approaches, like multistage quantization, have been used to bring the codeword increase from exponential to linear or logarithmic growth [4,25]. Some adaptive VQ techniques have been used for video coding [26] where the quantization is of such high resolution that the quantized vectors can be used to build and update the vector quantizer codebook without need for side information.

48.5 Modeling Natural Structures

Much of the information in sources such as audio and video is in the form of correlated structures. Consider the way images destined for human perception are structured. Most of the image consists of regions of similar intensity demarcated by sharp transitions. If we think of an image in terms of its spectral characteristics, the regions of similar intensity will contribute lower frequencies, while the demarcations will contribute higher frequencies. As the number of pixels involved in the demarcations, or the edges, is much fewer than the number of pixels in the regions of similar intensities, the amount of low-frequency content is much higher than the amount of high-frequency content. In fact, in many parts of the image, the amount of high-frequency information may be completely negligible. We can take advantage of this fact by decomposing the image into different frequency components, each of which can be treated differently. There are two principal approaches currently being used to do this: *transform coding* and the use of *wavelets* or *subbands* for decomposition. Transform coding has been most widely used in the compression of images and video, for example, the widely used JPEG image coding standard and the Moving Picture Experts Group (MPEG) video coding standard. Subband coding has been used mostly for audio compression, the most well-known application being *mp3* coding. Wavelets have been used in the JPEG 2000 image compression standard [27,28].

Natural structure can also be introduced by the method used to generate the information-bearing signal. Speech is an example of such a signal. We all generate speech using machinery that is very similar. Simply put, air is forced through a vibrating membrane known as the vocal cords; the pressure waves thus generated are modulated by the throat and mouth to generate speech. The physical requirements on the various components in this process impose constraints on the signal generated. Compression algorithms that take advantage of these constraints fall under the general heading of *linear predictive (LP) coding*. The ubiquitous cell phones would not be possible without this method of compression.

48.5.1 Transform Coding

In transform coding, the image is divided into blocks, usually 8×8 pixels in size, and each block is represented in terms of a set of basis images. For example, the basis images corresponding to the popular discrete cosine transform (DCT) used in JPEG image compression and MPEG video compression are shown in Figure 48.8. The block in the upper left corresponds to the average intensity of the pixels in

FIGURE 48.8 Basis images for the 8 × 8 DCT.

a block. The basis images increase in spatial frequency with their distance to the basis image in the upper left corner. The (i, j) th element of the DCT matrix \mathbf{C} is given by

$$[\mathbf{C}]_{i,j} = \begin{cases} \sqrt{\frac{1}{N}} \cos \frac{(2j+1)i\pi}{2N} & i = 0, j = 0, 1, \dots, N-1 \\ \sqrt{\frac{2}{N}} \cos \frac{(2j+1)i\pi}{2N} & i = 1, 2, \dots, N-1, j = 0, 1, \dots, N-1 \end{cases} \quad (48.39)$$

If we represent an 8×8 block of pixels by the matrix \mathbf{X} where $X_{i,j}$ is the value of the (i, j) th pixel in the block, coefficients corresponding to the various basis images, in other words the transform, are given by

$$\Theta = \mathbf{C}\mathbf{X}\mathbf{C}^T \quad (48.40)$$

where Θ is the matrix of transform coefficients. The pixels can be recovered from the coefficients through the inverse transform

$$\mathbf{X} = \mathbf{C}^T \Theta \mathbf{C} \quad (48.41)$$

The transform coding procedure involves three steps: the transform, quantization of the transform coefficients, and the binary encoding of the quantization labels. We briefly describe these steps for the popular JPEG image coding standard.

The first step in the JPEG encoding is a level shift. Essentially, this means subtracting 2^{b-1} from each pixel where b is the number of bits per pixel. In a grayscale image, the value of b is 8. The coefficients have different perceptual importance with the human visual system being much more sensitive to errors in low-frequency coefficients. The error introduced during transform coding is a result of the quantization process. As there is more sensitivity to errors at lower frequencies, we use coarser quantizers for higher-frequency coefficients than we do for lower-frequency coefficients. The stepsizes for different coefficients that are standard in JPEG compression are shown in Table 48.1. The step-size for the lowest-frequency coefficient is 16, while the stepsizes for higher-frequency coefficient are

TABLE 48.1 Sample Quantization Table

72	92	95	98	112	100	103	99

almost an order of magnitude bigger. The quantization process itself consists of dividing the coefficient by the stepsize and then rounding to the nearest integer. The reconstructed value of the coefficient can be obtained by multiplying the quantization label with the appropriate stepsize. For most of the 8×8 blocks in the image, the quantization label corresponding to the higher-frequency coefficients is 0. This is due to two factors. First, as mentioned earlier, the higher-frequency coefficients are generally small. And second, as can be seen from Table 48.1, the quantization stepsizes for the higher-frequency coefficients are much larger than those for the lower-frequency coefficients resulting in a large number of 0 labels. To efficiently code these long runs of 0s, the JPEG algorithm scans the coefficients in a zigzag fashion as shown in Figure 48.9. Notice that the coefficient at the upper left-hand corner is not included in the zigzag scan. As mentioned earlier, this particular coefficient corresponds to the average pixel value in a block. As an 8×8 block is a very small portion of the image, it is reasonable to assume that the average values of neighboring blocks of pixels are going to be similar. The JPEG algorithm takes advantage of this fact and transmits only the difference between these average values. The rest of the coefficients are encoded using a modified Huffman code. Each codeword in this code is indexed by two values: the number of 0 coefficients preceding the coefficient being encoded in the zigzag scan and the value of the coefficient. The last nonzero coefficient in the zigzag scan is followed by an end-of-block code.

Let’s work through the JPEG coding process with an example. Consider the 8×8 block shown in Table 48.2. If we subtract 128 from each value in this block and then take the DCT of this level-shifted block, we obtain the coefficients shown in Table 48.3. Quantizing this block of coefficients using the quantization table shown in Table 48.1, we obtain the quantization labels shown in Table 48.4. We have marked the upper left-hand coefficient with an X because that particular

FIGURE 48.9 The zigzag scan used by the JPEG algorithm to scan the quantization labels.

coefficient, as mentioned earlier, is quantized using a different strategy. If we arrange the other coefficients using the zigzag scan, we get the sequence

$$[-2 \ -43 \ -1 \ -100 \ \dots \ 0]$$

The encoder only has to encode 5 coefficients (out of 63 coefficients) before sending the code for end-of-block. This results in a significant amount of compression.

The coarse quantization of high-frequency coefficients makes sense both in terms of the perceptual quality of the reconstruction and the relatively small amount of high-frequency content in images destined for human viewing. However, at very low rates, the argument breaks down. This is because of an implicit assumption in the DCT-based decomposition that the signal being transformed is periodic. This means that if there is a significant difference between the values between opposite edges of a block, it is reflected in higher values for the high-frequency coefficients. Coarse quantization of these coefficients results in reconstructions that attempt to equalize the pixel values at opposite edges. This means that pixels with large values representing brighter portions of the image will be reconstructed as pixels

with smaller values that will be perceived as dark. This effect will be most apparent at the block boundaries leading to a *blocking* artifact. One way around this problem is to use a modified version of the DCT, known, appropriately enough, as the modified discrete cosine transform (MDCT). In this variation, the transform is taken over overlapping blocks, thus mitigating the blocking effect. Another is the use of subband and wavelet decompositions that we describe in the next section.

48.5.2 Wavelet and Subband-Based Coding

Using transforms is one way of separating the source information into spectral components. Another widely used approach relies on filterbanks rather than transforms for decomposing the signal into its spectral component. A typical subband coding system is shown in Figure 48.10. The discrete-time input signal is passed through a low-pass filter and a high-pass filter with bandwidth equal to half the bandwidth of the original signal. Thus, the output of the low-pass filter contains the lower half of the frequencies in the input signal, while the output of the high-pass filter contains the upper half of the frequencies contained in the input signal. The Nyquist criterion dictates that the signal be sampled at a rate that is at least twice the highest-frequency component of the signal. Assuming that the original signal was sampled at the Nyquist rate or higher and assuming ideal filters, the output of the filters will be oversampled by at least a factor of two. Therefore, the output of the filters can be downsampled by a factor of two. This downsampling is indicated by the circle with the down-pointing arrow. After downsampling, the total number of samples in the upper and lower branches is equal to the number of samples in the original signal. The low-pass and high-pass signals can be quantized and coded depending on their characteristics and transmitted or stored. In order to reconstruct the signal, the decoder outputs are upsampled by a factor of two, filtered, and summed. Where the filters are not ideal, the downsampling can introduce aliasing distortion. The design of filters that prevent the introduction of aliasing distortion has been a major subject of research in subband coding. The various designs begin with a prototype low-pass filter and derive the other filters from the prototype filter to satisfy *perfect reconstruction* conditions.

In the example earlier, we show the signal being split into two bands. In various applications, the signal can be split into multiple bands. This can be done in a number of ways. One is to design M -band filters that split the input into M spectral bands followed by a downsampling by a factor of M . Another is to use a sequence of two band splits, where generally the low-pass output is split repeatedly. The reason for the latter approach is that most of the information in many natural signals is contained in the lower frequencies; and therefore, there is a benefit to a higher-resolution decomposition of the low-frequency band.

One of the most popular applications of subband coding is the algorithm for the compression of audio signals, which is part of the MPEG standard. There are three audio compression strategies, Layer I, Layer II, and Layer III. The Layer III standard is better known as *mp3*. Each layer is backwards compatible with the previous layer, which means they have substantial commonalities. The input in each case is decomposed into 32 subbands, followed by a 32:1 downsampling. In *mp3*, the output of each subband is further decomposed into 6 or 18 coefficients using an MDCT with 50% overlap. The reason for this level of spectral decomposition is the nature of the hearing process. The human auditory system has a frequency-selective auditory threshold. Signals at frequencies below 300 Hz or above 6 kHz have to be

FIGURE 48.10 A basic subband coding system.

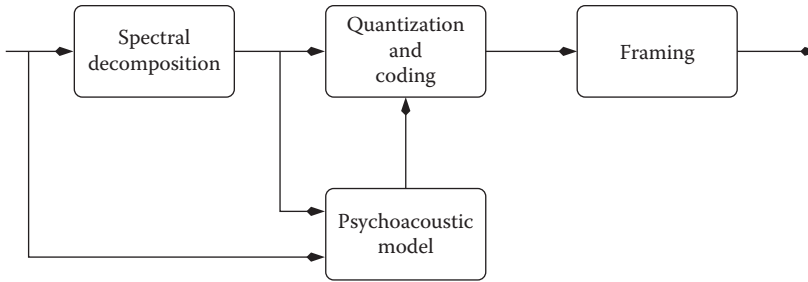

FIGURE 48.11 A conceptual picture of the *mp3* algorithm.

substantially louder to be heard than signals in the range of 1–5 kHz. Thus, small amplitude signals in the output of some of the subbands can be discarded without any perceptible impact on the audio quality. Furthermore, the auditory system uses several masking strategies that can be exploited to improve the level of compression. If two tones occur within a narrow range of frequencies, known as the critical band, one of the tones will mask the other. This kind of masking is called spectral masking. The auditory system also uses temporal masking; if two tones occur very close to each other, in time, the louder tone will mask out the more quiet one. By not encoding components of the signal that are going to be masked by the human auditory system anyway, we can get significant compression without the loss of perceived fidelity. A conceptual block diagram of this process is shown in Figure 48.11. The option in *mp3* to switch between an 18 and 6 coefficient MDCT is used to accommodate a wider range of sounds. For a more precise encoding of those portions of the audio signal that include time-limited sharp sounds, such as castanets, the six-coefficient MDCT is used. This permits a more accurate rendition of the sound by allocating more coding resources to the short period in which those sounds occur.

The filters used in subband coding are derived from a Fourier analysis point of view that can be thought of as a way of representing time functions using a basis set made up of complex exponentials that are defined for all time. Because these basis functions have support over the entire time axis, any representation using these basis functions provides no time localization. By looking at the spectral picture, one might be able to say that the signal contained a component of a particular frequency; but it is not possible to determine when that signal occurred. Wavelet analysis is based on translated and dilated versions of a time-limited waveform. This permits localization of components in both time and frequency. From the implementation point of view, however, subband decomposition and wavelet decomposition look very similar. In both cases, the decomposition is implemented using a setup very much like that shown in Figure 48.10.

While the method of decomposition is very similar, compression schemes using wavelets have employed very different coding strategies. The most well-known application of wavelet decomposition is the image compression standard known as JPEG2000 [28]. Unlike speech and audio signals, images are 2D objects; and, thus, the decomposition has to occur in two dimensions. For practical reasons, this decomposition is usually performed as a concatenation of two 1D decompositions. Each row of an $N \times M$ image is treated as a 1D signal and decomposed into a high and low band. After downsampling, we end up with two sets of coefficients of size $N \times M/2$. Each row of these coefficients is decomposed and subsampled to produce four $N/2 \times M/2$ subimages whose pixels are the coefficients. The subimage resulting from taking the low-pass filtered rows and then low-pass filtered columns of the resulting $N \times M/2$ image is called the low–low or LL image. Similarly, the other subimages are called the low–high (LH), high–low (HL), and high–high (HH) images. Figure 48.12 illustrates this process.

Most natural images have most of their energy concentrated in the LL subimage. This LL subimage can be further decomposed into $4 N/4 \times M/4$ subimages resulting in a total of 7 subimages. The LL image generated at each step can be further decomposed in a similar fashion. If a coefficient has a magnitude greater than a particular value, it is said to be *significant* at that value. As with other wavelet-based image

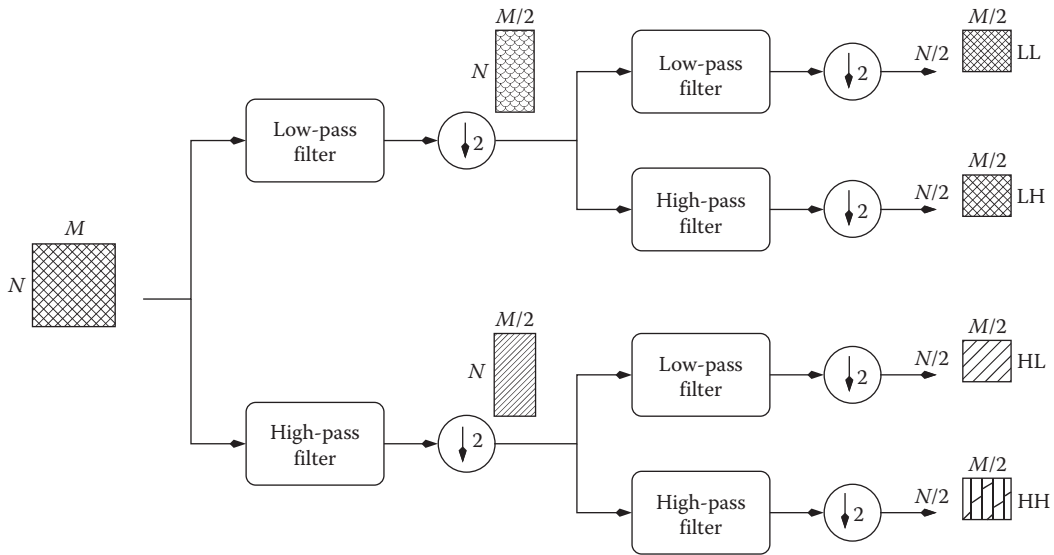

FIGURE 48.12 Decomposition of an $N \times M$ image into four $N/2 \times M/2$ images.

coding schemes [29,30], the JPEG2000 standard uses the concept of significance to improve compression efficiency. As the decomposition is being performed each time for coefficients corresponding to pixels at a particular spatial location, we can group coefficients depending on the pixels they correspond to. In these groups, if the low-frequency coefficient has a magnitude lower than a particular threshold, that is, it is insignificant at that threshold level, then it is highly likely that the other coefficients will also have values lower than that threshold. We can make use of this fact by comparing the low-frequency coefficient against a series of progressively lower threshold and then encoding entire groups of coefficients based on whether the low-frequency coefficient is significant or insignificant at that threshold. If we pick the thresholds to be powers of two, then the encoding of significant coefficients at progressively lower thresholds becomes the encoding of the bitplanes of an image.

The JPEG2000 algorithm divides the image into *tiles* that can be further subdivided into *precincts*. By encoding these subdivisions independently, the algorithm allows for random access to different parts of the image. Within each subdivision, the wavelet coefficients are encoded bitplane by bitplane using a sequence of three passes: a *significance propagation* pass, a *magnitude refinement* pass, and a *cleanup* pass. In the significance propagation pass, all bits in the neighborhood of coefficient locations previously declared significant are examined. Their significance status is encoded. If the coefficient becomes significant, the sign of the coefficient is encoded. In the magnitude refinement pass, the bits corresponding to coefficients declared significant in previous passes are encoded; and in the cleanup pass, all remaining bits are encoded. The bitstream thus generated is an embedded stream, that is, the earlier bits are more important to the reconstruction of the image. As more bits are made available, the decoder can progressively improve the quality of the reconstruction; we do not need to wait for the end of the bitstream to obtain a reconstruction of the image.

Once the bits have been generated and prior to framing, the JPEG2000 algorithm has the option of going through a post-compression rate distortion optimization step where the algorithm organizes the bits into quality layers. This provides the ability to generate the best reconstruction for a given number of bits.

48.5.3 Linear Predictive Coding

While images can be generated in a variety of ways, the mechanism used for generating human speech is relatively standard. Air is forced through a stretched membrane, the vocal cords; and the sound

generated is modulated by the vocal tract consisting of the laryngeal, oral, nasal, and pharyngeal passages to produce speech. We can model this process using an excitation source followed by a vocal tract filter. This was done in the eighteenth century by Wolfgang von Kempelen (aka Kempelen Farkas Lovag) [31] using bellows and a sequence of flexible tubes. The more modern version, which is widely used in cell phones, uses digital signals for the excitation sequence and digital filters to model the vocal tract. The basic algorithm consists of the application of two modeling steps to short segments of speech. The two steps are that of modeling the excitation sequences and that of modeling the vocal tract. These models are transmitted, along with framing information, to the receiver that then reconstructs the speech.

The simplest classification of the excitation sequence is between *voiced* sounds, such as the vowel sounds, and the *unvoiced* sounds, including the sibilant *s* and the fricative *f* sound. The voiced sounds have a pseudo-periodic structure where the period is called the *pitch* period. The unvoiced sounds are more noiselike. The excitation sequence can also be obtained as the outcome of a search process in which various elements of one or more excitation codebooks are used in conjunction with the vocal tract filter and a fidelity metric that selects the excitation sequence best matched to the input speech.

The vocal tract filter is a linear filter. An example of this is the filter used in the Federal Standard FS 1016:

$$y_n = \sum_{i=1}^{10} b_i y_{n-i} + \beta y_{n-p} + G \epsilon_n$$

where

- ϵ_n is the excitation signal
- P is the pitch period
- y_n is the synthesized speech

The term βy_{n-p} can be thought of as a correction term. The coefficients $\{b_i\}$ are known as the LP coefficients. These coefficients model the spectral envelope of the voice signal, and it can be shown [4] that the coefficients can be obtained by solving the set of equations:

$$\sum_{i=1}^M b_i R_{yy}(|i-j|) = R_{yy}(j); \quad j = 1, 2, \dots, 10 \quad (48.42)$$

These equations can be efficiently solved using the Levinson–Durbin algorithm [32,33].

To accommodate the rapidly changing sounds that make up the speech signal, this process is repeated every 20–30 ms depending on the particular standard being used.

48.5.4 Video Coding

Video coding has generally been seen as a combination of predictive coding and transform coding. Frames of a video sequence are generally quite similar to each other with the same objects appearing in a succession of frames. Therefore, the approach is to use predictive coding along the temporal axis followed by transform coding of the residual. In order to preserve some random access capability, a frame is periodically encoded without prediction. If we did not do so, we would have to reconstruct all previous frames to reconstruct an individual frame. By periodically encoding a frame without using interframe information, called an I-frame in MPEG parlance, we only need to begin decoding from the nearest I-frame.

The prediction technique used in almost all video coding algorithms is called *motion-compensated prediction*. The frame being encoded is divided into square blocks. For each of the blocks, the algorithm

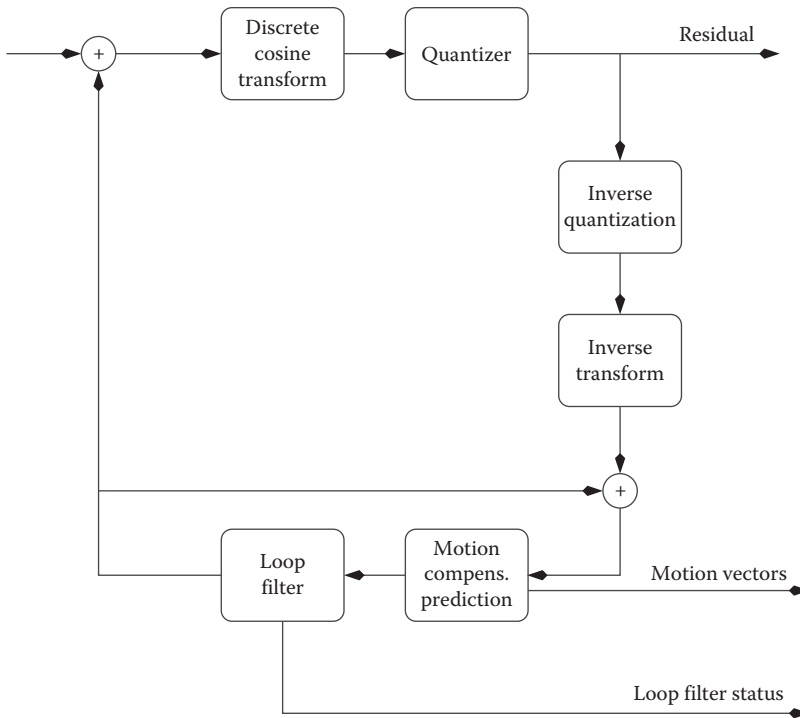

FIGURE 48.13 A block diagram of the H.261 video coding algorithm. (From ITU-T Recommendation H.261, video codec for audiovisual services at $p \times 64$ kbit/s, 1993.)

searches in the previous frame for the closest match in the spatial neighborhood of the frame being encoded. The idea is that as we move from frame to frame, objects will appear in slightly different locations in the frame. The horizontal and vertical offsets of the closest matching block are called the motion vector and can sometimes account for more than 90% of the video bitstream. The difference between the block being encoded and its motion compensated past is generally encoded using a transform coder. A block diagram of one of the earlier video coding schemes, H.261, is shown in Figure 48.13. While there are many differences in details between the H.261 standard and the more modern MPEG-1, MPEG-2, and H.264 (also known as MPEG-4 Part 10) standards, the basic approach has stayed the same. The standards H.261, MPEG-1, and MPEG-2 use an 8×8 DCT, while the H.264 standard uses a 4×4 integer DCT-like transform. While in H.261, the only prediction is based on past frames, the later standards allow for bidirectional prediction, that is, the prediction is formed using an average of the past and future frames. If bidirectional prediction is to be used, the transmission order cannot be causal as the frames used for generating the prediction need to be available to the decoder before the predicted frame can be reconstructed.

48.6 Conclusions and Further Reading

We have barely scratched the surface of the area of data compression in this review. We hope we have convinced the reviewer that in order to design good compression algorithms, one needs to understand the data that are being compressed. If the data can be effectively modeled, it can be compressed very efficiently. There is also a flip side to data compression algorithms. Because the data compression algorithms depend so heavily on discovering structure in the data, they can be used for the purpose of structure discovery rather than data compression. A review of some of the ways data compression algorithms can be used to understand biological sequences can be found in [35].

There are a large number of books dealing with data compression. There is also continued research that appears in various *IEEE* and *ACM* journals. The annual Data Compression Conference held in Snowbird, Utah, usually at the end of March or the beginning of April, is the venue for much of the research in this area. Some of the books in this area are as follows:

- *Text Compression* by T.C. Bell, J.G. Cleary, and I.H. Witten [36]. This is somewhat dated but is still one of the most lucid books on various lossless compression techniques used in text compression.
- *The Data Compression Book* by M. Nelson and J.L. Gailley [37]. One of the earliest and still one of the best introductions to many aspects of data compression.
- *Introduction to Data Compression* by K. Sayood [4]. A comprehensive introduction (and perhaps a bit more) to both lossy and lossless compression.
- *Digital Compression for Multimedia: Principles and Standards* by J.D. Gibson, T. Berger, T. Lookabaugh, D. Lindbergh, and R. Baker [38]. A book written more from a standards perspective.
- *JPEG2000: Image Compression Fundamentals, Standards and Practice* by D. Taubman and M. Marcellin [27]. The definitive reference book for JPEG2000, this book also introduces various compression techniques.

49.1 Introduction

UnderWater Acoustic Sensor Networks (UW-ASNs) [1] consist of a number of sensors and vehicles that interact to collect data and perform tasks in a collaborative manner underwater. They have been deployed to carry out collaborative monitoring tasks including oceanographic data collection, climate monitoring, disaster prevention, and navigation. Autonomous underwater vehicles (AUVs) are widely believed to be revolutionizing oceanography and are enabling research in environments that have typically been impossible or difficult to reach [21]. For example, AUVs have been used for continuous measurement of fresh water exiting the Arctic through the Canadian Arctic Archipelago and Davis Strait in order to study the impact of climate change to the circulation of the world's oceans. The ability to do so under ice is important so that, for example, scientists can measure how much fresh water flows through the strait—and at what times of year—so they have a baseline for comparison in coming years.

For these missions, position information is of vital importance in mobile underwater sensor networks, as the data collected have to be associated with appropriate location in order to be spatially reconstructed onshore. Even though AUVs can surface periodically (e.g., every few hours) to locate themselves using global positioning system (GPS)—which does not work underwater—over time, inaccuracies in models for deriving position estimates, self-localization errors, and drifting due to ocean currents will significantly increase the uncertainty in position of underwater vehicle. Moreover, in

* This chapter is based on our paper in *Proceedings of IEEE Conference on Sensor, Mesh and Ad Hoc Communications and Networks (SECON)*, Seoul, Korea, June 2012 [9].

extreme environments such as under ice, surfacing to get a GPS update is hardly possible and, therefore, position information is highly uncertain. In such environments, relying on standard navigation techniques such as long baseline (LBL) navigation is difficult as the use of static LBL beacons typically limits the operation range to about 10 km [18] and requires great deployment efforts before operation, especially in deep water (more than 100 m deep).

As AUVs are becoming more and more capable and also affordable, deployment of multiple AUVs to finish one mission becomes a widely adopted option. This not only enables new types of missions through cooperation but also allows individual AUVs of the team to benefit from information obtained from other AUVs. Existing localization schemes underwater generally rely on the deployment of transponders or nodes with underwater communication capabilities as reference points, which requires either much deployment effort or much communication overhead. Moreover, these schemes are not able to estimate the uncertainty associated with the calculated position, which is high in under-ice environments, and thus are not able to minimize position uncertainty.

To address this problem, we propose a solution that uses only a subset of AUVs without relying on localization infrastructure. Specifically, a position uncertainty model in [8] is introduced to characterize an AUV's position. This model is extended to estimate the uncertainty associated with the standard distance-based localization technique, resulting in the distance-based localization with uncertainty estimate (DISLU). We further propose a Doppler-based technique with uncertainty estimation capability, which is called Doppler-based localization with uncertainty estimate (DOPLU). The DISLU technique relies on packets (i.e., communication overhead) to measure the inter-vehicle distances (i.e., ranging), which, in conjunction with positions of reference nodes, are utilized to estimate the position. On the other hand, DOPLU, which measures Doppler shifts from ongoing communications and then uses these measurements to calculate velocities for localization, removes the need for ranging packets. As DOPLU only relies on relative measurements, it may not be able to fix displacement errors introduced by the rotation of the AUV group. In this case, DISLU is executed to bound such localization errors. Considering these tradeoffs, using the uncertainty model, the localization error and communication overhead of DISLU and DOPLU can be jointly considered and algorithms are devised to minimize the localization uncertainty and communication overhead while satisfying localization error requirement.

Our solution offers a way to estimate the degree of uncertainty associated with a localization technique and based on this estimation it further minimizes both position uncertainty and communication overhead. The contributions of this work include (1) a probability model to estimate the position uncertainty associated with localization techniques; (2) an algorithm to minimize localization uncertainty by selecting an appropriate subset of reference nodes (in general, other AUVs); (3) an algorithm to optimize the localization interval in order to further minimize the localization overhead; and (4) a Doppler-based localization technique that can exploit ongoing communications for localization.

The remainder of this chapter is organized as follows. In Section 49.2, we introduce the basic knowledge on UW-ASNs. In Section 49.3, we review the related work for localization algorithms in UW-ASNs. We present the motivation and background in Section 49.4 and propose our localization solution in Section 49.5; in Section 49.6, performance evaluation and analysis are carried out, while conclusions are discussed in Section 49.7.

49.2 Basics of Underwater Acoustic Sensor Networks

UW-ASNs are applied in a broad range of applications, including environmental monitoring, undersea exploration, disaster prevention, assisted navigation, and tactical surveillance. Underwater networking is a rather unexplored area although underwater communications have been experimented since World War II, when, in 1945, an underwater telephone was developed in the United States to communicate with submarines [24]. Acoustic communications are the typical physical layer technology in underwater networks. In fact, radio waves propagate at long distances through conductive sea water only at extra low frequencies (30–300:Hz), which require large antennae and high transmission power.

For example, the Berkeley Mica 2 Motes, the most popular experimental platform in the sensor networking community, have been reported to have a transmission range of 120 cm underwater at 433:MHz by experiments performed at the Robotic Embedded Systems Laboratory (RESL) at the University of Southern California. Optical waves do not suffer from such high attenuation but are affected by scattering. Moreover, transmission of optical signals requires high precision in pointing the narrow laser beams. Thus, *acoustic waves* are generally used for underwater communications [26].

The traditional approach for ocean-bottom or ocean-column monitoring is to deploy underwater sensors that record data during the monitoring mission and then recover the instruments [22]. This approach has the following disadvantages:

1. *No real-time monitoring*: The recorded data cannot be accessed until the instruments are recovered, which may happen several months after the beginning of the monitoring mission. This is critical especially in surveillance or in environmental monitoring applications such as seismic monitoring.
2. *No online system reconfiguration*: Interaction between onshore control systems and the monitoring instruments is not possible. This impedes any adaptive tuning of the instruments, nor is it possible to reconfigure the system after particular events occur.
3. *No failure detection*: If *failures* or *misconfigurations* occur, it may not be possible to detect them before the instruments are recovered. This can easily lead to the complete failure of a monitoring mission.
4. *Limited storage capacity*: The amount of data that can be recorded during the monitoring mission by every sensor is limited by the capacity of the onboard storage devices (memories and hard disks).

Therefore, there is a need to deploy underwater networks that will enable real-time monitoring of selected ocean areas, remote configuration, and interaction with onshore human operators. This can be obtained by connecting underwater instruments by means of wireless links based on acoustic communication.

Many researchers are currently engaged in developing networking solutions for terrestrial wireless ad hoc and sensor networks. Although there exist many recently developed network protocols for wireless sensor networks, the unique characteristics of the underwater acoustic communication channel, such as limited bandwidth capacity and variable delays [23], require very efficient and reliable new data communication protocols.

Major challenges in the design of underwater acoustic networks are

- The available bandwidth is severely limited
- The underwater channel is severely impaired, especially due to multi-path and fading problems
- Propagation delay in underwater is five orders of magnitude higher than in radio frequency (RF) terrestrial channels and extremely variable
- High bit error rates and temporary losses of connectivity (shadow zones) can be experienced due to the extreme characteristics of the underwater channel
- Battery power is limited and usually batteries cannot be recharged, also because solar energy cannot be exploited
- Underwater sensors are prone to failures because of fouling and corrosion

Underwater acoustic communications are mainly influenced by *path loss*, *noise*, *multipath*, *Doppler spread*, and *high and variable propagation delay*. All these factors determine the *temporal and spatial variability* of the acoustic channel and make the available bandwidth of the *underwater acoustic channel* limited and dramatically dependent on both range and frequency. Long-range systems that operate over several tens of kilometers may have a bandwidth of only a few kHz, while a short-range system operating over several tens of meters may have more than a hundred kHz of bandwidth. In both cases, these factors lead to low bit rate [5], in the order of tens of kbps for existing devices.

FIGURE 49.1 Path loss of short-range acoustic channel vs. distance and frequency in band 1–50 kHz.

Hereafter we analyze the factors that influence acoustic communications in order to state the challenges posed by the underwater channels for underwater sensor networking. These include the following.

Path loss: Attenuation is mainly provoked by absorption due to conversion of acoustic energy into heat. The attenuation increases with distance and frequency. Figure 49.1 shows the acoustic attenuation with varying frequency and distance for a short-range shallow water acoustic channel, according to the propagation model in [27]. The attenuation is also caused by scattering and reverberation (on rough ocean surface and bottom), refraction, and dispersion (due to the displacement of the reflection point caused by wind on the surface). Water depth plays a key role in determining the attenuation. *Geometric spreading* refers to the spreading of sound energy as a result of the expansion of the wavefronts. It increases with the propagation distance and is independent of frequency. There are two common kinds of geometric spreading: *spherical* (omni-directional point source), which characterizes deep water communications, and *cylindrical* (horizontal radiation only), which characterizes shallow water communications.

Noise: Man-made noise is mainly caused by machinery noise (pumps, reduction gears, and power plants) and shipping activity (hull fouling, animal life on hull, and cavitation), especially in areas encumbered with heavy vessel traffic. *Ambient noise* is related to hydrodynamics (movement of water including tides, current, storms, wind, and rain) and to seismic and biological phenomena. In [15], boat noise and snapping shrimps have been found to be the primary sources of noise in shallow water by means of measurement experiments on the ocean bottom.

Multipath: Multipath propagation may be responsible for severe degradation of the acoustic communication signal since it generates inter-symbol interference (ISI). The multipath geometry depends on the link configuration. Vertical channels are characterized by little time dispersion, whereas horizontal channels may have extremely long multipath spreads. The extent of the spreading is a strong function of depth and the distance between transmitter and receiver.

High delay and delay variance: The propagation speed in the acoustic channel is five orders of magnitude lower than in the radio channel. This large propagation delay (0.67 s/km) can reduce the throughput of the system considerably. The very high delay variance is even more harmful for efficient protocol design as it prevents from accurately estimating the round trip time (RTT), which is the key parameter for many common communication protocols.

Doppler spread: The Doppler frequency spread can be significant in acoustic channels [26], causing a degradation in the performance of digital communications: transmissions at a high data rate cause many adjacent symbols to interfere at the receiver, requiring sophisticated signal processing to deal with the generated ISI. The Doppler spreading generates a simple frequency translation, which is relatively easy for a receiver to compensate for; and a continuous spreading of frequencies, which constitutes a nonshifted signal, that is more difficult to compensate for. If a channel has a Doppler spread with bandwidth B and a signal has symbol duration T , then there are approximately BT uncorrelated samples of its complex envelope. When BT is much less than unity, the channel is said to be *underspread* and the effects of the Doppler fading can be ignored, while, if greater than unity, it is said to be *overspread* [16].

Most of the described factors are caused by the chemical–physical properties of the water medium such as temperature, salinity, and density, and by their spatio-temporal variations. These variations, together with the wave guide nature of the channel, cause the acoustic channel to be *highly temporally and spatially variable*. In particular, the horizontal channel is by far more rapidly varying than the vertical channel, in both deep and shallow water.

49.3 Related Work

A number of underwater localization schemes, many of which are summarized in [6], have been proposed to date, which take into account a number of factors like the network topology, device capabilities, signal propagation models, and energy requirements. Most of these localization schemes require the positions of some nodes be known. In order to estimate the positions of other nodes, measurements such as distances and angles are made. Range-based schemes, use round-trip time (RTT), time of arrival (ToA), time difference of arrival (TDoA), received-signal-strength (RSS), or angle of arrival (AoA) to estimate their distances to other nodes. Schemes that rely on ToA or TDoA require tight time synchronization between the transmitter and the receiver, whereas RTT does not. However, RTT comes with a higher network cost and associated error. RSS has been implemented in [10], but it comes with an additional network cost.

An hierarchical localization scheme involving surface buoys, anchor nodes, and ordinary nodes is proposed in [30]. Surface buoys are GPS based and used as references for positioning by other nodes. Anchor nodes communicate with surface buoys while ordinary nodes only communicate with the anchor nodes. This distributed localization scheme applied 3D Euclidean distance and recursive location estimation method for the position calculation of ordinary nodes. Mobility of the sensor nodes was not considered in the position estimate.

A recent proposal uses surface-based signal reflection for underwater localization [10]. This approach attempts to overcome limitations imposed by line of sight (LOS) range measurement techniques such as RSS, TOA, and AoA. These limitations are caused by multipath, line of sight attenuation and required reference nodes. The receiver in this approach accepts only signals that have been reflected off the surface. It accomplishes this by applying homomorphic deconvolution to the signal to obtain an impulse response, which contains RSS information. The algorithm then checks the RSS and compares it to calculated reflection coefficients. Mobility is allowed and high localization accuracy can be achieved.

These localization solutions are generally designed for UW-ASNs, which may not include mobile nodes such as AUVs. In the rest of this section, we review the work that is most related, that is, localization in UW-ASNs *using AUVs*. Localization is essential for underwater vehicle navigation, where many localization solutions, as summarized in [18], have been proposed. Short baseline (SBL) and long baseline (LBL) systems [18] are standard ways to localize vehicles underwater, where external transponder arrays are employed to aid localization. In SBL systems, position estimate is determined by measuring the vehicle's distance from three or more transponders that are, for example, lowered over the side of the surface vessel. The LBL systems are similar to SBL, with the difference that an array of transponders is tethered on the ocean bed with fixed locations.

In [12], a localization scheme called AUV aided localization (AAL) is proposed, where position estimation is done using a single AUV. In AAL, an AUV navigates a predefined trajectory, broadcasts its position

upon a node's request, and fixes its own position at the surface. Each node estimates the distances to the AUV while the AUV is at different locations, using the RTT between itself and the AUV. Algorithms such as triangulation or bounding box can then be used for position estimate. Another localization solution called dive-and-rise localization (DNRL) is proposed for both static and mobile networks in [11]. The DNRL solution is similar to AAL, with the difference that ocean currents are considered and time synchronization is required between nodes.

In [14], an online algorithm for cooperative localization of submerged AUVs is designed, implemented, and evaluated through experiments. This algorithm relies on a single surface vehicle called communication and navigation aid (CNA) for autonomous navigation. Using the CNA's GPS positions and basic onboard measurements including velocity, heading, and depth, this algorithm can use filtering techniques such as extended Kalman filter (EKF) to bound the error and uncertainty of the onboard position estimates of a low-cost AUV.

Simultaneous localization and mapping (SLAM), also known as concurrent mapping and localization (CML), attempts to merge two traditionally separated concepts, map building and localization. SLAM has been investigated using an imaging sonar and Doppler velocity log (DVL) in combination with dead reckoning [25]. However, despite recent research efforts this technology is still in its infancy and many obstacles still need to be overcome. As of November 2010, there have been several simulations carried out [29], but currently there is no operating solution to the AUV SLAM problem.

Among existing underwater localization techniques (which are generally not suitable for under-ice environments), relatively few under-ice localization techniques have been proposed. Despite these efforts, the technology remains expensive and out of reach for researchers. Current techniques employed in the under-ice environment include combinations of either dead-reckoning using inertial measurements [28], sea-floor acoustic transponder networks such as SBL or LBL [2], and/or a DVL that can be either seafloor or ice relative [17]. These current approaches require external hardware, are cost prohibitive, and suffer from error propagation. For accurate dead reckoning, highly accurate sensors are required because magnetic navigation systems are subject to local magnetic field variations and gyros are subject to drift over time. Quality inertial navigation sensors often cost more than \$10,000 [18]. In contrast, our solution is much more economical as it does not require these expensive sensors.

Two solutions for underwater collaborative localization using a probability framework are proposed in [19] and [20], where a sum-product algorithm and a Markov process that are based on the so-called factor graph are used to model the joint distribution of multiple nodes. Both solutions require the global information of the nodes that are involved in localization, which leads to high computation complexity and communication overhead. Our solution offers another probability framework that leverages the self-estimated uncertainty distribution for estimation of other nodes. Therefore, global information is not required, resulting in reduced computation complexity and communication overhead.

49.4 Motivation and Background

In UW-ASNs, inaccuracies in models for position estimation, self-localization errors, and drifting due to ocean currents will significantly increase the uncertainty in position of an underwater vehicle. *Hence, using a deterministic point is not enough to characterize the position of an AUV.* Furthermore, such a deterministic approach underwater may lead to problems such as routing errors in inter-vehicle communications, vehicle collisions, lose of synchronization, and mission failures. In order to address the problems due to position uncertainty, we introduce a probability model to characterize a node's position. In many applications such as geographic routing, AUVs need to estimate the positions of themselves and other AUVs. Therefore, depending on the view of the different nodes, two forms of position uncertainty are defined, that is, *internal uncertainty*, the position uncertainty associated with a particular entity/node (such as an AUV) *as seen by itself*, and *external uncertainty*, the position uncertainty associated with a particular entity/node *as seen by others*.

These two notions introduce a shift in AUV localization: *from a deterministic to a probabilistic view*. This shift can then be leveraged to improve the performance of solutions for problems in a variety of fields.

For example, in UW-ASNs, using the external-uncertainty region, routing errors can be decreased and a node can estimate better the transmission power to guarantee the signal-to-noise ratio for correct data reception by taking into account not only channel impairments but also position uncertainty [8]. The notion of external uncertainty can also be used in *underwater robotics* to minimize the risk of vehicle collisions; and in *underwater localization* to decrease the position uncertainty by selecting a proper subset of nodes to be used as “references,” as shown later.

Many approaches such as those using Kalman filter (KF) [3] have been proposed to estimate the internal uncertainty assuming that the variables to be estimated have linear relationships between each other and that noise is additive and Gaussian. While simple and quite robust, KF is not optimal when the linearity assumption between variables does not hold. On the other hand, approaches using nonlinear filters such as the extended or unscented KF attempt to minimize the mean squared errors in estimates by jointly considering the navigation location and the sensed states or features such as underwater terrain features, which are nontrivial, especially in an unstructured underwater environment.

Let us denote the internal uncertainty, a 3D region associated with any node $j \in \mathcal{N}$, where \mathcal{N} is the set of network nodes, as \mathcal{U}_{jj} , and the external uncertainties, 3D regions associated with j as seen by $i, k \in \mathcal{N}$, as \mathcal{U}_{ij} and \mathcal{U}_{kj} , respectively ($i \neq j \neq k$). In general, \mathcal{U}_{jj} , \mathcal{U}_{ij} , and \mathcal{U}_{kj} are different from each other; also, due to information asymmetry, \mathcal{U}_{ij} is in general different from \mathcal{U}_{ji} . External uncertainties may be derived from the broadcast/propagated internal-uncertainty estimates (e.g., using *one-hop* or *multihop neighbor discovery mechanisms*) and, hence, will be affected by end-to-end (e2e) *network latency* and *information loss*.

49.5 Proposed Localization Solution

With the notion of external uncertainty, we can model the uncertainty associated with localization techniques. Based on this uncertainty, optimization problems are formulated to minimize localization uncertainty and communication overhead. In this section, we first show how external uncertainty can be used to estimate the uncertainty with the standard distance-based localization technique (i.e., DISLU). Then we propose a novel Doppler-based localization technique DOPLU that jointly estimates localization uncertainty. The DISLU technique requires ranging packets to measure the distances for position calculation, which introduces communication overhead. This weakness in DISLU can be offset by DOPLU, which exploits ongoing inter-vehicle communications to avoid the need for ranging packets. Such an “opportunistic” approach (i.e., DOPLU) does not guarantee correct absolute locations (as Doppler shifts only characterize *relative* position change) so the team of AUVs needs to go back to DISLU to correct the locations when the error is too large. Based on this idea, we propose algorithms to solve two optimization problems, one for minimization of localization uncertainty and the other for minimization of communication overhead.

The communication protocol for our solution is presented in Figure 49.2. Each AUV first runs DISLU using the distances measured from the round-trip time. Then, DOPLU is run using Doppler-shift

FIGURE 49.2 Overview of the proposed approach.

information extracted from inter-vehicle packets. By overhearing the ongoing packets from the reference nodes, AUV i estimates the Doppler shifts and then extracts the relative velocity, from which the AUVs calculate their absolute velocities. The DISLU technique is run to fix the localization error introduced by DOPLU after T_p , which is the time after the last DISLU is started.

Both DISLU and DOPLU use the external uncertainty and corresponding probability distribution function (pdf) to estimate the uncertainty resulted from the localization technique, that is, the internal uncertainty and pdf of the AUV running the localization algorithm. Then this internal uncertainty information is broadcast for other AUVs to estimate external uncertainties. Our previous work in [8] provided a *statistical solution* to estimate the internal and external uncertainty, which is used for initial estimation here.

49.5.1 Distance-Based Localization with Uncertainty Estimate (DISLU)

We present here the DISLU technique, which is based on the following idea, to estimate its own position, vehicle i needs (1) to *estimate the distances* between itself and its reference vehicles, and (2) to *estimate its own position* based on these distances.

The DISLU technique relies on the round-trip time T_{RTT} to measure the inter-vehicle distance. By extracting the one-way propagation time, i is able to calculate the inter-vehicle distance. That is, the distance between transmitter i and receiver j is $d_{ij} = c \cdot (T_{RTT} - T_i^{(TX)} - T_j^{(TX)} - T_j^{(hold)}) / 2$, where $T_i^{(TX)}$ and $T_j^{(TX)}$ are the duration to transmit the packet at i and the duration to transmit acknowledgment at j (i.e., transmission delays), $T_j^{(hold)}$ is the holdoff time of j to avoid collisions. To reduce the transmission time, we can use the short ping packets. Once j receives the ping packet, it starts a hold-off timer, $T_j^{(hold)}$, which is a uniformly distributed random variable in $[0, 2T_{hold}^{mean}]$ where T_{hold}^{mean} is given by

$$T_{hold}^{mean} = \left(1 - \frac{d_{ij}}{R}\right)\tau + \frac{\phi_{ij}}{c}, \quad (49.1)$$

where

d_{ij} is the distance from AUV i to j

τ is the estimated transmission time for the current packet

$c = 1500$ m/s is the propagation speed of acoustic waves

R is the transmission radius of the underwater modem

$\phi_{ij} = \max\{0, R - d_{ij}\}$

The first term in (49.1) gives less time to the neighbor that is closer to i , and the second term is the extra delay that a node should wait so that all the nodes receive the packet. This gives fairness by providing synchronization in starting the hold-off timers of all the nodes receiving the data packet. The hold-off time $T_j^{(hold)}$ is then embedded in the acknowledge packet for i 's information.

After the calculation of d_{ij} 's, i estimates its own position as the point with the least mean squared error to the reference nodes. Then, i estimates its internal uncertainty region using *conditional probability* and the distribution of the reference nodes within their external-uncertainty regions.

Given the set of i 's neighbors \mathcal{N}_i , the external uncertainty regions \mathcal{U}_{ij} , the distances d_{ij} , and the pdf of j within region \mathcal{U}_{ij} , $\forall j \in \mathcal{N}_i$, i can estimate the pdf of being at generic point p as

$$g(P_i = p) = \int_{P_j \in \mathcal{U}_{ij}, j \in \mathcal{N}_i} g \left(P_i = p, \bigcap_{j \in \mathcal{N}_i} P_j = p_j \right) = \int_{P_j \in \mathcal{U}_{ij}, j \in \mathcal{N}_i} \left[g \left(P_i = p \mid \bigcap_{j \in \mathcal{N}_i} P_j = p_j \right) \cdot g \left(\bigcap_{j \in \mathcal{N}_i} P_j = p_j \right) \right] \quad (49.2)$$

where

$g(P_i = p)$ is the pdf of the position of i at point p

$g(\cdot)$ denotes conditional probability function

In our solution, p is calculated as the point that has the minimum squared error, that is, $p \in S_i$, where $S_i \equiv \left\{ q = \arg \min \sum_{j \in \mathcal{N}_i} \|d(p, p_j) - d_{ij}\|^2 \right\}$ (i.e., $\mathcal{U}_{ii} = S_i$). Here, $d(p, p_j)$ is the distance between point p and p_j . We assume point p to be uniformly distributed in S_i . In other words, we have

$$g(P_i = p | P_j = p_j, j \in \mathcal{N}_i) = \begin{cases} 1/|S_i|, & p \in S_i \\ 0, & p \notin S_i \end{cases} \quad (49.3)$$

where $|S_i|$ is the number of elements in S_i if S_i is a discrete set, or the area (or volume) of S_i if S_i is a non-empty nondiscrete set.

The joint pdf, $g\left(\bigcap_{j \in \mathcal{N}_i} P_j = p_j\right)$, can be approximated as

$$g\left(\bigcap_{j \in \mathcal{N}_i} P_j = p_j\right) \approx \prod_{j \in \mathcal{N}_j} g(P_j = p_j) \quad (49.4)$$

as the distributions of these AUVs are independent. Therefore, (49.2) can be expanded as

$$g(P_i = p) \approx \int_{p_j \in \mathcal{U}_{ij}, j \in \mathcal{N}_i} \left[g\left(P_i = p | \bigcap_{j \in \mathcal{N}_i} P_j = p_j\right) \cdot \prod_{j \in \mathcal{N}_j} g(P_j = p_j) \right] \quad (49.5)$$

Hence, i 's internal uncertainty \mathcal{U}_{ii} with $g(\cdot)$ being the pdf is estimated, which is then broadcast to other AUVs. The AUVs receiving this information then use \mathcal{U}_{ii} to estimate i 's external uncertainty.

49.5.2 Doppler-Based Localization with Uncertainty Estimate (DOPLU)

The DOPLU technique runs between two consecutive runs of DISLU. Obviously, whenever the Doppler shifts from more than three nodes are extracted, DOPLU can be run. The time between two consecutive runs of the DISLU is divided into subslots with appropriate duration T_s (Figure 49.2) so that the DOPLU will be run at an appropriate frequency. Within each subslot, the vehicle that runs DOPLU extracts Doppler shifts from the packet it overhears (even if the packet is not intended to be received by it) from the reference vehicles. With the additional information it obtains from the packet header (such as velocity of the reference node), it computes its own absolute velocity, which is then used to estimate its own position and internal uncertainty. This reduces the communication overhead for sending packets to estimate inter-vehicle distance.

An algorithm is designed so that the duration T_s can be adjusted dynamically according to the frequency of ongoing communication activities. Within T_s , a AUV is expected to collect enough Doppler shifts from its reference neighbors so that the DOPLU algorithm runs efficiently. Note that if T_s is too small, it is very likely that the velocity calculated by DOPLU is close to that obtained from the last calculation, which means waste of computation resources. On the other hand, T_s should not be too large as it would lead to too much localization error. After all, the less frequent a AUV calculates its position, the more position error accumulates.

In the rest of this section, we focus on the main problem, that is, how to estimate the position and internal uncertainty when Doppler shifts are available, and leave the optimization of T_s in Section 49.5.3. Using the Doppler shifts regarding to the reference nodes, i can estimate its own absolute velocity using the projected positions (i.e., by adding history position with history velocity times the time passed) and velocities. Using this relationship for all reference nodes, i obtains an equation group to solve, where absolute velocity \vec{v}_i can be estimated.

To see how to calculate the absolute velocity, assume that at the end of one subslot, AUV i has collected the Doppler shift Δf_{ij} from reference node j . From the definition of Doppler shift, we have $\Delta f_{ij} = -\frac{\overline{\mathbf{v}_{ij}} \circ \overline{P_i P_j}}{\|P_i P_j\|} \frac{f_0}{c}$, where \mathbf{v}_{ij} is the relative velocity of i to j , $\overline{P_i P_j}$ is the position vector from i to j , f_0 is the carrier frequency, $c = 1500$ m/s is the speed of sound, and \circ is the inner product operation. From this equation, we have

$$\frac{\overline{\mathbf{v}_{ij}} \circ \overline{P_i P_j}}{\|P_i P_j\|} = -\Delta f_{ij} \frac{c}{f_0}. \quad (49.6)$$

From (49.6), assume that i has collected the Doppler shifts of $N_i^{(ref)}$ reference nodes, we then have an equation group with $N_i^{(ref)}$ equations. We then can derive i 's velocity $\overline{\mathbf{v}_i}$. Assume $\overline{\mathbf{v}_i} = (v_x^{(i)}, v_y^{(i)}, v_z^{(i)})$ and $\frac{\overline{P_i P_j}}{\|P_i P_j\|} = (\alpha_x^{(ij)}, \alpha_y^{(ij)}, \alpha_z^{(ij)})$, (49.6) is then $\overline{\mathbf{v}_{ij}} \circ \frac{\overline{P_i P_j}}{\|P_i P_j\|} = (\overline{\mathbf{v}_i} - \overline{\mathbf{v}_j}) \circ \frac{\overline{P_i P_j}}{\|P_i P_j\|} = (v_x^{(i)} - v_x^{(j)})\alpha_x^{(ij)} + (v_y^{(i)} - v_y^{(j)})\alpha_y^{(ij)} + (v_z^{(i)} - v_z^{(j)})\alpha_z^{(ij)} = -\Delta f_{ij} \frac{c}{f_0}$. By manipulating this equation, we have

$$v_x^{(i)} \alpha_x^{(ij)} + v_y^{(i)} \alpha_y^{(ij)} = -\Delta f_{ij} \frac{c}{f_0} - v_z^{(i)} \alpha_z^{(ij)} + v_x^{(j)} \alpha_x^{(ij)} + v_y^{(j)} \alpha_y^{(ij)} + v_z^{(j)} \alpha_z^{(ij)} \quad (49.7)$$

In this equation, $v_x^{(i)}$ and $v_y^{(i)}$ in the left-hand side are variables to be solved, whereas $v_z^{(i)}$ in the right-hand side can be derived from pressure sensor reading, $(\alpha_x^{(ij)}, \alpha_y^{(ij)}, \alpha_z^{(ij)})$ is the normalized vector of $\overline{P_i P_j}$, and $(v_x^{(j)}, v_y^{(j)}, v_z^{(j)})$ is obtained from the velocity information embedded in the overheard packet header of j .

Considering all the $N_i^{(ref)}$ reference nodes, we can obtain a linear equation group, which can be expressed in a matrix form as $\mathbf{A}\mathbf{x} = \mathbf{b}$, where

$$\mathbf{A} = \begin{bmatrix} \alpha_x^{i1} & \alpha_y^{i1} \\ \alpha_x^{i2} & \alpha_y^{i2} \\ \cdot & \cdot \\ \alpha_x^{iN_i^{(ref)}} & \alpha_y^{iN_i^{(ref)}} \end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix} v_x \\ v_y \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} b_{i1} \\ b_{i2} \\ \cdot \\ b_{iN_i^{(ref)}} \end{bmatrix}. \quad (49.8)$$

Here $b_{ij} = -\Delta f_{ij} \frac{c}{f_0} - v_z^{(i)} \alpha_z^{(ij)} + v_x^{(j)} \alpha_x^{(ij)} + v_y^{(j)} \alpha_y^{(ij)} + v_z^{(j)} \alpha_z^{(ij)}$. We want to find the optimal \mathbf{x}^* such that the sum of squared errors is minimized. That is,

$$\mathbf{x}^* = \arg \min \|\mathbf{b} - \mathbf{A}\mathbf{x}\|^2. \quad (49.9)$$

From matrix theory, \mathbf{x}^* can be solved as $\mathbf{x}^* = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{A}^T \mathbf{b}$. Once the velocity is calculated, the position of i is updated as $p_i = p_i' + \overline{\mathbf{v}}$, where $\overline{\mathbf{v}} = (v_x^{(i)}, v_y^{(i)}, v_z^{(i)})^T$.

Assume that the uncertainty regions \mathcal{U}_{ij} and the distribution pdf of j within region \mathcal{U}_{ij} are known (by embedding these parameters in the header of the packet), $\forall j \in \mathcal{N}_i$, i can estimate the pdf of being at point p as $g(P_i = p) = \int_{p_j \in \mathcal{U}_{ij}, \forall j \in \mathcal{N}_i} [g(P_i = p | P_j = p_j, j \in \mathcal{N}_i) \cdot g(P_j = p_j, j \in \mathcal{N}_i)]$. Similar to the case of DISLU, i can calculate the distribution of its own location and, hence, its internal uncertainty region.

Minimization of location uncertainty: Obviously, localization using different references leads to different estimation of internal uncertainty and corresponding pdf. Our objective is to minimize the estimated internal uncertainty. Using our notions of internal and external uncertainty, this can be achieved by solving an optimization problem. To measure the degree of uncertainty, we use *information entropy* as the metric, that is,

$$H(\mathcal{U}_{ij}, g_{ij}) = - \int_{p \in \mathcal{U}_{ij}} g_{ij}(p) \log(g_{ij}(p)) dp \quad (49.10)$$

The bigger $H(\mathcal{U}_{ij}, g_{ij})$ is, the more uncertain \mathcal{U}_{ij} is. The reason to use information entropy instead of simply the size of uncertainty region is that it can better characterize uncertainty.

Example: Assume that an AUV is distributed in $[0,10]$ along x -axis with pdf being 9.9 in $[0,0.1]$ and $0.1/99$ in $[0.1, 10]$ (Case 1). Then its entropy is -3.17 bits, which is less than the entropy 3.32 bits when the AUV is uniformly distributed in $[0,10]$ (Case 2) or the entropy 3 bits when the AUV is uniformly distributed in $[0,8]$ (Case 3). Obviously Case 1 is the most certain in these three cases even though Case 2 has the same size and Case 3 has the smallest size of the region. Note that the information flow between AUVs can occur in loops; this may not amplify errors of the positioning algorithm, as our problem can make sure the neighbors that can minimize the uncertainty can always be selected.

With this metric, the problem to minimize localization uncertainty can be formulated as

Given : $\mathcal{N}_i, \mathcal{U}_{ij}, g_{ij}()$;

Find : \mathcal{A}_i^* ; **Minimize :** $H(\mathcal{U}_{ii}, g_{ii})$;

S.t. :

$$\mathcal{U}_{ii} \equiv \left\{ q = \arg \min \sum_{j \in \mathcal{A}_i} \|d(p, p_j) - d_{ij}\|^2 \right\}; \quad (49.11)$$

$$g(P_i = p) = \int_{p_j \in \mathcal{U}_{ij}, j \in \mathcal{A}_i} \left[g(P_i = p | P_j = p_j, j \in \mathcal{A}_i) \cdot \prod_{j \in \mathcal{A}_i} g(P_j = p_j) \right]; \quad (49.12)$$

$$|\mathcal{A}_i| \geq 3; \quad \mathcal{A}_i \subset \mathcal{N}_i. \quad (49.13)$$

Here \mathcal{A}_i represents a subset of i 's reference nodes, (49.11) and (49.12) estimate the internal uncertainty and corresponding pdf when nodes in \mathcal{A}_i are used as references; and (49.13) are the constraints for \mathcal{A}_i so that enough reference nodes are selected for localization.

To reduce the complexity, we can convert an uncertainty region (internal or external) into discrete counterparts. That is, we divide an uncertainty region into a finite number of equal-size small regions. When the number of small regions is sufficiently large, the pdf of the AUV's position on a point—such as the centroid—in this small region can therefore be approximated by the probability on a small region. Hence, the estimated external-uncertainty region can be approximated as the region contained in the hull of these estimated points. The pdf functions are also be approximated by the probability mass functions on discrete points, which simplifies the pdf estimation. The aforementioned optimization can then be solved using exhaustive search algorithm after the discretization. Depending on the computation capability of the onboard processor, appropriate number of small regions can be used. Further improvement of the solution can be done after converting it into appropriate optimization that can be solved efficiently and we leave this as future work.

49.5.3 Minimization of Communication Overhead

In this section, we discuss how to optimize T_s and T_p so that localization overhead can be minimized while keeping the localization uncertainty low. We first propose an algorithm to dynamically adjust T_s in order to maintain the performance of DOPLU. Then, T_p is optimized to minimize the localization overhead.

As for T_s , it should be large enough so that packets from enough reference nodes are overheard. Suppose K_{\min} is the minimum number of reference nodes (or $|\mathcal{A}_i|$ if the optimization algorithm in Section 49.5.2 is used) so that \mathbf{x}^* can be calculated using DOPLU. In the beginning, T_s is initialized as $T_s = (R/c) + T_{TX} \cdot K_{\min}$, that is, the minimum time to overhear packets from K_{\min} reference nodes. Suppose that during the last T_s' period, Doppler shifts from N' reference nodes with smaller degree of uncertainty (seen by i) than i 's are received. On average, it takes T_s'/N' to receive a useful Doppler shift. Then, the expected time to receive K_{\min} useful Doppler shifts is $T_s' \cdot K_{\min}/N'$. We update T_s using a weighted average. That is, $T_s = \beta \cdot T_s' + (1 - \beta) \cdot T_s \cdot K_{\min}/N'$, where $\beta \in (0,1)$ is a weight factor.

Using internal and external uncertainty, we can also optimize the interval T_p running DISLU. By optimizing T_p , we minimize the overhead to use DISLU and hence the overall overhead. The DISLU algorithm is run when the localization error is large. The localization error can be estimated by calculating the distance from the position estimated by DISLU to that estimated by DOPLU. When the localization error is greater than a threshold d_{th} , DISLU is run to correct the error. Since the position is not deterministic, this requirement is expressed in a probabilistic way. That is, DISLU should be run when the probability of the localization error being over d_{th} is above a threshold probability γ . Therefore, to minimize the overhead of running DISLU, T_p should be maximal under the constraint that the probability of the localization error being over d_{th} is below γ . This can be formulated into the following optimization problem:

Given : \mathcal{U}_{ij} , $g_{ij}(\cdot)$, γ

Find : T_p^* ; **Maximize :** T_p ;

S.t. : $\Pr\left\{\left\|\overline{p_i(T_p)} - \tilde{p}_i(T_p)\right\| > d_{th}\right\} < \gamma$,

where $p_i(T_p)$ and $\tilde{p}_i(T_p)$ are the prediction positions using the DOPLU and DISLU after T_p from the last DISLU run time, respectively. This prediction of future internal uncertainty is based on the current estimated internal uncertainty and AUV's trajectory. A solution has been proposed in [8] for underwater gliders (one type of buoyancy-driven AUVs), which we adopt in this work. As the previous optimization problem, we can also convert it into discrete variable optimization problem and solve it in a similar way.

49.6 Performance Evaluation

The communication solution is implemented and tested on our underwater communication emulator [7]. This emulator is composed of four WHOI micro-modems and a real-time audio processing card to emulate underwater channel propagation. The multiinput multioutput audio interface can process real-time signals to adjust the acoustic signal gains, to introduce propagation delay, to mix the interfering signals, and to add ambient/man-made noise and interference. Our solution is compared against AAL, DNRL, and CNA, as introduced in Section 49.3, under an environment that is described by the Bellhop model [4]. We use the typical Arctic sound speed profile as in [27] and the corresponding Bellhop profile is plotted in Figure 49.3. Note that we use 25 KHz, the sound frequency in use for our WHOI modem. We modify AAL, DNRL, and CNA, as they were originally designed for settings that are quite different from the under-ice environment. Specifically, AAL, DNRL, and CNA all use the AUV that surfaces last as reference node because intuitively the shorter an AUV stays underwater (the less time it stays in an uncertain environment after a GPS fix), the less uncertain its position is. Triangulation is employed for

FIGURE 49.3 Bellhop profile for a typical Arctic environment.

position calculation in AAL and DNRL, while EKF filtering is used in CNA. We are also interested in seeing the performance improvement that we get using the external uncertainty notion. Therefore, we implement another version of our proposed solution without using external uncertainty, that is, forcing the position uncertainty to be zero. We denote this modified version and the original version by “Proposed solution w/o EU” and “Proposed solution w/EU,” respectively.

In order to evaluate the localization performance, two metrics, the *localization error* and the *deviation of error*, are used. Localization error is defined as the distance between the actual and the estimated AUV position. The deviation of error is the amount the localization error deviating from the total averaged error. The average localization error \bar{E} and deviation of error σ are plotted. The formulae of \bar{E} and σ are expressed as

$$\bar{E} = \frac{1}{L_t} \sum_{j=1}^{L_t} \left(\frac{1}{N} \sum_{i=1}^N E_i \right); \quad \sigma = \sqrt{\frac{1}{N} \sum_{i=1}^N (E_i - \bar{E})^2}, \tag{49.14}$$

where

N is the number of AUVs in the UW-ASN

E_i represents the localization error for each AUV operating in the UW-ASN at that particular time

L_t is the number of times the localization is performed, such that $L_t = T_{end} / \Delta T$

49.6.1 Simulation Scenarios

The parameters for our simulations are listed in Table 49.1. We further assume that ongoing communication packets are generated according to the Poisson traffic model with arrival rate being three packets per minute. As shown in Figure 49.4, we utilize the following two specific scenarios.

Scenario 1: This scenario involves a team of AUVs who collaboratively explore an underwater region located under ice. These AUVs remain under-ice for the duration of the mission and do not return to the surface until the mission is completed.

TABLE 49.1 Simulation Parameters

Total time	10,600 s (~2.94 h)
Time interval, ΔT	60 s
Deployment 3D region	2,000(L) \times 2,000(W) \times 1,000(H) m ³
Confidence parameter, α	0.05
AUV velocity	0.25–0.40 m/s
AUV depth range	[0,1,000] m
Typical currents	0.01–0.03 m/s [13]
Extreme currents	0.04–0.06 m/s [13]
Water temperature range	[–2,2] °C
Salinity range	[32.5,35] ppt

FIGURE 49.4 Two scenarios for simulations: different dotted circles represent different scenarios.

Scenario 2: This scenario is similar to the first except that individual AUVs will periodically surface to update their positioning via GPS. These AUVs take turns to go back to the surface at a predefined interval, which is 4000 s in our simulations. In order to avoid ice cover, these AUVs return to the edge of the ice sheet where they were deployed. Once an AUV surfaces, it acquires a GPS fix and updates its current coordinate position (position uncertainty is also reset).

Both scenarios are tested with typical and extreme currents, whose speed ranges are listed in Table 49.1. A random 3D direction is chosen for the current throughout one round of simulation. The Doppler data are based on the 6-h Doppler speed measurement that we took using WHOI modems on November 20, 2011 in the Bayfront Park bay, Lavallette, NJ, as shown in Figure 49.5. Our measurement shows that most of the Doppler speeds are low, similar to the part we plot here. Note that the right-hand side in (49.6) is replaced with the measured Doppler speed here as there is no need to calculate the Doppler shifts.

49.6.2 Evaluation Results

Real-time (one simulation run) localization errors and deviations of error are plotted in the first two subfigures of Figures 49.6 through 49.9. Moreover, to obtain results of statistical significance, 250 rounds were conducted for varying numbers of AUVs. The average errors for the AUV’s predicted location are plotted in Figures 49.6 through 49.9c with 95% confidence intervals.

(b)

(c)

FIGURE 49.5 Doppler speed measurement. Only part of the measurements are plotted for clear visualization. Time coordinates vary due to different reception times. (a) Location: Bayfront Park bay, Lavallette, NJ. (b) Doppler speeds measured at node 1. (c) Doppler speeds measured at node 2.

Scenario 1: As shown in Figures 49.6 and 49.7, our original solution “Proposed solution w/ EU” performs the best. In the typical current setting, “Proposed solution w/ EU” obtains about 74.6% less error than “Proposed solution w/o EU” while it obtains 80.4% less error in the extreme current setting. This is mainly due to the use of the external uncertainty model to predict the position and distribution of the AUVs and the ability to minimize the localization uncertainty. “Proposed solution w/o EU” ranks the second in terms of error performance because an AUV can leverage the ongoing communications and cooperation of other AUVs for localization. Even though CNA uses EKF to predict the positions, its

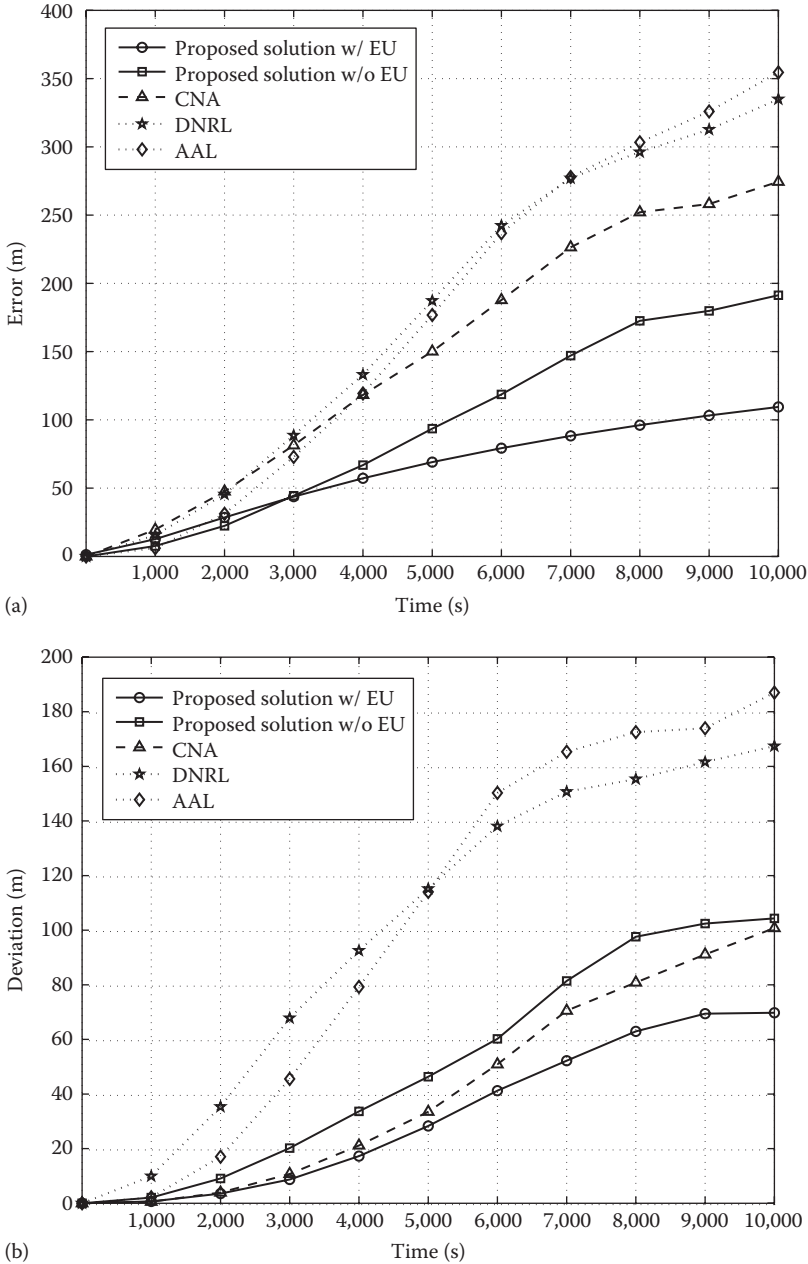

FIGURE 49.6 Scenario 1 with typical currents: under the ice mission with no resurfacing. (a) Localization error Comparison (6 AUVs). (b) Deviation Comparison (6 AUVs).

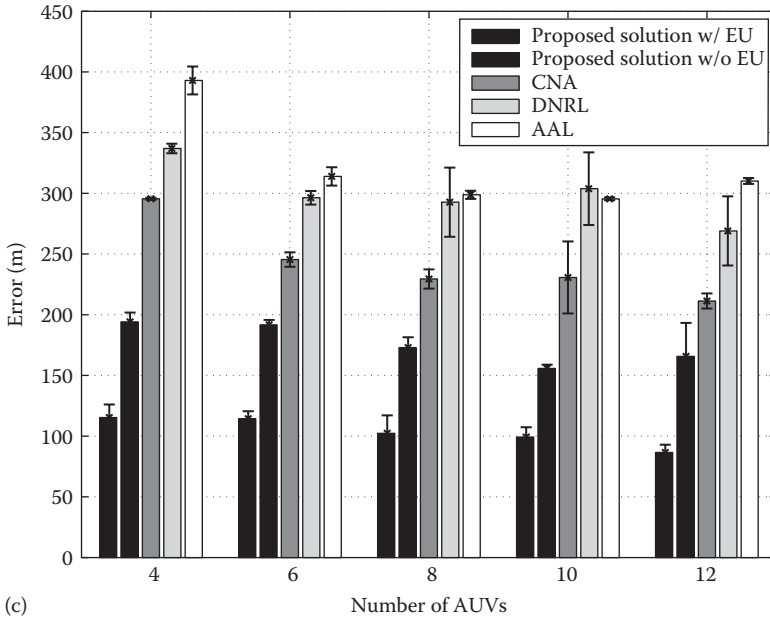

FIGURE 49.6 (continued) Scenario 1 with typical currents: under the ice mission with no resurfacing. (c) Localization error for number of AUVs.

(b)

(c)

FIGURE 49.7 Scenario 1 with extreme currents: under the ice mission with no resurfacing. (b) Deviation Comparison (6 AUVs). (c) Localization error for number of AUVs.

performance is worse than “Proposed solution w/o EU” since the AUV can only use its own states for position estimation. On the other hand, CNA is still better than DNRL and AAL due to the use of EKF filter, and DNRL performs better than AAL since it takes the current influence into account.

By comparing Figures 49.6 and 49.7, we can see that under extreme conditions, the localization error keeps increasing since more dislocation is incurred by the extreme currents. Interestingly enough, we can see that the performance of our solution without using external uncertainty is not much better than that using CNA. In this case, using Doppler information does not help improve the localization much

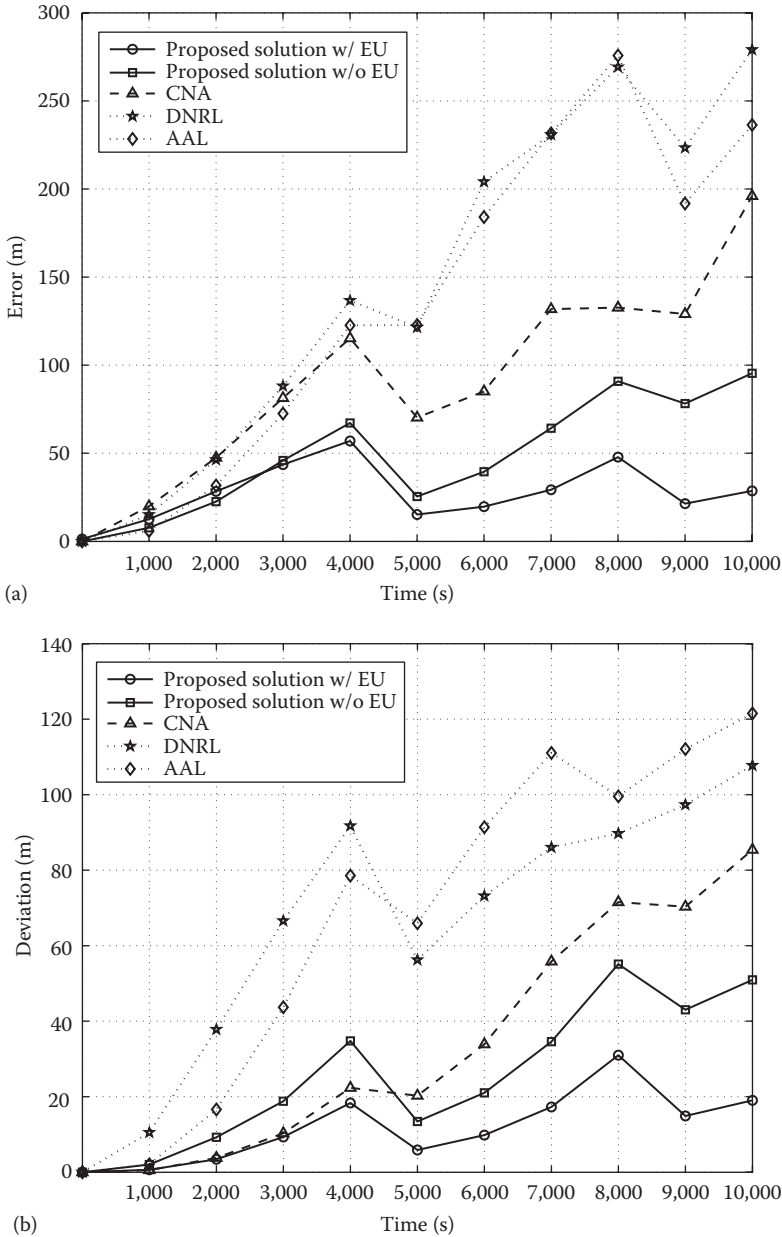

FIGURE 49.8 Scenario 2 with typical currents: under the ice mission with resurfacing. (a) Localization error Comparison (6 AUVs). (b) Deviation Comparison (6 AUVs).

(continued)

FIGURE 49.10 Comparison of communication overhead.

since the position uncertainties associated with other AUVs are also large and thus the performance is not too much better than that of using EKF. However, our solution using external uncertainty still performs the best due to the ability to estimate the position uncertainty and then use such information to minimize uncertainty.

Scenario 2: As shown in Figures 49.8 and 49.9, the performance ranking for these solutions closely resembles that in Scenario 1. However, the localization performance in Scenario 2 is much better than that in Scenario 1 since AUVs can obtain position correction periodically, as seen by comparing Figures 49.6 with 49.8 (or Figures 49.7 with 49.9). From these figures, we can see that localization error and deviation decrease when AUVs surface, that is, at 4000 s and 8000 s in the results. Moreover, we can see that for typical current settings in Scenario 2, the localization error and its deviation can stay within certain threshold for “Proposed Solution w/ EU,” while the error of other solutions tends to increase. This shows the effectiveness of our proposed solution in minimizing the localization uncertainty.

Communication overhead: Last, we compare the communication overhead of our solutions against other solutions. As shown in Figure 49.10, “Proposed solution w/o EU” achieves less overhead than CNA, DNRL, and AAL due to the ability to exploit the Doppler shifts of ongoing communications for localization, reducing the use of ranging packets. “Proposed solution w/ EU” has the biggest communication overhead in the beginning because of the need to broadcast external uncertainty information (such as pdf information). However, due to the ability to optimize the update intervals T_s and T_p as in Section 49.5.3, its communication overhead drops quickly to a level that is lower than CNA, DNRL, and AAL. CNA has higher overhead than DNRL and AAL as CNA needs to broadcast additional information such as velocities and sensor readings for EKF while DNRL and AAL only need to broadcast the position and time information that is embedded in the ranging packet. Note that in “Proposed solution w/ EU,” to save the overhead, when the AUVs broadcast the pdf information, they only broadcast the key parameters if the pdf is one of the well-known distributions (e.g., the average and standard deviation for a normal distribution). Otherwise, the point mass function of a finite number of points is broadcast.

49.7 Conclusion and Future Work

We proposed a localization solution that minimizes the position uncertainty and communication overhead of AUVs in the challenging under-ice environments. With the notion of external uncertainty, position uncertainties of the AUV can be modeled in a probabilistic way. This model is further used to estimate the uncertainty resulted from localization techniques, as shown for our proposed Doppler-based localization and the standard distance-based localization. Algorithms are then proposed to minimize the position uncertainty and communication overhead. Our solution is implemented and compared with several existing localization techniques using an acoustic communication emulator. It is shown that our approach achieves excellent localization results with low localization overhead.

Further work will be to implement our proposed localization solution on AUV platforms and evaluate its performance in ocean experiments. We are building our own AUV platform for performance evaluation of our solutions. Our proposed localization can be used as part of the adaptive sampling solution using AUVs to reconstruct the ocean temperature field. Specifically, given a field to sense, the AUVs should coordinate to take measurements with minimal cost such as time or energy in order to reconstruct the field with admissible error. To achieve this, we will propose a framework that jointly considers the online field measurements and multi-AUV trajectory planning. Novel distributed algorithms that can minimize the sampling cost for one-round sampling are proposed, and underwater communication protocols are designed to coordinate the vehicles. In this way, low sampling cost can be achieved while the computation complexity per vehicle can be reduced by using distributed algorithms.

Glossary

In this part, we give a brief introduction to the terms that are used.

Acoustic Transponders: Also called sonar transponders, which operate under water and are used to measure distance and form the basis of underwater location marking, position tracking and navigation.

Autonomous Underwater Vehicles: Programmable robots that, depending on their design, can drift, drive, or glide through the water without the real-time control by human operators. Generally, AUVs are equipped with onboard computers and sensors, which allow them to sense the underwater environment and collect the underwater data as they move through the water, and make decisions on their own. These AUVs, which are divided into two main classes—propeller-less/buoyancy-driven (e.g., gliders) and propeller-driven vehicles (PDVs)—rely on local intelligence with minimal onshore operator dependence.

Communication Overhead: Extra bits of data that does not contribute to the content of the message and that must be sent to convey information about, for example, where the information originated and where it is being sent to, how it is to be routed, time-stamps, or any other information that is not actually the “payload” representing the actual content to be communicated.

Dead Reckoning: The process of calculating the current position by using a previously determined position, and advancing that position based upon known or estimated speeds over elapsed time, and course. Dead reckoning is subject to cumulative errors as each position estimate is relative to the previous one. It is also affected by the accuracy of the velocity and direction estimation.

Deviation of Error: The amount the localization error deviating from the total averaged error. It measures the variation or dispersion of the position error is from the average.

- Doppler Velocity Log (DVL):** An acoustic device used to measure the speed of a vehicle over the seabed. It can serve as a fundamental component of dead-reckoning (DR) underwater navigation systems and aided-inertial navigation systems (INS). The measurement data comprise speed in three perpendicular directions, calculated from the Doppler shift of the acoustic signal returned from the seabed as the vehicle passes over. Altitude above the seabed is also calculated. Typically the DVL data are used to aid an integrated position calculation incorporating USBL, LBL, or inertial systems.
- End-to-end Network Latency (or Delay):** The time difference between a packet is sent from the source and the time it is received at the destination.
- Extended Kalman Filter (EKF):** The nonlinear version of the Kalman filter that is obtained using a linear approximation of the non-linear system based on the Taylor series expansion. In the case of well-defined transition models, the EKF has been proven to be a useful method of obtaining good estimates of the system state.
- External Uncertainty:** The position uncertainty associated with a particular entity/node as seen by others. External uncertainties may be derived from the broadcast/propagated internal-uncertainty estimates (e.g., using one-hop or multihop neighbor discovery mechanisms) and, hence, will be affected by e2e network latency and information loss. Information loss can be substantial and is attributed to packet losses caused by channel unreliability due to multipath, fading, and ambient noise.
- Inertial Navigation System (INS):** A self-contained navigation technique in which measurements provided by accelerometers and gyroscopes are used to track the position and orientation of an object relative to a known starting point, orientation and velocity. Inertial measurement units (IMUs) typically contain three orthogonal rate-gyroscopes and three orthogonal accelerometers, measuring angular velocity and linear acceleration respectively. By processing signals from these devices it is possible to track the position and orientation of a device. It is used in a wide range of applications such as the navigation of aircraft, missiles, spacecraft, submarines, and ships.
- Information Entropy:** A measure of the uncertainty associated with a random variable. It usually refers to the Shannon entropy (or continuous entropy), which quantifies the expected value of the information contained in a discrete random variable (or continuous random variable).
- Internal Uncertainty:** The position uncertainty associated with a particular entity/node (such as an AUV) as seen by itself. Many approaches such as those using Kalman filter (KF) have been used to estimate this uncertainty assuming that the variables to be estimated have linear relationships between each other and that noise is additive and Gaussian. When the linearity assumption does not hold, there is no guarantee of optimality and nonlinear filters such as the extended or unscented KF are used.
- Kalman Filter (KF):** An algorithm in control theory introduced by Kalman (1960). It operates recursively on streams of noisy input data to produce a statistically optimal estimate of the underlying linear (or nearly linear) system state.
- Localization Error:** The distance between the actual and the estimated AUV position. It measures the accuracy of the localization algorithm.
- Localization Overhead:** The communication overhead used for localization. This may include the positions of other nodes, the time-stamps to measure the round-trip time, or information about the time of arrival (ToA), time difference of arrival (TDoA), received-signal-strength (RSS), or angle of arrival (AoA) for distance measurement.
- Long Baseline (LBL):** One type of underwater acoustic positioning systems. It requires transponders deployed at fixed positions on the sea floor. Localization of a node is done by estimating the distances of this node to the transponders on the sea floor (i.e., acoustically measuring the round-trip time from this node to the transponders). The LBL technique can obtain very high positioning accuracy and position stability that is independent of water depth (generally better than 1-m or a few centimeters accuracy). It generally offer better accuracy than the short baseline systems.

- MultiPath Propagation:** The propagation phenomenon that results in signals (radio or acoustic) reaching the receiver by two or more paths. Causes of multipath include reflection and refraction, and reflection from boundaries.
- Propeller-Driven Vehicles (PDVs):** One class of AUVs that are driven by propeller(s). As the propulsion system consumes a lot of energy, the lifespan and operation coverage are limited due to the limited battery capacity. In general, PDVs have a life span ranging from several hours to a few days and can traverse distances of several hundred kilometers. The main benefit of using PDVs is that they can cover long distance in a short time (due to the high speed brought by the propulsion system). In addition, they generally have high maneuverability as the onboard computer can change the course or turn in time.
- Simultaneous Localization and Mapping (SLAM):** A technique used by robots and autonomous vehicles to update a map within a known environment (with a priori knowledge from a given map) while at the same time estimating their current location, or to build up a map within an unknown environment (without a priori knowledge).
- Short Baseline (SBL):** One of the major types of underwater acoustic positioning systems. In SBL systems, position estimate is determined by measuring the vehicle's distance from three or more transponders that are, for example, lowered over the side of the surface vessel. The positioning accuracy of SBL improves with transducer spacing. When deployed on larger vessels or a dock, the SBL system can achieve a precision and position robustness that is similar to that of the LBL systems, making the system suitable for high-accuracy survey work.
- Underwater Acoustic Sensor Networks:** Networks of underwater sensors and vehicles that that interact to collect data and perform tasks in a collaborative manner underwater. They are applied in a broad range of applications, including environmental monitoring, undersea exploration, disaster prevention, assisted navigation and tactical surveillance.
- Underwater Gliders:** Another class of AUVs that are not driven by propeller. For propulsion, they change their buoyancy in a small amount using a pump and rely on wings to convert vertical velocity into horizontal motion as they rise and fall through the ocean, forming a sawtooth trajectory. As a result, in contrast to PDVs, gliders spend very small amount of energy in propulsion and hence they can operate over long periods of time (weeks or months), even though they are not as fast as PDVs. They travel at a fairly constant horizontal speed, typically 0.25 m/s [1]. The impressive operation time and energy efficiency of these gliders make them a popular choice for oceanographic researchers.
- Underwater Localization:** The process to determine the 3D position of a sensor, network node, or vehicle underwater. Many localization schemes have been proposed, which can be categorized into range-based schemes and range-free schemes. Range-based schemes use different methods to estimate the distance between nodes and then determine the positions of the nodes. On the other hand, range-free schemes do not use range information to estimate positions of the nodes. Dead reckoning, for example, is such a scheme that relies on velocity measurement to estimate the position.

50.1 Introduction

The Semantic Web, as an interdisciplinary research field, arose out of the desire to enhance the World Wide Web in such a way that interoperability and integration of multiauthored, multithematic, and multiperspective information and services could be realized seamlessly and on-the-fly [8,14]. Thus, the Semantic Web is concerned with developing methods for information creation, annotation, retrieval, reuse, and integration. It draws from many disciplines, including knowledge representation and reasoning in artificial intelligence, databases, machine learning, natural language processing, software engineering, information visualization, and knowledge management [39,40].

Semantic (Web) technologies are under substantial investigation in many disciplines where information reuse and integration on the web promises significant added value, for example, in the life sciences, in geographic information science, digital humanities research, for data infrastructures and web services, as well as in web publishing. At the same time, semantic technologies are also being picked up to enhance solutions in application areas that are not primarily targeting the World Wide Web but have to access similar challenges, such as enterprise information integration, intelligence data analysis, and expert systems.

The Semantic Web spans from foundational disciplines to application areas. In terms of size and impact of its scientific community, amount of available project funding, and industrial impact, it has emerged as a major field within computer science during the last decade.

50.2 Underlying Principles

As the Semantic Web is driven by an application perspective, namely, to improve information retrieval beyond simple keyword search and foster semantic interoperability on the web, there is a wide variety of proposed and employed methods and principles which differ substantially and are under continuous discussion concerning their suitability for achieving the Semantic Web vision.

Nevertheless, some approaches have become well established and widely accepted. Probably the most commonly accepted principle is the idea of endowing information on the web with *metadata* that shall convey the meaning (or *semantics*) of the information by further describing (or *annotating*) it, and thus enable information retrieval, reuse, and integration. Shared schemas that formally specify the conceptualizations underlying a certain application area or information community are called *ontologies*. In the light of this approach, the development of suitable languages for representing ontologies has been, and still is, a key issue for Semantic Web research.

50.2.1 Languages for Representing Knowledge on the Web

Formal languages that support the representing of information semantics are commonly called *ontology languages*, and among the many proposals for such languages that can be found in the literature, those that have become recommended standards by the World Wide Web Consortium* (W3C) are of primary importance; namely, the *Resource Description Framework RDF* [31], the *web Ontology Language OWL* [22,32], and the *Rule Interchange Format RIF* [10,11]. Syntactically, they are based on XML [12], although their underlying data models are significantly different. During the last years other serializations have gained popularity, for example Notation3 [7] and Turtle [35] for representing RDF graphs. Historically, all ontology languages can be traced back to traditions in the field of knowledge representation and reasoning [23]. We briefly describe each of these languages in turn.

The **Resource Description Framework (RDF)** is essentially a language for representing *triples* of the form `subject predicate object`, where each of the entries is a uniform resource identifier (URI) for web resources. Predicates are usually also called *properties*. An object of one triple may be the subject of another triple and so forth. An example for such triples would be

```
ex:HoratioNelson ex:diedIn ex:BattleOfTrafalgar and
ex:BattleOfTrafalgar ex:during ex:NapoleonicWars
```

where `ex:` is a namespace identifier so that `ex:HoratioNelson` expands to a proper URI like `http://www.example.org/HoratioNelson`. The RDF specification furthermore includes pre-defined vocabulary, the meaning of which is defined by means of a *formal semantics*, described further later. The most important examples for this are `rdf:type`, `rdfs:subClassOf`, and `rdfs:subPropertyOf`, where `rdf`, respectively `rdfs`, are used as namespace identifiers for the pre-defined namespaces of RDF and RDF Schema, respectively. In fact, RDF Schema is part of the RDF specification, but has been given a separate name to indicate that it has additional expressive features, that is, a richer predefined vocabulary. The informal meaning of this vocabulary examples is as follows. A triple such as

```
ex:BattleOfTrafalgar rdf:type ex:NavalBattle
```

indicates that the individual event `ex:BattleOfTrafalgar` is an instance of the class `ex:NavalBattle` and is interpreted as set membership. A triple such as

```
ex:NavalBattle rdfs:subClassOf ex:Battle
```

* <http://www.w3.org/>

indicates that every instance of the class `ex:NavalBattle` is also an instance of the class `ex:Battle`. A triple such as

```
ex:diedIn rdfs:subPropertyOf ex:participatedIN
```

indicates that, whenever some a is in a `ex:diedIn`-relationship to some b (e.g., because a triple `ex:diedIn b` has been specified), then a and b are also in `ex:participatedIN`-relationship.

An RDF document now represents, essentially, a finite set of such triples. It is common practice to think of such a set as representing a finite labeled graph, where each triple gives rise to two vertices (subject and object) and an edge (the predicate). The labels of such subject–predicate–object triples are URIs. Note, however, that it is possible that a URI occurring as a predicate (i.e., an edge) also occurs as a subject or object (i.e., as a vertex) in a different triple. This means that edges can at the same time be vertices, thus breaking what would commonly be considered a graph structure. The W3C recommended standard SPARQL* [37] serves as a language for querying RDF triples that are often stored in a so-called *triplestore*. It is currently undergoing a revision [18], which is expected to make SPARQL also useful for the other ontology languages introduced later.

The **Web Ontology Language (OWL)** has been developed for representing knowledge, that is more complex than what can be represented in RDF. In particular, OWL provides predefined vocabulary to describe complex relationships between classes. For example, in OWL, we can specify that some class is the *union* (logically speaking, the disjunction) or the *intersection* (logically speaking, the conjunction) of two (or more) other classes. Class union and intersection are two examples of *class constructors* that OWL provides. Others also involve properties or even URIs that stand for *individuals* (which should be thought of as instances of classes), such that complex relationships like *Cape Trafalgar is a headland that witnessed at least one battle*, or *Every naval battle has (among other things) two or more involved parties, at least one location, a time span during which it took place, and a reason for engaging in it* can be expressed. Conceptually speaking, OWL is essentially a fragment of first-order predicate logic with equality and can be identified as a so-called *description logic* [6].

The OWL standard defines a number of variants that differ in sophistication and anticipated use cases. OWL EL, OWL QL, and OWL RL correspond to relatively small description logics for which reasoning algorithms (see Section 50.2.2) are relatively easy to implement. The larger OWL DL encompasses the former three and corresponds to a very expressive description logic called *SR_QIQ(D)*, while OWL Full is the most general variant and encompasses both OWL DL and RDF—but it is not a description logic, and usually attempts are made to remain within smaller fragments when modeling ontologies.

The **Rule Interchange Format (RIF)** follows a different paradigm than OWL by addressing knowledge modeling by means of rules as those used in logic programming, Datalog, and other rule-based paradigms. Its main purpose is to facilitate the interchange of rules between applications, but it also constitutes a family of knowledge representation languages in its own right. In particular, RIF-Core corresponds to Datalog, while RIF-BLD (from *Basic Logic Dialect*) corresponds to Horn logic (essentially, definite logic programs). Rule paradigms essentially cater for the expression of if-then type relationships such as *If two parties agree on a cease-fire, then a combat operation started by one of these parties constitutes a violation of the agreement*. Rules in the sense of RIF-Core or RIF-BLD also correspond to certain fragments of first-order predicate logic [24].

* “SPARQL” is a recursive acronym that stands for “SPARQL Protocol and RDF Query Language.”

50.2.2 Formal Semantics

Ontology languages can be understood as *vocabulary specification languages* in the sense that they can be used to define relationships of vocabulary terms related to a domain of interest. For example, they could be used to define a set of vocabulary terms describing spatial classes and relationships, such as *Headland*, *Coastal Landform*, *Erosion*, or *contributesTo*. Furthermore, terms can be associated via relations to each other, for example, in a taxonomy format: *Headland* is a subclass of *Coastal Landform*, which in turn is a subclass of *Landform*. More complicated relationships are also expressible, such as “every land form has at least one event that contributed to its creation,” which, for instance, relates the terms *Erosion* and *contributesTo* to *Headland*, without saying that there is only one erosion per headland or that erosions are the only kind of events that are in a *contributesTo* relation to headlands. Note how we exploit the fact that erosions are subclasses of events and headlands are landforms. The exact kinds of relationships that are expressible depend on the ontology language chosen for the representation. Such vocabulary definitions are often referred to as *terminological* or *schema knowledge*. In the context of OWL, a set of such definitions is often referred to as a *TBox*.

Ontology languages furthermore allow for the expression of *assertional* knowledge or *facts* (often called *ABox* statements in the context of OWL). This refers to statements involving instances of classes, such as “Cape Trafalgar is a headland” or “Nelson is a Person.”

Each of the W3C ontology languages presented in Section 50.2.1 comes endowed with a so-called *formal semantics*, which is described in model-theoretic terms borrowed from first-order predicate logic [19,34]. This formal semantics describes in mathematical terms how to draw valid *logical conclusions* from an ontology. For example, if *Headland* is specified as a subclass of *Coastal Landform*, and the ontology furthermore specifies that “every landform was shaped by at least one event,” then one such logical consequence would be that “every headland was shaped by at least one event.” While this example may seem obvious, in more complex cases it is often difficult to decide intuitively whether a statement is a logical consequence of an ontology. In these cases, the formal semantics serves as a *formal specification* for the valid logical consequences, and it is in this sense in which formal semantics provides a “meaning” to ontologies.

Logical consequences can be understood as knowledge that is *implicit* in an ontology. The formal semantics states that this implicit knowledge constitutes things that are *necessarily true*, given the ontology. As such, formal semantics enables *interoperability*, since it describes consequences which can be drawn from combining previously separated pieces of knowledge. Formal semantics can also be used in various ways when creating ontologies. For example, if an ontology engineer observes that her ontology has some logical consequences which seem to be undesirable from an application perspective, then this is an indication that parts of the ontology may have to be corrected or revised.

50.2.3 Key Issues in Realizing the Semantic Web Vision

A standard template to using ontology languages would thus be as follows. Entities are represented on the web using URIs, for example, *Battle of Trafalgar* could be represented by a URI such as <http://example.org/BattleOfTrafalgar> and the Napoleonic Wars by <http://example.org/NapoleonicWars>. Likewise, vocabulary elements are represented by URIs, such as <http://example.org/during> or <http://example.org/participatedIn>. In a background ontology, terminological information could then express, for example, that “during” is a transitive relation. Now consider, for example, the situation where metadata in a historical knowledge base is provided along with the human-readable content, which states that the Battle of Trafalgar took place during the

Napoleonic Wars, while another, more generic web portal lists facts about historic periods, including the fact that the Napoleonic Wars took place during the age of the Industrial Revolution. By collecting all this information, for example, using a Semantic Web crawler, this information could be combined, and due to the transitivity of “during” we would be able to also obtain the implicit knowledge, through logical deduction, that the Battle of Trafalgar took place during the Industrial Revolution. Even more, by adding semantics to the *participatesIn* relation discussed before, we could infer that Nelson lived during the Industrial Revolution.

The example just given indicates how Semantic Web technologies can in principle be used for information sharing, integration, and reuse across knowledge bases. However, in order to cast this idea into practical approaches, several obstacles need to be overcome. We list some of the most important ones:

- Different websites and knowledge bases may use different URIs for identifying entities on the Semantic Web. For information integration, we need to be able to identify these so-called *co-references*.
- Different websites may use different background ontologies. For information integration, these different ontologies need to be understood in relation to each other and formally related using suitable formats, preferably by using ontology languages or derivatives thereof. This issue is known as *ontology alignment*.
- Information on the web may be *semantically heterogeneous*. For example, on the instance level, different sources may specify other start and end dates for historical periods and, thus, may not agree whether the Napoleonic Wars also fall into the period known as Age of Enlightenment. On the schema level, the meaning assigned to terms such as *Headland*, *Erosion*, or *NavalBattle* may differ to a degree where they may become incompatible. Such issues are addressed by *semantic mediation and translation* research.
- Who is going to endow information on the web with metadata? Can we automate or partly automate this process using data mining or machine learning techniques? What are good interfaces and tools for developers and domain experts to support the creation of metadata?
- Algorithms for deducing logical consequences from ontologies are usually very dependent on input which constitutes ontologies of very high modeling quality. The creation of ontologies of such high quality can currently not be automated, and their creation usually requires experts in both ontology modeling and in the application domain under consideration. Consequently, their creation and maintenance can be very expensive. The creation of methods, workflows, and tools to support ontology modeling (and any other part of the ontology lifecycle) is, thus, of utmost importance for the development of the field and its applications.
- How can we deal with evolving information, for example, when data changes or is revised, or if vocabulary terms change their meaning over time? How can we deal with uncertainties or noise in metadata, which seem to be unavoidable in many realistic settings?

50.2.4 Linked Data

*Linking Data** [9] is a community effort that started in 2007 and is supported by the W3C. Its declared goal is to bootstrap a global graph of interlinked data called the *Web of Data* by converting existing datasets into the format of ontology languages, and interlinking them with meaningful relationships. Linked Data has been a key driver for research and development in the Semantic Web since its inception,

* <http://linkeddata.org/>

and has in particular created substantial interest in the industry and governments around the world. This Web of Data is currently growing rapidly. As of 2011, it had an estimated size of about 32 billion RDF triples, with contributions coming increasingly from industry and from public sector bodies such as governments and libraries.

In its current form, Linked Data contains mainly assertional knowledge expressed in RDF, and there are only very few light-weight guiding principles for its creation. Methods and tools for making use of Linked Data, and the question how to advance from Linked Data toward the more general Semantic Web vision, are among the most prominent current research questions. Similarly, ontologies that have been developed to annotate and interlink these datasets are often light-weight to a degree where they fail to restrict the interpretation of terms toward their intended meaning [25].

50.3 Impact on Practice

In order to assess the impact of the Semantic Web field in practice, it is important to realize that Semantic Web technologies can also be applied in contexts other than the World Wide Web. They likewise apply to (closed) intranets, but also to many other settings where information creation, retrieval, reuse, and integration are of importance. Typical examples include enterprise information integration and knowledge management systems. In many other cases, for example, search engines, ontologies, and Semantic Web technologies are used in the backend, and, while of major importance, are not visible to the end users.

Indeed, early adoption of Semantic Web technologies in nonweb areas can be traced back to at least the first years of the twenty-first century, when the first spin-off companies left the research realm and applied their methods to enable industrial applications. In the next few years, industry interest kept growing, but slowly, and at the same time other research disciplines that rely on information management and integration adopted Semantic Web technologies for their purposes. A leading role in this latter development was taken by the life sciences, in particular related to health care and bioinformatics.

Usage of Semantic Web technologies on the *web*, however, hardly happened in these years, apart from use-case studies and prototypes. One prominent exception was *Semantic MediaWiki** [30], a semantic enhancement of the MediaWiki software that underlies Wikipedia.† It was presented in 2006 and very quickly found substantial uptake with thousands of known installations worldwide. Indeed, efforts are currently under way to customize the extension for the use in Wikipedia.‡

Since 2007, and substantially driven by the advent of Linked Data, industrial uptake is rising significantly, both on and off the web. At the time of this writing,§ Semantic Web technologies have started to deeply penetrate information technologies and can be expected to become part of the mainstream arsenal for application developers in the near future. This adoption of Semantic Web technologies does not necessarily mean the use of the exact standards described in Section 50.2, but rather the adherence to the general principles of using machine-readable and understandable metadata for information sharing, retrieval, and integration.

Adoption in practice of Semantic Web technologies is, to date, often restricted to the use of simple metadata, and in particular the systematic use of formal semantics is currently only possible in particular application areas and settings, since stronger solutions for some of the key issues listed in Section 50.2.3 need to be developed first (see also Section 50.4).

* <http://semantic-mediawiki.org/>

† <http://www.wikipedia.org/>

‡ http://meta.wikimedia.org/wiki/New_Wikidata

§ August 2012.

In the following, we list some of the most visible recent achievements of Semantic Web technologies with respect to practical applications:

- The need for meta-modeling has recently been picked up by some of the most prominent companies on the web. Facebook’s Open Graph protocol* is a prominent example, as is schema.org,† a joint effort by Bing, Google, and Yahoo! for improving web search. RDF versions are endorsed by these companies, and the schema.org ontology is officially available in OWL/RDF.‡
- In February 2011, the Watson system by IBM [15] made international headlines for beating the best humans in the quiz show *Jeopardy!*.§ The performance is already being considered as a milestone in the development of artificial intelligence techniques related to general question answering. Semantic Web technologies have been one of the key ingredients in Watson’s design.¶
- A significant number of very prominent websites are powered by Semantic Web technologies, including the New York Times,** Thomson Reuters,†† BBC [36], and Google’s Freebase, as well as sites using technology such as Yahoo! SearchMonkey [33], or Drupal 7** [13].
- The speech interpretation and recognition interface *Siri* launched by Apple in 2011 as an intelligent personal assistant for the new generation of iPhone smartphones heavily draws from work on ontologies, knowledge representation, and reasoning [17].
- Oracle Database 11g supports OWL.§§
- Recently, The Wall Street Journal ran an article¶¶ announcing that Google is in the progress of enhancing its web search using Semantic Web technologies.
- The *International Classification of Diseases*, ICD, is the international standard manual for classifying diseases, endorsed by the World Health Organization and in use worldwide. It is currently revised, and ICD-11 (the 11th revision) is scheduled to appear in 2015. The revision is driven by a collaborative platform using OWL as underlying technology [41].
- Many governments and large companies now publish a plethora of governmental and other information as Linked Data, with England and the United States being early adopters.***

50.4 Research Issues

Currently, the Semantic Web field is mainly driven by developments regarding Linked Data (see Section 50.2.4). The amount of information available as Linked Data has shown exponential growth since its inception, and there are no indications that this will slow down soon. The Linked Data cloud indeed serves as an interlinked data source that is available in form of readily processable syntax (namely, RDF), and as such has the potential for widespread usage in data-intensive applications.

However, while it is certainly very helpful that Linked Data is available in RDF, there are very few general principles that would guide its creation.††† Consequently, Linked Data still suffers from many

*** See <http://www.data.gov/semantic> and <http://data.gov.uk/linked-data/>

††† This is, in principle, a good thing, and, in fact, is in line with the “bottom-up” nature of the World Wide Web itself.

heterogeneity challenges which the Semantic Web field has initially set out to overcome [25,27]. In reference to the issues identified in Section 50.2.3, we note that co-reference identification is still a central and unsolved issue, even for Linked Data [42]. Likewise, efficiently addressing semantic heterogeneity in Linked Data, for example, by means of ontology alignment, has only recently started to be studied [26], in particular for the difficult quest of providing question answering systems based on Linked Data [29]. The development of special techniques for dealing with evolving Linked Data is also in very early stages.

Thus, there currently is a significant disconnect between the factually deployed Linked Data on the web, and the already established research results regarding the use of Semantic Web technologies and ontology languages. It appears to be the foremost current research question, how to enable these strongly and formally semantic approaches for use on and with Linked Data. And this quest is inherently tied with the current lack of useful schema knowledge in Linked Data [25].

The question, how Linked Data can indeed be evolved into a Semantic Web in the stronger sense of the term, is indeed very controversially discussed. And while it is certainly also a question about good underlying conceptual principles, it is foremost also a question of practicability, of finding suitable next steps for development that can find significant adoption in practice.

To address the relative lack of schema knowledge in Linked Data, a foremost requirement is the availability of strong tool support that makes Semantic Web technologies more easily accessible for practitioners. This includes the automated, semi-automated, or manual generation of metadata, and ontologies, powerful ontology alignment systems, lifecycle support for metadata and ontologies such as versioning approaches and revision processes, and tools that enable an easier reuse of metadata and ontologies in applications for which they were not originally developed. In all these aspects, the research community has provided significant research advances which nevertheless remain to be further strengthened before they can find widespread adoption.

At the same time, a significant body of best practices guidelines need to be developed, which includes ontology creation and lifecycle aspects, but also methods and processes for making use of Semantic Web technologies. Of growing importance in this respect is the development of useful ontology design patterns for ontology modeling [16].

Eventually, in order to meet the goals of the Semantic Web vision, strongly semantic approaches—including ontology reasoning—will have to be embraced and brought to bear on realistic web data. In order for this to happen, researchers need to find clear answers on how to establish semantic interoperability without giving up on semantic heterogeneity [28], to scalability issues of reasoning algorithms, and to the question how to deal with metadata which arises from the strongly collaborative web without central control, that is, metadata which substantially varies in modeling quality [21,25].

50.5 Summary

The Semantic Web is an interdisciplinary research field that aims at augmenting the existing World Wide Web with machine-readable and understandable metadata such that information on the web becomes available for processing in intelligent systems. In particular, it shall establish solutions for seamless information creation, retrieval, reuse, and integration on the web.

The key underlying technology is the use of so-called ontology languages for representing metadata information. There exist several such languages endorsed by the World Wide Web Consortium. They support formal semantics that enables automated reasoning using deductive logical methods.

Industry is increasingly adopting Semantic Web technologies, and this also includes adoption for purposes other than for information on the World Wide Web. One of the driving recent developments is the publishing of significant amounts of data in ontology language formats on the World Wide Web—this information is referred to as Linked Data.

Despite its success, many core issues still require further in-depth, and partially foundational, research, such as the systematic use of deep semantics on the web by means of automated reasoning techniques.

Key Terms

- Annotation:** The attaching of metadata information to entities on the web, such as web pages, text, text snippets, words or terms, images, tables, etc. These annotations are usually not visible in normal web browsers, but can be retrieved from the source code of the web page for further processing. For example, a picture could bear the annotation “Barack Obama,” indicating that it is a picture of Barack Obama.
- Co-reference:** This occurs when two different identifiers are used for one real-world entity. The identification of co-references in ontological data on the Semantic Web is a challenging research problem. The term is borrowed from linguistics.
- Datalog:** A rule-based knowledge representation language based on function-free Horn logic. It is used in deductive databases.
- Description logics:** A family of closely related knowledge representation languages. Traditionally, they are strongly based on first-order predicate logic from which they inherit their open-world semantics. Description logics are usually decidable.
- Horn logic:** A fragment of first-order predicate logic that can be expressed in the form of rules. It is the basis for the logic programming paradigm, and thus also for the logic programming language Prolog.
- Linked Data:** Data on the World Wide Web that is represented using RDF, following a few simple principles. These datasets are strongly interlinked, thus forming a network of knowledge, often referred to as the *Web of Data*. If the data are available under an open license, it is called *Linked Open Data*, but often this distinction is not made in the literature. Linked Data is considered a major milestone in the development of the Semantic Web.
- Logic programming:** A knowledge representation and programming paradigm usually based on Horn logic with some modifications and extensions. In particular, it uses a closed-world paradigm. Prolog is the most widely known logic programming language.
- Metadata:** Data that provides information for other data, often through the process of annotation. Metadata can be of many different forms; in the simplest case it consists only of keywords (often called *tags*), but in a Semantic Web context metadata is usually expressed using some ontology language.
- Ontology:** A term borrowed from philosophy. In modern computer science, an ontology is a knowledge base that is expressed by describing relationships between concepts in a given domain of interest. The relationships are described using knowledge representation languages—then called ontology languages—which are usually derived from first-order predicate logic or from the logic programming paradigm.
- Ontology alignment:** The establishing of formal relationships between the concepts and other terms in two different ontologies. This can be done manually, but there is also a significant area of research that develops automated ontology alignment systems.
- Ontology design patterns:** Schemas for sets of concepts and relations occurring frequently in ontology modeling. They are typically expressed in some ontology language.
- Semantics:** Semantics, more precisely *formal semantics*, usually refers to the notion of model-theoretic semantics in first-order predicate logic, adapted for an ontology language. The main purpose of such a formal semantics is to define a notion of *logical consequence*. In this sense, a formal semantics is an implicit specification for all the logical consequences that can be derived from an ontology or a knowledge base.

URI: An abbreviation for *uniform resource identifier*. URIs are used to represent resources on the World Wide Web, for example, websites. It is not required that an entity identified by an URI can in fact be located or accessed on the World Wide Web.

Web of Data: See Linked Data.

World Wide Web Consortium W3C: The main international organization that develops standards for the World Wide Web.

XML: XML stands for *Extensible Markup Language*. It is a text-based format for the representation of hierarchically structured data. XML is ubiquitous on the World Wide Web, and often used for the interchange of data on the World Wide Web.

Further Information

Semantic Web as a field of research and applications is still under rapid development. Textbooks on the topic thus tend to be outdated rather quickly, unless they focus on fundamental issues that already find a broad consensus in the community. We recommend the following three books as thorough introductions: *Foundations of Semantic Web Technologies* [23] by Hitzler, Krötzsch, and Rudolph; *Semantic Web for the Working Ontologist* [1] by Allemang and Hendler; and *Semantic Web Programming* [20] by Hebel, Fisher, Blace, Perez-Lopez and Dean. The first mentioned book [23] focuses on foundations, in particular on a thorough treatment of the standardized ontology languages, including their formal semantics. The other two books [1,20] are written from a more practical perspective—they convey more hands-on knowledge, but are less comprehensive in the formal foundations. All three books are widely acclaimed as excellent introductions.

The Handbook on Ontologies [39] edited by Staab and Studer is a popular resource that introduces many aspects of Semantic Web technologies. The chapters are written by well-known experts in the field. The book is necessarily much less systematic and thorough than a textbook, but its coverage is much wider and includes many topics that are of central importance for the Semantic Web, but that have not been developed far enough yet to be included in a standard textbook.

Primary resources for state-of-the-art developments in the field are the major journals and conferences in the area. Many journals in computer science and adjacent fields in fact publish papers related to Semantic Web, but there are also some prominent ones that are dedicated exclusively to the field. These include the *Journal of Web Semantics*,* the *Semantic Web journal*,† and the *International Journal on Semantic Web and Information Systems*.‡ Major conferences in the area are the International Semantic Web Conference§ (see, e.g., [4,5]) and the Extended Semantic Web Conference¶ (see, e.g., [2,3]), which attract primarily researchers, and the Semantic Technology Conference** which targets industry. Many other major conferences also publish research papers in Semantic Web, for example, the comprehensive World Wide Web Conference†† (see, e.g., [38]).

51.1 Introduction

The existence of an abundance of dynamic and heterogeneous information on the web has offered many new opportunities for users to advance their knowledge discovery. As the amount of information on the web has increased substantially in the past decade, it is difficult for users to find information through a simple sequential inspection of web pages or recall previously accessed URLs. Consequently, the service from a search engine becomes indispensable for users to navigate around the web in an effective manner.

General web search engines provide the most popular way of identifying relevant information on the web by taking a horizontal and exhaustive view of the world. Vertical search engines focus on specific segments of content and offer great benefits for finding information on selected topics. Search engine technology incorporates interdisciplinary concepts and techniques from multiple fields in computer science, which include computer systems, information retrieval, machine learning, and computer linguistics. Understanding the computational basis of these technologies is important as search engine technologies have changed the way our society seeks out and interacts with information.

This chapter gives an overview of search techniques to find information on the web relevant to a user query. It describes how billions of web pages are crawled, processed, and ranked, and our experiences in building Ask.com's search engine with over 100 million North American users. Section 51.2

is an overview of search engine components and historical perspective of search engine development. Section 51.3 describes crawling and off-line processing techniques. Section 51.4 describes the online architecture and query-processing techniques. Section 51.5 explains ranking signals and algorithms. Section 51.6 discusses the metrics for evaluating a search engine. Finally, Section 51.7 concludes this chapter.

51.2 Search Engine Components and Historical Perspective

In general, a search engine consists of three main components as shown in Figure 51.1: a crawler, an off-line processing system to accumulate data and produce searchable index, and an online engine for real-time query handling. Their roles are summarized as follows:

- *Crawling and data acquisition.* A crawler discovers and adds the content of the web to the search engine’s data repository. Type of content gathered includes text pages, images, videos, and other types of content. Most crawlers find information by beginning at one page and then follow the outgoing URL links on that page. Therefore, if a page is not linked to from another page, this page may never be found by a search engine. In some cases, a search engine may acquire content through private data feeds from other companies. All of the information that a web crawler retrieves is stored in a data repository, which provides a foundation to build an online index searchable by users.
- *The data repository and off-line processing.* Some search engines have extremely large databases with billions of pages while others have comparatively smaller ones. A search engine may aggregate results from its own database and from other search engines hosted in different locations to expand the database coverage. Off-line processing mainly takes a collection of pages and builds appropriate data structure for search. The off-line system also performs duplicate and spam detection and conducts additional data analysis to identify properties of a page as ranking signals.
- *Online search engine and ranking.* A search engine runs as a web service to answer queries from users. The query-processing system uses the index to find relevant documents and rank them. It generates a result page that contains top-ranked documents and serves this page to a user. As users interact with the search results, a search engine logs their browsing behavior and leverages such data for improving search quality.

Information retrieval researchers have studied document search for many years [1] before web search became popular in the early 1990s. An earlier system for locating Internet content was Gopher, used for file name lookup. One of the first “full-text” crawler-based search engines was WebCrawler, which came out in 1994. As the World Wide Web became popular, a number of search engines and portals offered search services, including AltaVista, Excite, Infoseek, Lycos, Inktomi, Northern Light, Yahoo!, and AOL.

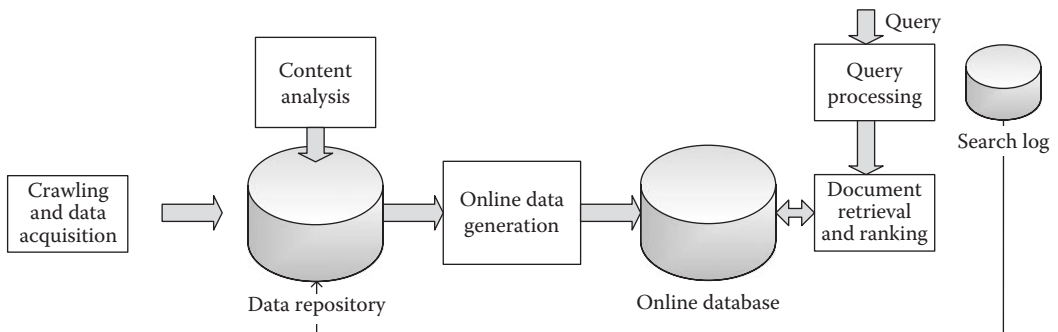

FIGURE 51.1 Components of web search.

In earlier 1999, Google's search engine started to gain popularity with its new link-based ranking paradigm and a simple user interface. In 2002 and 2003, Yahoo! acquired Inktomi search and Overture, which owned AltaVista and All the Web, building its own search technology. Ask.com (formally called Ask Jeeves) acquired Teoma search in 2001 for providing search and question answering. Microsoft initially used search results from Inktomi and has gradually built its own engine: MSN search, Windows Live Search, Live Search, and Bing.

In Europe, Fast search was launched in 1999 to compete with Google and was acquired partially by Overture in 2003 and partially by Microsoft in 2007. In China, Baidu was started in 1999 and has become a dominating search engine. In Russia, Yandex search launched in 1998 and is currently dominating, while in South Korea, Naver is a popular search engine launched in 2000.

Technology behind the major search engines has been seldom published because of fierce competition while some of their techniques have gradually appeared in patents and academic conferences. Academic conferences that cover more on search algorithms and data analysis include SIGIR, WWW, WSDM, and ECIR. Other related conferences for web data analysis include KDD, CIKM, SIGMOD, and VLDB. The system technology covering large-scale Internet systems and data platforms has appeared in various system conferences such as OSDI. Search engines have a major traffic impact to websites, and the search industry activity is closely watched by webmasters and various organizations including searchenginewatch.com. Recent textbooks that describe search algorithms and mining techniques can be found in [2–5].

There exist a number of open-source search engines and related data-processing tools available for search engine research and applications. The Apache Lucene/Solr package [6] is a Java-based search engine in which Lucene provides data indexing and full-text search capability while Solr provides a search user interface built on top of Lucene with additional support such as caching and replication management. Lemur [7] and Xapian [8] are open-source search engines with C++. Various open-source codes are available for underlying system support. Hadoop's MapReduce [9] is a popular clustering package for parallel processing of off-line data. Apache HBase [10] and Cassandra [11] provide the key-value data store support for accessing large datasets.

51.3 Crawling and Data Processing

51.3.1 Crawling

A web crawler is part of the search engine to gather data from the Internet; it can recognize and collect HTML pages and other types of documents including PDF, PowerPoint, Word, and Excel. It extracts text information from these documents through conversion software so that corresponding text information is indexable and searchable. Figure 51.2a illustrates the architecture of a large-scale crawler we have developed in the past for discovering and downloading billions of web pages:

- The URL downloader fetches web pages following the hypertext transfer protocol (HTTP) protocol. Typically, a crawler uses a thread to handle an HTTP connection and maintains many concurrent threads to saturate the available download bandwidth. Since there can be a high latency in downloading a page from a site, a crawler machine can have a large number of HTTP requests outstanding. That increases system resource requirement as each machine needs to maintain information on all open connections.
- A DNS server resolves the IP address of URLs. Since there is a massive amount of DNS lookup of URL hosts, extra caching support can be useful.
- The URL extraction module parses downloaded pages and identifies the outgoing links. It may filter some of those URLs identified as low quality or duplicates. After filtering, it adds the extracted outgoing URLs to a URL queue. Since a crawler typically runs its service on a cluster of machines, extracted URLs from one machine may be distributed to URL queues in multiple machines as illustrated in Figure 51.2b.

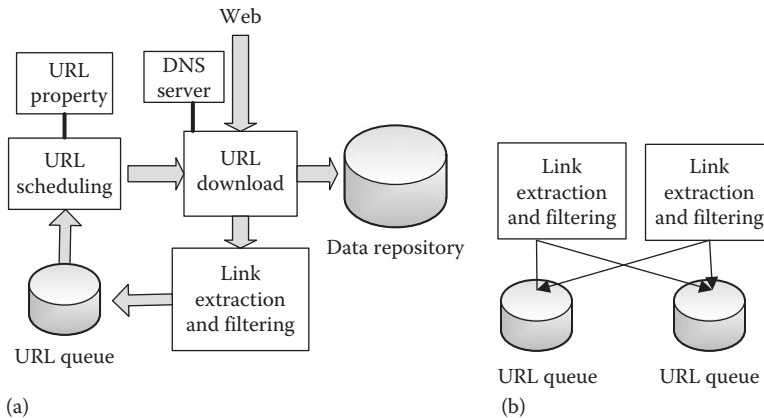

FIGURE 51.2 (a) Architecture of a web crawler. (b) Collaborative outgoing link extraction and URL distribution.

- The URL scheduling decides which URLs are to be visited in the next round of crawling. Given that websites have variable sizes, small sites can be crawled quickly while it takes a long time to visit a large site. A URL scheduler periodically analyzes the properties of the queued URLs, prioritizes them, and selects a subset of URLs to the URL download process, to accomplish the following goals: (1) large sites are crawled completely; (2) URLs are recrawled frequently to ensure freshness; (3) revisiting for recently crawled URLs are excluded to avoid the endless revisit of the same URLs; and (4) low-quality or duplicate pages are not crawled or crawled with a low priority.
- The URL property service maintains properties of URLs. There is a resource contention to accomplish these goals in parallel, and the URL scheduler uses properties of URLs such as the last successful crawling time and unsuccessful data fetch attempts to make a sound decision. Since there is a large number of data accesses in parallel at each second on each crawling machine and there are a large number of URLs to be crawled, accessing URL property information can become a crawling bottleneck. The design of an efficient data structure and crawler architecture is therefore crucial.

There are a number of factors that further complicate crawler management:

- *Politeness.* A website often hosts a large number of pages. To fetch these pages quickly, a crawler can occupy a significant amount of computing and bandwidth resource from this site, and this can affect the normal operation of such a site. To mitigate the negative impact on the site's resources, a crawler must follow a politeness policy to limit its crawl rate. For instance, a crawler may not make more than one request to the same host at the same time, and possibly it should add a time delay between two consecutive requests to the same host.
- *Robots exclusion protocol.* A web administrator can exclude their pages from the index of a search engine by providing the `/robots.txt` file in the top directory of the website. This file specifies the visit restriction for a search engine's crawler [12]. For example, a line with text `"Disallow: /tmp/"` in `example.com/robots.txt` means that visiting `example.com/tmp` is not allowed. When fetching a page from a site, a crawler must check the `robots.txt` from the corresponding web host. To avoid repeated access of the `robot.txt` file from the same host, a crawler may save a copy of such a file in its local cache system with a periodical update.
- *Crawling abnormality.* Some sites respond to a crawler's request slowly or even fail to respond. Some sites may return wrong or broken results to a crawler. A crawler needs to be resilient to the failure or slowness of a website and be able to retry at a later time.

Another type of crawling abnormality is called *crawling traps*. In this case, a website keeps a crawler busy by dynamically feeding an infinite number of useless web pages. For example,

there can be an infinite number of calendar pages generated dynamically and accessible through “next day” button in a site. Such a trap can be detectable by site-oriented similar content analysis.

- *Hidden web and sitemap.* Crawlers from major search engines can effectively collect surface-level web pages, but there is a vast amount of hidden deep web information invisible to search engines. Any page that is not explicitly pointed by other web pages cannot be found by a crawler through hyperlink analysis. Dynamically generated pages that require HTML-form or Javascript submission are often invisible. Automatic form filling can explore deep web [13], and there is still a challenge to reach high accuracy or coverage. An alternative method is to use the sitemaps protocol [14], which enables webmasters to inform search engines about a list of pages that are available for crawling from their sites. A sitemap is an XML file that lists URLs for a site along with additional metadata about each URL. Thus, webmasters can advertise deep URLs, which are not even hyperlinked from the surface web.

The freshness and content coverage of a data collection crawled are important for the quality of a search engine. The challenge a crawler faces is to discover newly created or updated pages on the web quickly. For known URLs, a crawler can revisit them frequently to detect if their content has been changed. The historical change frequency of a page and its site can guide how often a crawler should revisit this page. While crawling sites frequently can discover new pages, leveraging information published by a site such as RSS feeds can speed up this discovery process. An RSS feed is an XML-based file that provides a structured list of new pages added to a site. The RSS feeds are commonly associated with blogs and other information publishers. For example, CNN provides news RSS feeds under different categories. Amazon publishes RSS feeds on popular products with tags. There are additional signals that can be mined from the web to facilitate the discovery of new URLs, especially for hot or new topics. This includes the detection of new URLs that appear in news, blogs, search logs, and social network sites.

Earlier work that addresses parallel crawling and freshness appears in [15,16]. The order of crawling to fetch important pages under resource constraints was studied in [17]. A research crawler and related techniques were discussed in [18]. Focused crawling was addressed in [19] with content classification. A survey of crawling techniques appears in [20].

51.3.2 Off-Line Data Processing and Content Management

Off-line data processing for a search engine collects and parses web documents to produce a searchable index. The additional information collected in online database generation includes ranking features extracted from page links, anchor text, and user query log data. Content management organizes an online index with classification and partitioning; it also guides the crawling system to discover and refresh web documents. Some search engines have large databases with tens of billions of documents while others have comparatively smaller ones with a few hundred millions of pages, designed to handle a certain type of queries.

51.3.2.1 Document Parsing and Index Compression

Document parsing breaks apart the components of a document to form indexable tokens. Tokenization is straightforward for English documents while it is challenging for documents of other languages such as Chinese, Japanese, or Arabic. In those languages, words are not clearly delineated by white space. Natural language processing techniques can identify boundary of words with a good accuracy. A parser also detects the language of a document and its format because documents do not always clearly or accurately identify their language. Since documents do not always obey the desired format or syntax, a parser has to tolerate syntax errors as much as possible.

In tokenizing a document, there is an option to stem words and remove stop words. Stemming is the process for reducing inflected words to their base form. For example, a stemming algorithm [21,22] reduces the words “fishing,” “fished,” “fish,” and “fisher” to their root word “fish.” Stemming can produce

an improvement in ranking by matching more relevant documents while it can sometime cause a relevance issue. For example, people search for “fishing” will be less interested in types of “fish.” Thus, stemming has to be applied conservatively, and one example is to restrict stemming and only derive plural forms for a selected set of keywords. Stemming is a language-specific technique, and some languages such as Chinese have no or little word variations while stemming for languages such as Arabic and Hebrew is more complex and difficult. Stop words are those words that contribute little on the topic of a document. The examples of stop words in English include “the” and “who.” Removing stop words explicitly from an index can impact search relevance because a stop word may carry a meaning in some cases. For example, “the who” is an English rock band. Typically a search engine indexes every word while incorporating removal of some stop words during query-time processing when appropriate.

Given a set of tokens (or called *terms*), a search engine normally represents a searchable database using a data structure called *the inverted index*, and a survey of inverted indexing can be found in [23]. An inverted index consists of a list of terms in the vocabulary of the data collection. For each term, the inverted index maintains a list of documents that contain such a term. This list of documents is often called a *posting* of the corresponding term.

For example, given two documents $d_1 = \{a, b, c, a\}$ and $d_2 = \{c, e, c\}$, the inverted index is

$$a \rightarrow \{d_1\}, b \rightarrow \{d_1\}, c \rightarrow \{d_1, d_2\}, e \rightarrow \{d_2\}$$

In addition to document identifications, a posting can store other information such as frequency of a term and positions of this term in each document. For example, the previous inverted index can be augmented as

$$a \rightarrow \{d_1, 2, (1, 4)\}, b \rightarrow \{d_1, 1, (1)\}, c \rightarrow \{d_1, 1, (3), d_2, 2, (1, 3)\}, e \rightarrow \{d_2, 1, (1)\}$$

The meaning of the posting for term “a” is interpreted as follows. This term appears in document d_1 with frequency 2 at positions 1 and 4.

The inverted index for a large web dataset takes a huge amount of space, and compression of the index data is necessary to enhance engine’s online performance and reduce hosting cost [24,25]. Typically document identifications in a posting are stored in an increasing order, and term positions of each document are also arranged in an increasing order. To compress a sequence of these numbers in a posting, a transformation called *delta encoding* is applied first to represent these numbers using their difference gap. For example, given a list $\{23, 40, 104, 108, 200\}$, this list can be reformulated as $\{23, 17, 64, 4, 92\}$. The first number of this list is not changed. The second number is the gap between the second number and the first number. The average number in the reformulated list is much smaller than that in the original list. This motivation for using delta encoding is that compressing small numbers is easier.

The next step of compression is to represent these gaps using an encoding method. A bit-aligned encoding method is called *Elias- γ* [26], which encodes each number G using a pair of two numbers (b, r) . They satisfy $G = 2^b + r$ and $r = G \bmod 2^b$. Next, we discuss how to store the pair (b, r) . The first number is stored as a unary code with b digits of 1s. The second number is stored as a standard binary number with b bits. Bit “0” is inserted to separate these two numbers. For instance, $17 = 2^4 + 1$; the γ code for 17 is 111100001. The leading 4 digits are all 1s, representing 2^4 . Offset 0001 is found after the first 0 is encountered. In general, for each number G , this method costs $2 \log G + 1$ bits to encode. Thus, γ encoding is only attractive to compress small numbers. To improve the effectiveness in compressing a larger number, the concept of δ encoding can be applied recursively to the first component b in the previous expression. Namely, $G = 2^{2^b + \delta} + r$. This method is called *Elias- δ* method, which costs approximately $2 \log \log G + \log G$ bits for each number G .

A bit-oriented encoding method has its weakness in performance because computer operations are relatively more efficient toward byte-oriented programs. A simple byte-aligned method is called

v-byte [27] that uses one byte to represent G if $G < 128$ and two bytes or more bytes for a bigger number. Seven bits of each byte store the content of G while 1 bit of such a byte indicates whether this byte is the last byte or not for the corresponding number. A comparison of compression algorithms can be found in [28,29].

51.3.3 Content Management

Content management plays the following roles in off-line data processing:

- Organize the vast amount of pages crawled to facilitate online search. For example, the online database is typically divided into content groups based on language and country. For each content group, there is a further division of content by tiers based on quality. Such a division also affects the crawling decision to prioritize on crawling targets and frequency.
- Perform in-depth analysis for better understanding of information represented in a document. Examples of such analysis are recognizing document title, section titles, and highlighted words that capture the meaning of a document with different weights; identifying the structure of a page and recognizing site menus, which do not contain primary material; and interpreting Javascript embedded in a page to capture the true content of the page.
- Collect additional content and ranking signals. While on-page text features are important for a search engine, critical ranking information can also be gathered from other sources. For example, user search log provides a feedback on how users interact with search results given their queries. There is a variety of special information available on the web, for instance, movie titles and show schedule. Such information can be organized for answering a class of queries or vertical search. For example, Ask.com has built a large database containing question–answer pairs extracted from the web and used this index for matching and answering live question queries.

An online database is often divided into multiple tiers and multiple partitions. One reason is that the capacity constraint of a data center often restricts the size of a database index that can be hosted. Another reason is the requirement for geographical data distribution. Commonly accessed content hosted close to users' location in a targeted market can reduce the engine's response time. In a multi-tier online database, the first tier usually contains frequently visited content of good quality. Even though there are tens of billions of pages available on the web, a query from a vast majority of users can be answered by using a small percentage of these pages. The lower tiers of an online database contain pages that are less likely to be used to answer queries. To partition content, one can exploit characteristics of pages such as reputation and the historical visit frequency.

Anti-spamming is an important task of content management to detect pages with malicious attempts to influence the outcome of ranking algorithms. For example, some websites present different content to a search engine's crawler compared to what is presented to users' web browsers. These websites differentiate a crawler with a web browser based on the IP addresses or the user–agent header of the HTTP request. This spamming technique, called *web cloaking*, is often used by low-quality sites to deceive search engines. Other spamming tactics include link farms, invisible text with stuffed keywords, and exploitation through user-generated contention such as blogs. Automatic or semiautomatic techniques can be employed to identify spamming pages by examining content features, user browsing patterns, and hyperlink structure.

Search content management has adopted various classification techniques based on document features. The supervised learning techniques [30] fit well for this purpose using a set of labeled data to train a classifier that can label future cases. The examples of automatic or semiautomatic classification tasks include language categorization (e.g., English vs. German), country classification (e.g., United States, United Kingdom, and Canada), and spam detection. Another use of classification is to aid online result ranking for intent matching or result diversification. Page segmentation was conducted in [31] to detect semantic content structure in a web page. While text features represent the important characteristics

of a web page, link structure among pages and feedback from a search log dataset also provide critical information in making classification decisions. Surveys of web page classification and text categorization appear in [32,33]. A survey of related techniques can be found in [34].

51.3.3.1 Duplicate Elimination

A large number of pages crawled from the web have near-identical content. For example, several studies [35,36] indicate that there are over 30% of near duplicates in crawled pages. Search services need to return the most relevant answers to a query, and presenting identical or near-identical results leads to bad user experience. By removing duplicates, search result presentation would be more compact and save users' time to browse results. Near duplicate detection can also assist low-quality page removal. For example, by identifying a set of spam pages with certain patterns, other pages that are similar to these pages are the candidates for being classified as spam pages.

There are two types of duplicates among web pages. The first type of duplicates is caused by page redirection when one web page redirects to another, either through permanent or temporary HTTP redirect. Although the source and destination of redirection have identical contents, the crawler may visit them at different times and download different versions. Our experience is that up to 10% of duplicates in a large-scale database can be redirection-based. The second type is content-based when two web pages have near-identical information. This is measured by the percentage of content overlapping between the two pages. A popular way to model content similarity of two documents is to represent each document using shingles [37]. Let each document contain a sequence of terms, and each k -gram shingle contains k consecutive terms in this document. For example, let $D = \{a, b, c, e, f, g\}$, and its 2-gram shingle set is $D^2 = \{ab, bc, ce, ef, fg\}$. Let A^k and B^k denote a set of k -gram shingle signatures derived from pages A and B , respectively. The Jaccard similarity of these two documents is

$$Sim(A, B) = \frac{|A^k \cap B^k|}{|A^k \cup B^k|}.$$

An English web page on average has a few hundreds of words, and computing the Jaccard similarity of web pages is expensive when computation is conducted for every pair. The MinHash technique can be used to speed up with an approximation. The MinHash value with respect to a random permutation function R is

$$MinHash(A^k) = \min_{x \in A^k} (R(x)).$$

It has been shown that $Sim(A, B)$ value is the same as the probability that $MinHash(A^k) = MinHash(B^k)$. Thus, $Sim(A, B)$ can be approximated by using n random permutation functions and by computing the overlapping percentage of the corresponding n MinHash values.

In general duplicate removal can be conducted during online query processing or in an off-line processing stage. Removing redundant content in an off-line system requires a very high precision in duplicate judgment. Fast approximation algorithms [37–43] are often not sufficient to simultaneously deliver high precision and high recall. A combination of these algorithms with additional features can improve precision (e.g., [44]). As a result, processing cost increases. Major search engine companies have often taken a compromised approach: while a relatively small percentage of duplicates can be removed conservatively in the off-line process, a large portion of duplicates are kept in a live online database. During online query processing, duplicates are detected among top results matching a query, and only one result from duplicate pages is shown in the final search results. Such an approach simplifies off-line processing but increases the cost of online serving. To develop cost-conscious search applications, duplicates need to be removed in an off-line stage as much as possible [45].

51.3.3.2 Distributed and Incremental Index Update

It is time consuming to process a large web data collection; this affects its freshness because data is continuously updated. Parallel processing using MapReduce [46] or other programming platforms can be used. Handling a large database from scratch still takes too much time, even in parallel on a large computer cluster. It is more effective to perform incremental update of the online database.

Figure 51.3 illustrates the architecture of a large-scale off-line system we have developed in the past for incremental processing of billions of web pages. The key service modules of this system include page repository, update manager, URL property, online content controller, indexer, link manager, and content analysis subsystem. Each of them is running on a cluster of machines:

- Once a set of crawled pages is received, the update manager consults with a URL property service and runs a quick classifier to determine whether these pages are new or have significant content update. If appropriate, these new or updated pages are routed to the online database controller, link manager, and content analysis manager for further data update.
- The online content controller manages the online partition structure. It decides when a new partition should be added to the online service and notifies that some URLs in the existing online partitions are stale.
- The indexer module fetches pages of the desired partition to construct an inverted index; it creates a partition to include new or updated URLs. Noted that the same URLs in the existing partitions will be marked as stale.
- The link manager maintains hyperlinks among web pages and summarizes anchor text from incoming links to a document. The content analysis subsystem detects duplicates incrementally, and it conducts classification and other mining tasks.

Various underlying system support is incorporated for implementing the previous pipeline. That includes a middleware for managing continuously running services on a large cluster of machines, key-value stores with fast disk I/O [47] for page repository, high-throughput property services with a distributed hash table [48], and distributed message queuing for inter-component coordination.

The previous approach for incremental index has an advantage that online data management is simplified: the modification to the existing partitions only needs to mark staleness when pages are updated. The online content controller makes a decision to remove an online partition when it contains too many stale URLs. Another approach for incremental index update is to merge the old index with new index [49]. The search system support for notification-based data updating is discussed in [50].

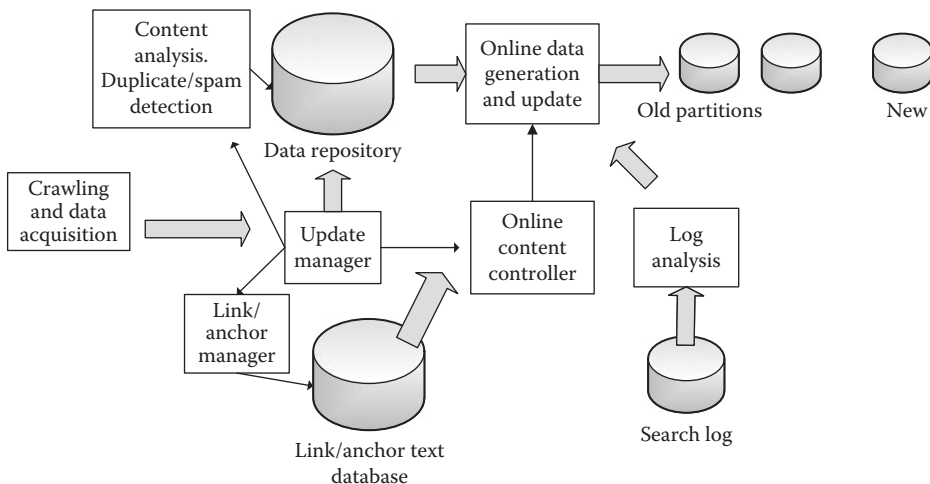

FIGURE 51.3 Architecture of an off-line data-processing system with incremental update.

51.4 Query Processing and Online Architecture

An online system of a search engine typically contains the following components:

1. *Query processing.* This step classifies a query and rewrites it for better matching of relevant results.
2. *Document retrieval.* That is to search the inverted index distributed in a cluster of machines and to collect relevant results.
3. *Result ranking.* Given a large number of matched relevant results, this step filters out low-quality results and ranks top results.
4. *Snippet generation.* This step provides a description for each URL to be shown in a search engine results page (SERP).
5. *Result aggregation and displaying.* Search results may be aggregated from multiple databases including the advertisement engine; this step merges these results and organizes them in a SERP.

51.4.1 Query Processing with Classification

Query processing classifies a query and rewrites it if needed with the goal of closely matching the searcher's intent. Examples of query classification include detecting query language and user location and identify whether this query demands time-sensitive results or entity-oriented information such as a person, an organization, a movie, or a commercial product. The classification of a query helps the search engine to prioritize certain types of results in the final ranking, and it can also gives an indication if highly relevant results from some vertical channels should be included. For example, a query "white house" can trigger the inclusion of news, map, and image search results.

Common query rewriting operations involve stop word elimination, case folding, and spell correction. Stop word elimination detects the use of some popular terms, which may not be able to effectively reflect the intention of a user. For example, terms "the" and "of" may be removed from query "the address of white house." Spell handling involves the examination of popular spell errors to suggest a correction. Case folding commonly used in web search engines does not differentiate cases. Case-insensitive search is more acceptable to users as it includes more relevant results to match users' queries without differentiating cases.

The query rewriting process may be explicit or implicit to users, which can be categorized into the following three situations:

- *Suggestion without query rewriting.* A search engine may not change query terms but recommend a suggestion for correction. That is especially useful when the engine is not certain if the suggested correction is necessary for most of users.
- *Explicit alteration.* For certain queries, the search engine may automatically alter user queries while informing users the correction incorporated.
- *Implicit alternation.* For many queries, a search engine may automatically rewrite without informing users. It may incorporate multiple rewrites and aggregate results based on an internal ranking method. For example, the results for query "NJ tax return" may be supplemented with some additional results from "new jersey tax return." Rewriting has to be conservative based on query context. For instance, while the short form of state "Virginia" is VA, "VA" can also stand for "US Department of Veterans Affairs."

51.4.2 Page Partitioning and Retrieval

The index data of a search engine are typically partitioned and distributed in many machines at one or possibly multiple data centers. There are two ways to distribute data to multiple machines—term-based or document-based:

- Document-based partitioning divides the index data among machines based on document identifications. Each machine contains the inverted index only related to documents hosted in this machine. During query processing, a search query is directed to all machines that host subsets of the data.

- Term-based partitioning divides the index based on terms and assigns postings of selected terms to each machine. This approach fits well for single-word queries, but it requires inter-machine result intersection for multi-word queries.

Document-based partitioning has several advantages. (1) It simplifies the database update process. When documents have a change of their content, only few machines that host these documents are affected. (2) It allows for good load balancing as the term distribution is more skewed. (3) It is more resilient to faults compared to term partitioning. If some machines fail, only the index of documents on these failed machines becomes unavailable, and the search engine may still be able to serve relevant results from other machines. For term-based partitioning, the failure of one machine could lead to more noticeable errors for certain queries, which contain terms hosted in the failed machines. The disadvantage of document-based distribution is that all machines need to participate in query answering. Thus, the serving cost per query is more expensive. A combination of document- and term-based partitioning would be an option to exploit in hosting a large index database.

After the initial query processing, a search engine accesses the index following the semantics of a query. By default, query terms are considered to be conjunctive. Namely, a document is considered to be a match if and only if it contains all query terms. In a disjunctive mode, a document is considered to be a match if only one query term presents in the document. While a search engine often provides an advanced search feature that supports a combination of conjunctive and disjunctive search, the common usage of user queries follows a conjunctive format due to its simplicity.

Since the index is distributed to machines using document- or term-based partitioning, each of these machines returns a set of documents fully or partially matching the processed query; therefore, additional processing is needed. For example, for the query “Britney Spears,” the posting of term “Britney” is intersected with the posting of term “Spears.” If two postings are hosted in different machines, inter-machine communication is necessary to accomplish this intersection. For document-based partitioning, the posting intersection is done within a machine, and each machine will report a subset of distinct documents that match this query. Once the search engine gathers matched documents, it ranks these matched documents and presents top results to users. We discuss page ranking in the next section.

Retrieval of relevant results during index matching is time consuming when searching a large dataset and various techniques are developed to speed up this process. One technique is to divide the list of documents from the posting of a term into multiple chunks and add skip pointers in the data structure [51,52]. In performing conjunctive search among postings for multiple query terms, the maximum document identification of a chunk can be used to determine if a chunk can be skipped when intersecting with a document identification from another posting. A skipping pointer for a chunk can be inserted into the data structure of inverted index so that the scanning of this chunk can be easily avoided.

51.4.3 Result Caching and Snippet Generation

Caching is a commonly adopted technique to speed up the query answering process because there are often over 50% of queries that can use previously computed search results. Caching provides load smoothing to deal with traffic spikes caused by hot events during which different users often type the same or similar queries again and again to check the latest development. A search engine may adopt a variety of hierarchical caching strategies. For example, cache the top HTML response with snippets, cache the top results without snippets, cache a matched URL list in a local machine before result aggregation, and cache the postings of frequent query terms.

Given a limitation on cache size, results for most frequent queries can be cached, and some results may be pre-cached in anticipation of its popularity. Other replacement policies may consider weighted factors such as recomputing cost [53]. A key issue to consider for caching is freshness of cached results. As the search index is updated continuously, the concern can arise for the staleness of cached results. For example, a query

that contains news results may not be cacheable because a later query needs to be answered with the latest news results. One strategy is to cache results only for relatively stable answers.

When top search results are presented to users, each document is described with a summary of its content, which is known as a snippet. There are two categories of techniques for document summarization. One is query-independent static snippet where a document is summarized without knowing queries. The second category is query-dependent dynamic summarization in which a snippet is composed of several short pieces of text, and each short piece often contains query terms. The selection of these text pieces depends on a number of features including the percentage of query terms covered, positions of text pieces in a document, importance of query terms covered, and the readability of the summary. A study on snippet readability was done in [54]. Producing high-quality snippets is time consuming, and efficient techniques for snippet generation were discussed in [55].

51.4.4 An Example of Online Search Architecture

Figure 51.4 illustrates an online search architecture we have developed in the past in hosting billions of web documents and answering queries from tens of millions of queries every day. The database is divided following language and country classification of documents, and the query-processing module can route a query to a proper collection of index based on the targeted user region. For example, English queries are processed using English data partitions. There is a small percentage of queries that contain mixed languages; for those queries, multiple-language content groups are involved in search.

Once a query is received by the online system, this query is distributed to one of query-processing front ends through a load-balancing traffic switch. The query-processing module consults a multi-level cache to see if this query can be answered using the previously computed result with or without snippets. If a query cannot be found from the cache, the page retrieval module searches URLs in Tier 1 of the online index and visits Tier 2 (or other lower priority tiers) only if the results matched from Tier 1 are not satisfactory. Our experience is that up to 70% of queries can be handled by Tier 1 without searching other tiers. There is an internal cache deployed for each partition so that retrieval results for frequent queries or compute-intensive queries are cached within each partition. There is also an aggregation module that combines results from multiple partitions and eliminates duplicates when needed, and this module can be deployed hierarchically also [56].

Ranking is conducted hierarchically. The page retrieval module selects top results from each partition, and these results are combined in an aggregation module, which performs additional filtering. Signals for ranking are discussed in the next section. Once top-ranked results are derived, the snippets for these results can be computed by accessing the text content of these documents from a page repository.

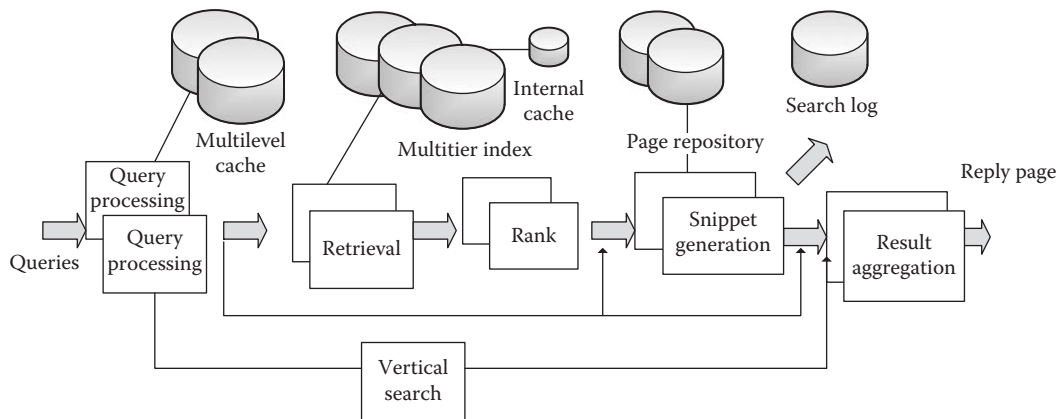

FIGURE 51.4 An online web search architecture.

There is a heavy I/O activity involved in accessing disk data for snippet generation, and caching snippets for popular queries can be used to improve the performance.

In addition to finding results from the HTML page collection, a query is also routed to vertical search channels including the advertisement engine and other types of popular web collections such as news and blogs, maps, images, and videos. The top results from multiple channels are combined in the SERP. Optimizing the selection and placement of these results from different channels in a SERP is critical for users' experience with a search engine. Once a user browses URLs listed in the SERP, the search engine keeps a log on the click activity of this user. The user behavior extracted from this log provides a feedback for adjustment of ranking of results, triggering and placement of vertical search.

Each logical system component in Figure 51.4 runs on a large-scale computer cluster. As we mainly use a document-based distribution for search index, processing of each search request goes through thousands of machines. System support for the previous engine includes request and internal traffic scheduling, fault tolerance, and replication support; the middleware and related system techniques were discussed in [56–59].

51.5 Ranking

Ranking plays the most visible role in a search engine since most users only look at top results. Ranking can be conducted in a centralized manner or hierarchically so that each subsystem selects the best results first before submitting selected results for the next round of ranking. Relevance scores for documents are computed by exploiting their text and authority features, which are often called *ranking signals*.

We first give an overview of query-dependent and query-independent ranking signals and describe feature analysis based on text, link, and click data. Then we will discuss score aggregation by using these signals.

51.5.1 Ranking Signals

There are four aspects of ranking in matching the intent of a user.

1. *Relevancy*. Top documents need to be relevant to a user query.
2. *Authoritativeness*. High-quality content is normally preferred since users rely on trustful information to learn or make a decision.
3. *Freshness*. Some queries are time sensitive and latest information is more appropriate for such type of queries.
4. *Preference*. Personal or geographical preference can also impact the choices of answers.

Rank signals are designed to reveal those aspects from the query or document point of view, and we summarize two categories of ranking signals as follows:

Query-Dependent Ranking Signals

- *Document text*. This feature measures the closeness between query words and what appears in a document. A web document can be divided into multiple text sections such as document title and body, and query words matched in different sections carry different weights. Additional weighting can be considered if query terms are highlighted in a document. Proximity, positions, and frequency of query words matched in a document area prominent indicator of relevance.

Some of text features in a web document are not visible to users, for example, description and keyword tags of an HTML document. Spammers often exploit such a feature to present irrelevant keywords; thus, such features have to be used with caution.

- *Anchor text*. Anchor text of a web page appears in the hyperlinks of other web documents referring to this page. There can be many hyperlinks pointing to the same web document, and some of anchor text can be meaningless or of low quality. The commonality in anchor text and popularity of source web pages can be helpful in determining quality of anchor text.

- *URL text.* Text of a URL, especially when appearing in a position within or close to the host name, may sometime reveal the semantic of its content. For example, “download” in <http://www.microsoft.com/en-us/download/> is an important keyword for matching query “Microsoft download.”
- *Historical click-through data.* A search engine collects the behavior data from users when they search and browse matched results. These URLs clicked by a user following a search query are often relevant to such a query.
- *Query classification and preference.* Implicit features of a query can be extracted during classification to select preferred documents. For example, the language of a query prioritizes the language type of web documents to be matched. The originating geographical location of a query may direct the ranking system to select more content from this region. If a query matches a hot news topic, time-sensitive fresh content is preferred.
- *Link citation.* This feature uses the web hyperlink connectivity among those pages whose text matches a given query. A page cited by many other matched web pages can be a good indicator of authoritativeness for this query.

Query-Independent Signals

- *Link popularity.* This feature analyzes how pages link to each other and then uses this information to determine the importance of each page on the web. If a page is cited from a large number of pages, it is often ranked more prominently.
- *Documentation classification and spam analysis.* A classification of web documents can provide a signal in matching user preference. For example, users are more likely to be looking for content in their own language than in other languages. File types such as HTML and Microsoft Word can also be a preference for users. Since spam analysis leads to a rating of page quality, a spam score is also a useful quality indicator.
- *URL preference.* In many cases, users prefer a URL with a short length and prefer a static URL instead of a dynamically generated URL. Dynamically generated URLs tend to change content from time to time, and their average quality is often lower than that of static URLs.
- *Site or page properties.* Some additional information on a web page or its site can be an indication of web page quality. For example, frequency of user visits, the time duration of visit, and serving speed or reliability of the web host.

There are many methods for modeling above ranking signals, and we next describe some of techniques for analyzing text, links, and click data.

51.5.2 Text Analysis

The goal of text analysis is to quantify the relevance of a document based on how query words appear in this document. Boolean and phrase operators are available in a search engine for advanced retrieval semantics, for example, “Retrieval” or “Search.” Since most people use simple and short queries, we focus on text analysis of a search query with conjunctive semantics.

There are three issues in developing a formula measuring the text closeness of document–query matching:

- What are basic units of information to match a query with a document? A document is normally tokenized a sequence of words after excluding HTML tags, and each word is a basic term for matching. Thus, a document can be considered as a bag of words. On the other hand, the order and closeness of terms play an important role. For example, “Paris Hilton” is the actress name while “Hilton Paris” could mean the Hilton hotel at Paris.
- What is the proximity of search words appeared in a document? When search words appear close to each other in a document, this document is often considered to have a high relevancy.

To capture word proximity, an n -gram term can be considered, which is defined as a consecutive sequence of n words in a document. An n -gram of size 1 is referred to as a “unigram,” size 2 is a “bigram,” and size 3 is a “trigram.”

Another model for proximity is to use a text *span* [60,61]. A document is segmented into multiple disjoint spans that cover search terms. Each span may not contain every query term, and it is a minimum text window containing search terms as much as possible. Each span starts with the position of the first query term in a document and contains consecutive query terms in a document. This span ends when the distance between the current query term match position and the next query term match position exceeds a threshold. This span also ends if the current and next matches are the same term, or the previous query term is the same as the next query term.

- How are terms weighted? One method is to use a simple weighting based on where they appear. If a query term appears in the body of a document, it will receive credit. When it appears in the title, it receives weighted credit. Another method that uses the frequency information is known as term frequency and inverse document frequency (TF-IDF) weighting. In this scheme, the importance of a term increases when it appears many times in a document. If a term appears many times in many documents, its weight decreases because it becomes less effective in differentiating a relevant document from a non-relevant document. A common formula for TF-IDF is defined as follows:

$$tfidf(t, d) = tf(t, d) * \log \frac{n}{df_t}$$

where n is the number of documents in the collection, $tf(t, d)$ is the occurrence count of term t in document d , and df_t is the number of documents that term t appears. Because denominator df_t may be zero, it is often adjusted as $1 + df_t$. Additionally, $tf(t, d)$ is sometime normalized against the length of document d . Variations of the TF-IDF weighting have been suggested in the literature, for example, Okapi BM25 [62].

- How can the closeness of matching be represented by aggregating weights from multiple query terms? One model is to use the cosine-based similarity function. Let document d contain a set of terms with weight w_i for each term, and let query q contain a set of query terms with weight qw_i . These weights are normalized, and the aggregated text score is

$$Score(d, q) = \sum_{t_i \in q} w_i * qw_i$$

There are other ways to aggregate weights. Since text features can be represented in multiple ways to capture the appearance and proximity of search terms, they can be aggregated using a weighted summation function or a machine learning model. We discuss a weight-learning technique in Section 51.5.5.

51.5.3 Link Analysis

51.5.3.1 PageRank Algorithm

As a query-independent ranking signal, the earlier PageRank algorithm [63] measures the importance of a web document based on its presence in a large web graph. In this graph, each node is a web page and each edge is directed, representing a link from one page to another using the HTML hyperlink notation. The intuition underlying this link analysis is that highly linked pages are more important than pages with just few links, but not all links carry the same importance. A page with a link from a popular site may be ranked higher than other pages with more links but from obscure places.

Let n be the number of pages in a web graph, and let x be a page. A simplified version of the PageRank model can be expressed as

$$R(x) = \frac{\lambda}{n} + (1 - \lambda) \sum_{y \in P(x)} \frac{R(y)}{|S(y)|}$$

where $S(x)$ is the set of pages that x points to and $P(x)$ is the set of pages that point to x .

PageRank computation can be conducted iteratively. Initially, every page has its initial value as $\frac{1}{n}$. Then all pages will be assigned with a λ -linear combination of a rank value $\frac{1}{n}$ and additional rank credit propagated from its predecessors in the graph. After that, vector $R()$ is normalized. This process repeats until all nodes have a converged rank value.

Computing the in-degree of a web page can approximate its link popularity score, but this score can be less resilient to link spamming. That is because it is relatively easy to create thousands of pages on the web pointing to a page. The PageRank algorithm was initially viewed as the key to Google's differentiation compared to other search engines when Google was launched. Various modifications have been suggested in the literature to improve relevancy or speed up computation. For instance, see [64,65].

51.5.3.2 HITS Algorithm

The HITS algorithm [66] provides query-dependent scoring to determine the authoritativeness of a web page relevant to a query. The key difference compared to PageRank is that HITS computes link scores within a subgraph of a web graph derived based on a user query. The HITS algorithm derives two scores for every page. The first score is called *the authority score*, representing the authoritativeness of a page relevant to the subject of a user query. The second score is called *the hub score* representing its rank value in serving as the compilation of relevant information. Let the authority score of a page x be $A(x)$, and let the hub score of this page be $H(x)$:

$$A(x) = \sum_{y \in P(x)} H(y) \quad \text{and} \quad H(x) = \sum_{y \in S(x)} A(y)$$

where $P(x)$ contains the predecessors of page x in this graph and $S(x)$ contains the successors of x .

The computation of these scores is performed iteratively. After an initial score assignment, all pages update their hub and authorities based on the previous formula. These values are normalized at each iteration, and this process repeats until all pages have a converged value. Mathematically speaking, the previous process computes the principal eigenvector of matrix $C^t C$ and CC^t where C is the connectivity matrix based on the link structure of the query graph, and C^t is the transpose of C .

The major challenge in using HITS is its online computation cost. There are several extension or follow-up work to improve the seminal work of PageRank and HITS. That includes topic distillation [67] and multi-community hub authority [68,69]. A fast algorithm for computing hub authority scores with sparse matrix approximation was developed at Teoma/Ask [70].

51.5.4 Click Analysis

Users interact with a search engine by clicking search results of a query, browsing them, reformulating their queries, and performing additional browsing. Such interaction is logged in a search engine, and the click data can be thought of as a tuple (t, u, q, c) indicating that user u clicks result c for query q at time t . While click data can be noisy, URLs clicked by users are likely to convey some information for relevance judgment. A document may be ranked high if it has attracted the greatest number of previous users for the same query. A log dataset can be divided into a sequence of search sessions for each user. Each user

session contains a sequence of queries and results picked by this user. The following correlations among queries and URL results can be extracted from session analysis:

- *Query-to-pick (Q2P)*. A Q2P correlation associates a query with a pick. When a search engine returns a result in response to a query, and a user picks this result, that constitutes a correlation candidate. When multiple independent users make the same association, that makes this Q2P correlation more plausible.

As an extended association, after a user enters a query, picks recorded for a different query within the same user session can be associated with the initial query. Another extension is that different pages browsed as a result of a URL pick may also be associated with the original query. The previous two extensions represent the fact that a user often reformulates a query or browses beyond a search link to look for right content. Such an approach carries data errors and additional noise filtering techniques need to be applied. For instance, a restriction can be applied using query similarity from one pick to another in a session, the order and depth of query rewriting or browsing steps, dwelling time, and the first and last choice of browsing.

- *Query-to-query (Q2Q)*. This correlation associates queries issued during a user session. The confidence for such association depends on various factors including query similarity, the issuing time between queries, the number of intervening queries or picks, the order of association, and the number of sessions sharing such an association. The Q2Q correlation can help the generation of query suggestions in search engine response pages.

For example, “electronic eavesdropping” is related to a query “eavesdropping devices.” Misspelled “Hotel Mariot” is related to “Hotel Marriott.”

- *Pick-to-pick (P2P)*. This correlation associates picks issued during a user session, which is analogous to the Q2Q correlation described earlier. The P2P correlation can reveal a set of URLs that are similar or related for certain topics. As an example, toyota.com is the top answer for answering “Toyota car,” honda.com and ford.com may also be listed as similar results in case users are interested in exploiting similar products.

While click-through data can be very noisy and incomplete with a sparse structure, it still provides valuable information for search quality improvement. Ask.com that bought DirectHit.com in 1999 was the earlier system that ranked search results based on URLs’ click-through rates, and the adjustment is applied when URLs with a relatively lower rank may receive more clicks compared to those with a higher rank. Ask.com further adopted session-based click data to improve ranking with Q2P and Q2Q correlations [71]. The use of click data to derive user’s relative preference was studied in [72] to train a ranking function. Query reformulation that expands the Q2P correlations in learning to rank was considered in [73]. The relevancy impact of integrating a number of click-based features was demonstrated in [74]. The bipartite graph structure of query–document relationship from a query log for modeling Q2P, Q2Q, and P2P correlations was studied in [75,76]. Integrating browsing activities of a search session for ranking was considered in [77].

51.5.5 Score Aggregation and Learning to Rank

There are many ranking signals that can be extracted or characterized for each matched document in responding to a query. Those signals need to be aggregated, and their weights can be imposed empirically or derived using a machine learning method. Aggregation of these signals can be performed hierarchically. In this way, ranking signals can be divided into several semantically relevant components for fine tuning.

Machine-learned ranking uses supervised or semi-supervised techniques that automatically construct a ranking model from training data. Training data consists of a set of queries, and each query has a list of documents with a relevance label. The example of a relevance label is “relevant,” “related,” or “irrelevant” for a three-level judgment. There are various ways to model a learning function based on

a training dataset, and multiple models can be combined by an ensemble method such as bagging and boosting [78–80] to further improve the learning accuracy.

We illustrate a simple learning function as follows using the RankSVM method [72,81]. Let \vec{x}_i be a feature vector representing a set of ranking signals for document d_i . An aggregated score function $f(x_i)$ is a product of a weight vector \vec{w} with \vec{x}_i . Function $f()$ defines ranking as follows: if $f(\vec{x}_i) > f(\vec{x}_j)$, document d_i should be ranked before d_j in answering a query. This condition implies that we need to find \vec{w} so that $\vec{w} \times (\vec{x}_i - \vec{x}_j) > 0$.

Following the previous condition, a training dataset is converted based on the pairwise relationship of documents. Assume that page d_i with a feature vector x_i and another page d_j with a feature vector x_j are labeled for answering the same query. Define a new label $e_{i,j}$ for pair (d_i, d_j) as 1 if d_i should be ranked before d_j and -1 if d_i should be ranked after d_j . The new training data can be thought of as a set of triplets. Each triplet is $(Q, \vec{x}_i - \vec{x}_j, e_{i,j})$, where Q is a test query and d_i and d_j are from the labeled result list of Q . Then the hard-margin linear SVM model is to minimize $\|\vec{w}\|^2$ subject to a constraint for all points in the training data: $\vec{w} \times (\vec{x}_i - \vec{x}_j) \times e_{i,j} \geq 0$.

The previous process demonstrates that a ranking problem can be transformed to a classification problem, and other classification-based algorithms can also be used. Learning-to-rank algorithms have been categorized as pointwise, pairwise, and list-wise [82]. The pointwise approach predicts the relevancy score of each document for a query using a supervised learning method such as regression and classification. The pairwise approach considers learning as a binary classification problem to decide if a document should be ranked prior to another document. Examples of this approach are RankSVM [72,81], RankBoost [80], and RankNet [83]. The list-wise approach tries to directly optimize the cost function, following a relevancy evaluation measure. Examples of such an approach include LambdaMART [84], SVM^{map} [85], and AdaRank [86]. Machine-learned ranking has its advantage for leveraging a large training dataset while interpreting and adjusting its behavior in the failed cases can be hard sometime. In practice, a ranking model that combines machine learning with human tuning may be used.

51.6 Search Engine Evaluation

51.6.1 Strategies in Quality Evaluation

A common evaluation for search engine quality is the relevance of search results as well as the speed in answering a query. It is not easy to define the metric for measuring the relevance of search results. This is because in many cases, it is hard to tell what a user really wants by viewing a query. Precise detection of user's query intent is the holy grail of search. For navigational queries such as Microsoft, most users want to navigate to the respective sites. Queries such "US open" can have multiple answers from time to time. Intent of some queries can be heavily biased by locations or languages used. For instance, CMU can mean Central Michigan University, Carnegie Mellon University, or Central Methodist University, depending users' location.

One way to judge result relevance of a search engine is to employ a team of evaluators, and let them type queries collected from an engine log, and assess if the returned answer matches the typed query. This has a challenge since sometime an evaluator may not be able figure out the right answers. Another complexity is that today's search engine users expect more than just result relevance, and there are multiple aspects of a search engine affecting the satisfactory degree of an end user. For example, are the results from authoritative sources? Are they free of spam? Are their titles and snippets descriptive enough? Are they fresh and timely? Does the answer include additional visual elements such as maps or images that may be helpful? A thorough evaluation needs to cover each of these dimensions when appropriate.

The search log data can be used to assess the quality of an engine and to capture the satisfactory degree of end users. When users engage a search engine and select presented results more frequently, this is a good indicator that users like this engine. The key metrics that can be derived from a search log include the daily or weekly user traffic, the visit frequency of users, result pick rate, and abandon

rate when users do not select any result. The metrics derived from a search log carry certain noise. For example, result pick rate is often affected by the placement of results and interface design in a SERP. Site traffic can be also affected by seasonality. The interpretation of these metrics requires a deep data analysis from multiple aspects.

51.6.2 Evaluation Metrics

To measure whether an information retrieval system returns relevant results or not, precision and recall are the two metrics developed in the earlier studies. Precision is the percentage of returned results that are relevant, and recall is the percentage of all relevant results covered in the returned list. For web search, when there are many results relevant to a query, a user normally only browses top few results; thus, precision is more critical than recall in such a setting. When there are only very few results relevant to a query, a recall ratio measures the ranking and crawling capability in finding these documents.

Another measure called *the normalized discounted cumulative gain (NDCG)* [87] that considers the graded relevance judgment and the usefulness of a document based on its position in the ranked result list. In this scheme, the result quality is judged using graded relevance with a multi-level label. For example, a six-level label can be “perfect,” “excellent,” “good,” “fair,” “poor,” or “bad.” The NDCG value starts with a following concept called *the discounted cumulative gain (DCG)* at a particular rank position k :

$$DCG[k] = \sum_{i=1}^k \frac{2^{rel_i} - 1}{\log_2(1+i)}$$

where rel_i is the graded relevance value at position i . For example, 0 stands for “bad,” 1 stands for “poor,” 2 stands for “fair,” and so on. The NDCG value normalizes the DCG value as

$$NDCG[k] = \frac{DCG[k]}{DCG'[k]}$$

where $DCG'[k]$ is the ideal DCG at position k . The $DCG'[k]$ value is computed by producing the maximum possible DCG till position k . The NDCG value for all queries is averaged to assess the average ranking quality.

The other evaluation metrics for a search engine includes freshness and coverage. To assess the freshness, one metric can be the time from creation of a document on the web to the time when it appears in the online index. To measure the completeness, the size of database can be used. Since there are a large amount of low-quality URLs on the web, the size alone is not sufficient. An additional strategy is topic-based sampling to measure the satisfactory degree in answering users’ queries for selected topics.

The speed of the engine performance can be measured by the round-trip response time of a query. Typically a search engine is required to return a query result within a second, but in practice a search engine is able to deliver a search result within a few hundred milliseconds. During search engine capacity planning, the throughput of an online system is also measured so that a system can be optimized to answer as many queries as possible at every second. When the engine configuration such as the database size changes, its performance metrics may be affected and need to be examined.

51.7 Concluding Remarks

The main challenge of search engine technology is the handling of big data with significant noise. Search engine technology has been improved steadily in the last decade while the expectation of Internet users has also increased considerably. There are still a large number of unsolved technical problems

to accurately capture the intent of search users. As more and more ranking signals are introduced to improve result relevance for different categories of queries, the interaction of these signals can sometimes yield to subtle side effects. Thus, further improvement of search quality toward the next level requires more effort. In the next ten years, mobile and multimedia search is a key battleground among search providers. With popularity of social networking, social search is also another hot topic to facilitate information sharing. Search-based information technology will continue to advance and evolve in multiple directions, so Internet and mobile users can find the information that they need quickly.

52.1 Introduction

Process *synchronization* (also referred to as process coordination) is a fundamental problem in operating system design and implementation. It is a situation when two or more processes coordinate their activities based on a condition. An example is when one process must wait for another process to place a value in a buffer before the first process can proceed. A specific problem of synchronization is *mutual exclusion*, which requires that two or more concurrent activities do not simultaneously access a shared resource. This resource may be shared data among a set of processes where the instructions that access these shared data form a *critical region* (also referred to as a critical section). A solution to the mutual exclusion problem guarantees that among the set of processes only one process is executing in the critical region at a time.

Processes involved in synchronization are indirectly aware of each other by waiting on a condition that is set by another process. A form of this synchronization is waiting on an event, which may occur because of an action of the operating system, of another process or an entity external to the immediate system. Processes can also communicate directly with each other through *interprocess communication (IPC)*. IPC causes communication to be sent between two (or more) processes. A common form of IPC is message passing.

The origins of process synchronization and IPC are work in concurrent program control by people such as Dijkstra, Hoare, and Brinch Hansen. Dijkstra described and presented a solution to the mutual exclusion problem (Dijkstra 1965) and proposed other fundamental synchronization problems

and solutions such as the dining philosophers problem (Dijkstra 1971) and semaphores (Dijkstra 1968). Hansen (1972) and Hoare (1972) suggested the concept of a critical region. Hansen published a classic text with many examples of concurrency in operating systems (Hansen 1973). Hoare (1974) provided a complete description of monitors following work by Hansen (1973).

In discussing process synchronization and communication, it is critical to understand that these are no longer just operating system concerns, but broadly affect system and application design, particularly because multithreaded applications employed on multiprocessor and multicore architectures are now commonplace. Many of the primitives used for synchronizing processes also work for synchronizing threads, which are discussed in the chapter on Thread Management. Investigation is being done on mechanisms that work in multicore/processor environments, discussed in the chapter on Multiprocessing and Multicore Programming, and extend to distributed ones. Concurrent programming using synchronization and IPC in a distributed environment is more complex because there may be a failure by some processes participating in synchronization while others continue, or it is possible for messages to be lost or delayed in an IPC mechanism.

The remainder of this chapter discusses the underlying principles and practices commonly used for synchronization and IPC. Section 52.2 identifies fundamental problems needing solutions and issues that arise in considering various solutions. Section 52.3 discusses prominent results for synchronization and IPC problems and discusses their relative merits in terms of these issues. The chapter concludes with a summary, a glossary of terms that have been defined, references, and sources of further information.

52.2 Underlying Principles

Process synchronization and IPC arose from the need of coordinating concurrent activities in a multiprogrammed operating system. This section defines and illustrates traditional as well as more modern synchronization and IPC problems and characterizes the issues on which to compare the solutions.

52.2.1 Synchronization Problems

A fundamental synchronization problem is mutual exclusion, described by Dijkstra (1965). Lamport (1986) provides a formal treatment of the problem with Anderson (2001) surveying Lamport's contributions on this topic. In this problem, multiple processes wish to coordinate so that only one process is in its critical region of code at any one time. During this critical region, each process accesses a shared resource such as a variable or table in memory. The use of a mutual exclusion primitive for access to a shared resource is illustrated in Figure 52.1, where two processes have been created that each access a shared global variable through the routine `Deposit()`.

The routines `BeginRegion()` and `EndRegion()` define a critical region ensuring that `Deposit()` is not executed simultaneously by both processes. With these routines, the final value of `balance` is always 20, although the execution order of the two processes is not defined.

To illustrate the need for mutual exclusion, consider the same example without the `BeginRegion()` and `EndRegion()` routines. In this case, the execution order of the statements for each process is time dependent. The final value of `balance` may be 20 if `Deposit()` is executed to completion for each process, or the value of `balance` may be 10 if the execution of `Deposit()` is interleaved for the two processes. This example illustrates a *race condition*, where multiple processes access and manipulate the same data with the outcome dependent on the relative timing of these processes. The use of a critical region avoids a race condition.

Many solutions have been proposed for the implementation of these two primitives; the most well known of which are given in the following section. Solutions to the mutual exclusion synchronization

```

int balance = 0; /* global shared variable */

ProcessA()
{
    Deposit(10);
    print("Balance is %d\n", balance);
}

ProcessB()
{
    Deposit(10);
    print("Balance is %d\n", balance);
}

Deposit(int deposit)
{
    int newbalance; /* local variable */

    BeginRegion(); /* enter critical region */
    newbalance = balance + deposit;
    balance = newbalance;
    EndRegion(); /* exit critical region */
}

```

FIGURE 52.1 Shared variable access handled as a critical region.

problem must meet a number of requirements, which were first set forth in Dijkstra (1965) and are summarized in Stallings (2012). These requirements are as follows:

- Mutual exclusion must be enforced so that at most one process is in its critical region at any point in time.
- A process must spend a finite amount of time in its critical region.
- The solution must make no assumptions about the relative speeds of the processes or the number of processes.
- A process stopped outside of its critical region must not lead to blocking of other processes.
- A process requesting to enter a critical region held by no other process must be permitted to enter without delay.
- A process requesting to enter a critical region must be granted access within a finite amount of time.

Another fundamental synchronization problem is the producer/consumer problem. In this problem, one process produces data to be consumed by another process. Figure 52.2 shows one form of this problem where a *producer* process continually increments a shared global variable and a *consumer* process continually prints out the shared variable. This variable is a fixed-size buffer between the two processes, and hence this specific problem is called the bounded-buffer producer/consumer problem.

The ideal of this example is for the consumer to print each value produced. However, the processes are not synchronized and the output generated is timing dependent. The number 0 is printed 2000 times if the consumer process executes before the producer begins. At the other extreme, the number 2000 is printed 2000 times if the producer process executes before the consumer begins. In general, increasing values of n are printed with some values printed many times and others not at all. This example illustrates the need for the producer and consumer to synchronize with each other.

The producer/consumer problem is a specific type of synchronization that is needed between two processes. In general, many types of synchronization exist between processes. An increasingly important one in the context of parallelization is a *barrier*, which is illustrated in Figure 52.3. A barrier synchronizes the actions of multiple processes (or threads), shown as A, B, etc., in Figure 52.3, such that the execution of each process reaching the barrier is blocked until all processes have reached the barrier.

```

int n = 0; /* shared by all processes */

main()
{
    int producer(), consumer();
    CreateProcess(producer);
    CreateProcess(consumer);
    /* wait until done */
}

producer() // produce values of n
{
    int i;
    for (i=0; i<2000; i++)
        n++; // increment n
}

consumer() // consume and print values of n
{
    int i;
    for (i=0; i<2000; i++)
        printf("n is %d\n", n); /* print value of n */
}

```

FIGURE 52.2 Example of producer/consumer synchronization problem.

FIGURE 52.3 Barrier synchronization for a set of processes.

This type of synchronization is common for computations that have a mix of serial and parallel phases where a barrier is placed at the end of each parallelized phase.

Another type of synchronization problem that has always existed within operating systems, but has become increasingly important in other contexts is the detection and handling of external events that occur. Solutions to this problem must consider whether such events should be handled asynchronously via event handlers to handle the event when it occurs or synchronously via polling or blocking to stall execution until the event occurs. Solutions may also be needed that allow for one of many events to occur, such as waiting a maximum timeout period for a network packet to arrive.

52.2.2 Synchronization Issues

There are many approaches available for solving mutual exclusion and synchronization problems. There are a number of issues concerning the implementation of solutions to these problems, with the primary ones described in the following:

- *Processor and store synchronicity*: Solutions to synchronization problems that are processor synchronous require that processors can be made uninterruptable. These solutions work for uni-processor machines but not for multiprocessors where disabling the interrupts on one processor

does not affect another. Solutions to synchronization problems that are store synchronous, which assumes individual references to main memory are atomic, are applicable to both uni- and multiprocessor machines.

- *Busy waiting*: Another issue in synchronization solutions is the consumption of CPU resources while a process is waiting for a condition to occur. Some solutions require *busy waiting*, the continued polling of a condition variable. These solutions are less efficient, particularly on a uniprocessor where busy waiting continues until the time slice of the waiting process is complete.
- *Programmer errors*: Potential programming errors inherent in using a particular synchronization approach must also be considered. Ordering of synchronization primitives is necessary for correct solutions with some primitives. Other primitives for synchronization have been specifically designed to minimize the possibility of such a programmer error.
- *Starvation*: It is possible for synchronization solutions to lead to the condition of *starvation*. Starvation occurs when a process is indefinitely denied access to a resource while other processes are granted access to the resource. Starvation is an issue in mutual exclusion if it is possible for one process to be indefinitely denied access to its critical region while access is granted to other processes.
- *Deadlock*: Another fundamental problem confronted by solutions is *deadlock*. Deadlock is the condition when a set of processes using shared resources or communicating with each other are permanently blocked. Coffman et al. (1971) describe three necessary, but not sufficient, conditions that must exist for deadlock to occur among a set of processes sharing resources:
 1. *Mutual exclusion*: A resource may be used by only one process at a time.
 2. *Hold and wait*: Processes holding resources can request new resources.
 3. *No preemption*: A resource given to a process cannot be taken back.
 For deadlock to actually take place, a fourth condition must also exist:
 4. *Circular wait*: A set of processes are in a circular wait; that is, there is a set of processes $\{p_0, p_1, \dots, p_n\}$ where p_i is waiting for a resource held by p_{i+1} , and p_n is waiting for a resource held by p_0 .

When combined with the three necessary conditions, the presence of the circular wait condition indicates that a deadlock has occurred and that no means exists for breaking the deadlock. When designing solutions to synchronization problems such as mutual exclusion, preventing deadlock involves disallowing one or more of the preceding conditions. Specific solutions to the deadlock problem are given in Section 52.3.

52.2.3 Interprocess Communication Problems

Interprocess communication problems generally involve direct communication between two or more processes, in contrast to synchronization where processes communicate indirectly by waiting on or setting a condition. Thus, communication is indirect between the processes when using synchronization, whereas IPC mechanisms generally communicate by passing messages directly between processes. The primitives for handling messages are

- `send(pid, &message)`
- `pid = receive(&message)`

where `send()` sends the given message to a specific destination process and `receive()` receives the last message sent to it returning the process identifier (`pid`) of the sender.

Message passing is commonly used in operating systems and user applications for communicating between processes. In a message-based operating system where server processes perform many of the functions associated with an operating system, message passing is used to pass requests to the appropriate server and to receive replies, as is shown in the example of Figure 52.4.

```

int serverpid;          /* well-known pid of the server */
Server()               /* server process code */
{
    int pid;           /* process id of the requesting process */
    Message request_msg, reply_msg;

    while (TRUE) {
        pid = receive(&request_msg);    /* receive message */
        /* handle request and build reply message */
        send(pid, &reply_msg);         /* send the reply */
    }
}

int ServiceRequest(args) /* service request function with arguments */
{
    Message request_msg, reply_msg;

    /* load args into request_msg */
    send(serverpid, &request_msg);
    (void)receive(&reply_msg);
    return(reply_msg.status);
}

```

FIGURE 52.4 Service request for a message-based operating system.

52.2.4 Interprocess Communication Issues

As described in the previous example, IPC mechanisms typically involve the exchange of messages from one process to another. There are a number of issues concerning the implementation of a message passing mechanism, with the primary ones described in the following. Implementations of IPC mechanisms, which address these issues, are described in Section 52.3.

- *Direct vs. indirect communication:* A key issue in a message passing system is how messages are addressed to their recipient. In a direct message passing scheme, the delivery address is a process id. This approach is illustrated in Figure 52.4. In an indirect scheme, the address is an intermediate repository, such as a mailbox or port, that is a drop-off point for the message for later pick up by the recipient.
- *Buffering of data:* Another issue is whether the message passing mechanism allows messages to be buffered if the receiving process is currently not ready to receive a message. If buffering is allowed, then another issue is the size of this buffer.
- *Blocking vs. nonblocking operations:* Related to the issue of buffering is the semantics of the `send()` operation when the message cannot be delivered. The operation can either block until the message can be delivered or the operation can immediately return with an error if blocking would occur. Similarly, the `receive()` operation can be defined to either block and wait for message delivery if no message is available or not block and return an error.
- *Fixed- or variable-sized messages:* Fixed-size messages allow for easier implementation but may require more work for the programmer. In contrast, variable-sized messages are easier to program but require more work to implement.
- *Synchronous vs. asynchronous reception:* Message passing mechanisms allow more process control if messages are received only when the `receive()` operation is invoked. However, some mechanisms allow for communication to be received when it arrives through an asynchronous approach using message handlers.

52.3 Impact on Practice

This section discusses prominent results for synchronization and IPC. Each solution contains an example of its use, its relative merits, and problems for which it is useful. More examples of synchronization mechanisms can be found in operating system texts (Tanenbaum 2008, Flynn and McHoes 2011, Silberschatz et al. 2012, Stallings 2012). Comer (2011) and Tanenbaum (1987) present code for actual operating systems to show how synchronization and IPC mechanisms can be implemented. More concurrent programming examples can be found in Ben-Ari (1990), Raynal (1986), and Hansen (1973). Andrews and Schneider (1983) provide a survey of synchronization and IPC techniques. The chapter concludes with more classic synchronization problems and specific solutions to the deadlock problem.

52.3.1 Synchronization Mechanisms

The mechanisms for synchronization are divided into four types based on their level of implementation and support: software only, hardware support, operating system support, and language support. In addition, hybrid solutions exist that combine more than one of these approaches. Each approach shows a solution to the mutual exclusion problem along with other applicable synchronization problems and discusses the relevant synchronization issues.

52.3.1.1 Software Solutions

Software-based synchronization solutions require only that multiple processes can access shared global variables. The solutions use these variables to control access to the critical region. Dekker was the first to devise a software solution that correctly handles the mutual exclusion problem among a set of processes. A discussion of this solution is given in Dijkstra (1965). Peterson (1981) provided a simpler solution of the same problem, which is given in Figure 52.5 for two processes in terms of the `BeginRegion()` and `EndRegion()` routines.

This solution works correctly on any hardware (uni- or multiprocessor) in which references to main memory are atomic. The main disadvantage is that it requires busy waiting, continued polling of a status variable, before gaining access to the critical region if another process is already in the critical region. The solution can generalize to more processes, but better solutions are available.

```

int turn;                /* whose turn is it? */
int flag[2];            /* want the mutex? Initially FALSE */

BeginRegion(int pid)    /* pid is 0 or 1 */
{
    int other;          /* pid of other process */

    other = 1 - pid;    /* the opposite of pid */
    flag[pid] = TRUE;   /* express interest in mutex */
    turn = pid;        /* set flag */
    while ((turn == pid) && (flag[other] == TRUE))
        ;              /* busy wait */
}

EndRegion(int pid)
{
    flag[pid] = FALSE; /* drop interest in mutex */
}

```

FIGURE 52.5 Peterson's solution of mutual exclusion for two processes.

52.3.1.2 Solutions Using Hardware Support

Not all problems of synchronization, particularly ones in the operating system itself, can be handled solely with software-based solutions. As in other aspects of computing, hardware support can not only make the task easier but is also necessary for some levels of synchronization within the operating system.

One of the simplest ways to enforce mutual exclusion is to disable hardware interrupts at the start of the critical region, thus ensuring that the process does not give up the CPU (through a context switch) before completing the critical region. When the critical region is done, the process re-enables interrupts. The `BeginRegion()` and `EndRegion()` routines with this approach are shown in Figure 52.6.

This approach is fast and is used for manipulation of shared operating system data structures on a uniprocessor but in general has many disadvantages for general purpose use:

- Programmers must be careful not to disable interrupts for too long; devices that raise interrupts need to be serviced.
- The programmer must be careful about nesting. Activities that disable interrupts must restore them to their previous settings. In particular, if interrupts are already disabled before entering a critical region, they must remain disabled after leaving the critical region. Code in one critical region may call a routine that executes a different critical region.
- Disabling interrupts prevents all other activities, even though many may never execute the same critical region. Disabling interrupts is like using a sledge hammer; it is a powerful tool but bigger than is needed for most jobs.
- The technique is ineffective on multiprocessor architectures, where disabling interrupts on one processor still allows other processes to run on other processors.

Rather than perform mutual exclusion by controlling interrupts, a common approach is to use special instructions provided by the hardware to implement mutual exclusion. One such instruction is `Test_and_Set`, which is functionally defined by the procedure of Figure 52.7. It returns the previous value of a target variable and sets the target to the given value. Most importantly, this instruction is performed in an atomic manner so a context switch cannot occur in the middle of it. In addition, operations performed on two separate processors of a multiprocessor are guaranteed to occur in sequential order because of store synchronicity. Figure 52.7 shows how the `BeginRegion()` and `EndRegion()` primitives are implemented using this instruction. The variable `mutex` is also referred to as a lock variable, and this approach to mutual exclusion is called a *spin lock* because a process spins in an infinite loop waiting for the lock. When the `mutex` variable is set to `FALSE` by a process exiting from its critical region, another process is allowed to gain access to its critical region.

This type of solution is particularly attractive for threaded environments because it allows for *wait-free* or *non-blocking* atomic updates of shared resources. Herlihy (1991) shows that other primitives such as `Compare_and_Swap` are even more computationally strong than `Test_and_Set`. Fraser and Harris (2007) used these primitives as a basis to create practical programming solutions for atomic, nonblocking updates to multiword data structures.

```

BeginRegion()
{
    DisableInterrupts();
}

EndRegion()
{
    EnableInterrupts();
}

```

FIGURE 52.6 Mutual exclusion by disabling/enabling hardware interrupts.

```

int mutex = FALSE;                /* global variable for mutex */

int Test_and_Set(int *pVar, int value) /* atomic machine instruction */
{
    int temp;

    temp = *pVar;
    *pVar = value;
    return(temp);
}

BeginRegion() /* Loop until safe to enter */
{
    while (Test_and_Set(&mutex, TRUE)) ;
    /* Loop until return value is FALSE */
}

EndRegion()
{
    mutex = FALSE;
}

```

FIGURE 52.7 Mutual exclusion using the test_and_set machine instruction.

The primary disadvantage of this approach is its use of busy waiting, thus wasting CPU resources. The use of busy waiting also allows for process starvation if multiple processes are contending for a critical region. Finally, deadlock is possible on a uniprocessor machine if a lower priority process gets interrupted in the middle of its critical region and then a higher priority process tries to gain access to the same critical region. The higher priority process busy waits forever because the lower priority process never runs. This is a situation of *priority inversion* where a lower priority process affects access to a resource by a higher priority process. It is typically solved by temporarily raising the priority of the lower priority process.

52.3.1.3 Operating System Support

All of the synchronization approaches shown thus far can be implemented with the bare features of the hardware. The approaches also cause busy waiting if another process already is in its critical region. *Semaphores*, an important synchronization primitive, can be constructed by adding process coordination support to the operating system. Semaphores are data structures consisting of an identifier, a counter, and a queue; where processes waiting on a semaphore are blocked and placed on the queue, processes signaling a semaphore may unblock and remove a process from the queue, and the counter maintains a count of waiting processes.

The concept of a semaphore was first introduced by Dijkstra (1968). Dijkstra defined two atomic semaphore operations: wait and signal, which he termed the P-operation (for wait; from the Dutch word *proberen*, to test) and the V-operation (for signal; from the Dutch word *verhogen*, to increment).

A restricted version of a semaphore, called a *binary semaphore*, limits the value of the counter to 0 and 1. However, the more general case is to use a *counting semaphore*, which has the following properties concerning the counter:

- A nonnegative count always means that the queue is empty.
- A count of negative n indicates that the queue contains n waiting processes.
- A count of positive n indicates that n resources are available and n requests can be granted without delay.

There are four basic operations defined for creating, deleting, waiting on, and signaling a semaphore.

1. `semid = semcreate(val)`: Create a semaphore with the given initial value for the counter.
2. `semdelete(semid)`: Delete a semaphore.

```

int semid;

Initialization()
{
    semid = semcreate(1); /* initialize the semaphore count to 1 */
}

BeginRegion()
{
    semwait(semid);
}

EndRegion()
{
    semsignal(semid);
}

```

FIGURE 52.8 Mutual exclusion using semaphores.

3. `semwait(semid)`: Wait on a semaphore. Decrement the semaphore counter. If the counter is negative, then suspend execution of the process and place it in the semaphore queue.
4. `semsignal(semid)`: Signal a semaphore. Increment the semaphore counter. Make the first process in the semaphore queue ready for execution.

Given these operations, a simple solution to the mutual exclusion problem is shown in Figure 52.8. Unlike previous solutions, a process waiting for its critical region does not busy wait. While it is waiting, it is in a suspended state, allowing the CPU to perform other activities. Because semaphores are provided by the operating system, they work correctly on either uni- or multiprocessor machines.

Semaphores also provide a mechanism to solve the bounded-buffer producer/consumer problem, which was introduced in the example of Figure 52.2. A solution for this problem using semaphores is shown in Figure 52.9. This solution ensures that the consumer process prints all integer values from 1 to 2000 by alternating between the producer and consumer.

Although semaphores provide straightforward solutions to both of these problems, semaphores themselves must be implemented in the operating system with lower level primitives such as the `Test_` and `_Set` machine instruction. Semaphores work well for processes, which are allowed to block, but must not be used in code that cannot block such as interrupt service routines.

52.3.1.4 Language Constructs

The solutions presented thus far to the mutual exclusion problem each require the programmer to take explicit action to ensure mutual exclusion. To guarantee mutual exclusion some programming languages provide constructs to implicitly guarantee mutual exclusion. One such construct is a *monitor* (Hoare 1974), which permits only one process to be executing in a monitor at a time.

Monitors are a programming language construct, similar to abstract data types in that the programmer defines a set of data types and procedures that can manipulate the data, procedures can be exported to other modules, and the system invokes an initialization routine before execution begins. Monitors differ in that they support guard procedures. When a process invokes a guard procedure, its execution is delayed until no other processes are executing a guard procedure within the monitor. The Java programming language supports monitors using the `synchronized` primitive on methods within a class to prevent threads from simultaneously access of these methods (Arnold et al. 2005). Figure 52.10 revisits the mutual exclusion problem of Figure 52.1 using a solution written in Java. The definition of a monitor guarantees that the variable `balance` is not updated and read simultaneously.

Monitors are a programming language construct that must be implemented using a lower level facility provided by the hardware or operating system, such as semaphores. Although monitors provide

```

int psem, csem; /* semaphores */
int n = 0;      /* shared by all processes */
main()
{
    int producer(), consumer();
    csem = semcreate(0); /* consumer initially blocks */
    psem = semcreate(1); /* producer initially allowed to run */
    CreateProcess(producer);
    CreateProcess(consumer);
    /* wait until done */
}
producer()
{
    int i;
    for (i=0; i<2000; i++) {
        wait(psem);
        n++; /* increment n by 1 */
        signal(csem);
    }
}
consumer()
{
    int i;
    for (i=0; i<2000; i++) {
        wait(csem);
        printf("n is %d\n", n); /* print value of n */
        signal(psem);
    }
}

```

FIGURE 52.9 Bounded-buffer producer/consumer problem with semaphores.

```

public class Account {
    private int balance;

    public Account() {
        balance = 0; /* initialize balance to zero */
    }

    // use synchronized to prohibit concurrent access of balance
    public synchronized void Deposit(int deposit) {
        int newbalance; // local variable

        newbalance = balance + deposit;
        balance = newbalance;
    }

    public synchronized int GetBalance() {
        return balance; /* return current balance */
    }
}

```

FIGURE 52.10 Mutual exclusion using Java monitors.

mutual exclusion, they need additional primitives to provide synchronization. To do so, monitors are defined to have condition variables, which are waited on and signaled similar to semaphores. Java provides a single, unnamed condition for a class with the `wait()` method used by a thread to wait on the condition and the `notify()` or `notifyAll()` methods to wake up one or all waiting threads. These primitives allow other synchronization problems such as the producer/consumer problem to be implemented with monitors.

52.3.1.5 Hybrid Solutions

Modern operating systems have migrated from monolithic systems written for a uniprocessor in which critical regions were used to access shared data structures. These critical regions were guarded by setting the interrupt level appropriately. Current operating systems must not only support multiprocessors but also provide real-time capabilities, thus leading to multithreaded designs. In these designs, the use of interrupts to control access to shared data does not work. Rather, these systems have moved to solutions using complex locks, which combine the use of spin locks with the semantics of semaphores.

As one example, the Solaris operating system uses adaptive mutex locks (Eykholt et al. 1992), a type of complex lock, to protect access to shared data among a set of threads. The adaptive lock starts out executing like a standard spin lock. If the lock is currently free, then the issuing thread immediately obtains the lock. However, if the lock is in use, then the operating system checks the status of the thread holding the lock. If this thread is currently in the run state (as could be the case on a multiprocessor), then the issuing thread continues in a spin lock waiting for what is expected to be a short time for the lock to be released. If the holding thread is not in the run state (as would always be the case on a uniprocessor), then the issuing thread is suspended until the lock is released. The rationale is to use a spin lock if the wait for the lock is expected to be short and to actually suspend the thread if the wait is expected to be longer.

This hybrid approach tries to minimize overhead and maximize performance. If the size of a critical region is large (hundreds of instructions), then the adaptive mutex lock is less desirable compared to a lock that simply causes a thread to suspend when the lock is not available.

Another hybrid solution is the Linux construct *futex* (fast userspace mutex) (Franke et al. 2002). This construct allows a task to acquire a lock without making a system call if there are currently no other tasks waiting for the lock, but if it fails to acquire the lock then a system call is made to wait.

Another type of complex lock used in multithreaded operating systems is a read/write lock. These locks allow either a single writer or multiple readers to simultaneously hold the lock, thus increasing the parallelism when reading of a shared data structure predominates. Writers must wait until all readers have released the lock before obtaining the lock, whereas readers are granted immediate access to the lock in the absence of a writer. To prevent starvation of a writer, all read requests after a write request has been issued are queued until the write request has been satisfied. Starvation of readers in the face of multiple writers is similarly avoided.

52.3.1.6 Earlier Solutions

Many other synchronization primitives were initially proposed, but in general can be expressed in terms of the solutions already given. A sampling of these earlier primitives are critical regions (Hansen 1972, Hoare 1972), serializers (Atkinson and Hewitt 1979), path expressions (Campbell and Habermann 1974), and event counts and sequencers (Reed and Kanodia 1979).

52.3.2 Interprocess Communication Mechanisms

As with synchronization, a variety of IPC mechanisms are available. The following discusses a number of these mechanisms and how they handle the IPC issues raised in Section 52.2.

52.3.2.1 Direct Message Passing

The simplest form of message passing is to send messages directly from one process to another. An example of this approach is the low-level message passing facility used in the Xinu operating system (Comer 2011). Where `send()` sends a fixed, integer-sized message to a specific process and `receive()` returns the last message sent to it. A process can buffer only one message. If `send()` detects a message already buffered at the process then it returns immediately with an error, not delivering the message. If no message is buffered, then `send()` buffers the message and readies the receiving process if it is waiting for a message. The `receive()` operation blocks if a message is not available.

Another direct message passing mechanism is implemented in Minix (Tanenbaum 1987) where `send()` sends the given message to a specific destination process and `receive()` receives a message from a particular process. The source process for `receive()` can contain a wildcard value of `ANY`, indicating that messages from any process are accepted. Messages are a fixed size, but there is no buffering. Rather the `send()` and `receive()` operations *rendezvous* so that both operations block until the receiving process has actually copied the message from the sender. The use of *rendezvous* explicitly synchronizes the execution of the sending and receiving process.

52.3.2.2 Mailboxes/Ports

Rather than send directly to process, a more common approach is to define another operating system abstraction called a *mailbox* (also referred to as a port). Mailboxes are buffers that hold messages sent by one process to be received by another process. Thus, there is indirect communication between the two processes. The primitives for handling messages are

- `send(mailbox, &message)`
- `receive(mailbox, &message)`

where `send()` buffers the message in the given mailbox and `receive()` removes a message from the mailbox.

As an example, the Unix operating system provides ports to allow for intra- and inter-machine communication between processes. Ports often represent well-known services where a server process binds to a port and client processes of the service send requests to the port. The port buffers communication sent to the buffer until it is read by the receiving process. The messages sent to the port can be of variable size.

Message passing can also be implemented by using shared memory and semaphores, illustrating the equivalence of synchronization and IPC primitives. Figure 52.11 shows message passing with shared memory and semaphores to implement a set of mailboxes. The mechanism uses fixed-size messages with each of four mailboxes containing eight message buffers. The `send()` operation blocks if there is no buffer space in the mailbox; similarly, the `receive()` operation blocks if there is no message available in the mailbox. The mutex semaphore is needed to guarantee that no more than one process tries to send to or receive from a mailbox at the same time. This semaphore would not be needed if only one process could send to and receive from a mailbox. The mutex semaphore would also not be needed if a mailbox contained only one buffer slot. This is also an example of a bounded-buffer producer/consumer problem where sending processes produce messages and receiving processes consume them.

52.3.2.3 Pipes

A special case of IPC is the pipe abstraction available, which was first available in the Unix operating system. A *pipe* is a unidirectional, stream communication abstraction. One process writes data to the write end of the pipe, and a second process reads data from the read end of the pipe. The pipe itself is a buffer between the two processes that causes the reader to block if no data are available and the writer to block if the buffer is full. As it implements a stream abstraction, there is no notion of fixed-size messages. A pipe is another example of a solution to the bounded-buffer producer/consumer problem where the writing process is a producer and the reading process is a consumer.

Figure 52.12 shows a simple example of the use of pipes in the Unix operating system. Pipes are typically requested and set up by a Unix command interpreter, but the example shows one process creating another process with `fork()` with a pipe between them. A string of characters is then written to and read from the pipe.

52.3.2.4 Events

Events provide synchronization via a primitive form of IPC. They allow a process to learn of an externally generated event. Environments with events may provide primitives for asynchronously handling

```

#define N 8                /* number of msgs buffered in a mailbox */
#define M 4                /* number of mailboxes */

Message mailboxes[M][N];  /* shared memory for mailboxes of messages */

int semidMsg[M];          /* message available */
int semidSlot[M];        /* slot available */
int semidMutex[M];       /* controls access to critical region */

Initialization()
{
    int i;
    for (i = 0; i < M; i++) {
        semidMsg[i] = semcreate(0); /* no messages are available */
        semidSlot[i] = semcreate(N); /* N slots are available for messages */
        semidMutex[i] = semcreate(1); /* one process can enter region */
        /* initialize indices for inserting/deleting in mailboxes[i] */
    }
}

send(int m, Message *pmsg) /* send message to mailbox m */
{
    semwait(semidSlot[m]); /* is a slot available */
    semwait(semidMutex[m]); /* enter critical region */
    addmessage(m, pmsg); /* add msg to circular queue for mailbox m */
    semsignal(semidMutex[m]); /* exit critical region */
    semsignal(semidMsg[m]); /* signal message available */
}

receive(int m, Message *pmsg) /* retrieve message from mailbox m */
{
    semwait(semidMsg[m]); /* is a message available */
    semwait(semidMutex[m]); /* enter critical region */
    removemessage(m, pmsg); /* remove next msg from queue for mailbox m */
    semsignal(semidMutex[m]); /* exit critical region */
    semsignal(semidSlot[m]); /* signal slot available */
}

```

FIGURE 52.11 Message passing with semaphores and shared memory.

events, synchronously handling events or synchronously handling one of multiple events. An example for each of these in Unix operating system is provided in the following.

Events for a Unix process are generated as software interrupts. They are similar to hardware interrupts in that when an interrupt of a process occurs, an interrupt handler routine corresponding to the type of interrupt is invoked. Interrupts are asynchronous so, when an interrupt is received, execution of the process stops and is restarted after the interrupt handling routine has been executed. Software interrupts are sent to a process using the process id of the process. Many interrupts are used for well-known functions such as when the user types the interrupt key, a child process completes, or an alarm scheduled by the process has expired.

Two routines are used to send and handle software interrupts:

- `SendInterrupt(pid, num)`: An interrupt of type `num` is sent to process `pid`. In the Unix operating system this routine is `kill()`.
- `HandleInterrupt(num, handler)`: This specifies that user supplied `handler` routine should be invoked when interrupt of type `num` occurs. Typical handlers are to ignore the interrupt, terminate the process, or execute a user supplied interrupt handler. In the Unix operating system, this routine is `signal()`.

```

#define DATA "hello world"
#define BUFFSIZE 1024

int rgfd[2];          /* file descriptors of pipe ends */

main()
{
    char sbBuf[BUFFSIZE];

    pipe(rgfd);       /* create a pipe returning two file descriptors */
    if (fork()) {     /* parent, read data from pipe */
        close(rgfd[1]); /* close write end */
        read(rgfd[0], sbBuf, BUFFSIZE);
        printf("Pipe contents: %s\n", sbBuf);
        close(rgfd[0]);
    }
    else {            /* child, write data to pipe */
        close(rgfd[0]); /* close read end */
        write(rgfd[1], DATA, sizeof(DATA)); /* write data to pipe */
        close(rgfd[1]);
        exit(0);
    }
}

```

FIGURE 52.12 Pipe example in the Unix operating system.

Figure 52.13 shows a sample program for the Unix operating system with software interrupts. It sets up two interrupt handlers for signals 1 and 2 and then goes into an infinite loop where it updates a counter and sleeps for 1 s. Figure 52.13 also shows a command line script with this program. Invoking the interrupt character from the command interpreter causes interrupt 2 to be sent to the process. The second invocation of the program causes it to be run in the background with a process id of 20822. The kill program is then used to send interrupts to the background process.

In some cases, it is desirable to wait for such events in a synchronous manner. Unix provides system calls that block a process until a given interrupt is received. For example, `sleep()` causes a timer to be set with the process blocking until the corresponding alarm software interrupt is generated. Similarly, the `wait()` system call blocks a process until a software interrupt signals the completion of a child process is generated.

In other cases, a process may need to wait for one from a number of events to occur. One example of this situation is a networked server, which may be looking to know when incoming data or connections from multiple network sockets are available while at the same time wanting a timeout event if none occur within a period of time. Figure 52.14 shows a sample function for the Unix operating system using the `select()` system call to multiplex the occurrence of multiple events where activity is detected on a file descriptor (socket) or the given timeout is reached. The function can be easily extended to handle detection of activity on multiple file descriptions.

52.3.3 Classic Problems

Two classic synchronization problems—the critical region and bounded-buffer producer/consumer—have already been discussed. A slight variation of the producer/consumer problem is to use an unbounded buffer, in which case the producer never blocks because the buffer never fills. Many other classic synchronization problems have been proposed and solved. The following describes two such problems.

52.3.3.1 Readers/Writers Problem

The readers/writers problem occurs when multiple readers and writers want access to a shared object such as a database. The problem was introduced in Courtois et al. (1971). In the problem, multiple

```

#include <signal.h>

int n;

main(int argc, char **argv)
{
    void InterruptHandler(), InitHandler();

    n = 0;

    signal(SIGINT, InterruptHandler); /* signal 2 */
    signal(SIGHUP, InitHandler);     /* signal 1 */
    while (1) {
        n++;
        sleep(1);                    /* sleep for one second */
    }
}

void InterruptHandler()
{
    printf("The current value of n is %d\n", n);
    exit(0);
}

void InitHandler()
{
    printf("Resetting the value of n to zero\n");
    n = 0;
}

% cc -o signalex signalex.c
% signalex
^C          (interrupt character)
The current value of n is 3
% signalex &
[1] 20822
% kill -1 20822
Resetting the value of n to zero
% kill -2 20822
The current value of n is 19
[1] Done          signalex

```

FIGURE 52.13 Software interrupt program and script in the Unix operating system.

```

int WaitForEvent(int fdIn, int timeout)
{
    fd_set bvfdr;
    struct timeval tv;

    tv.tv_sec = timeout; /* put timeout secs into timeval struct */
    tv.tv_usec = 0;
    FD_ZERO(&bvfdr);
    FD_SET(fdIn, &bvfdr); /* fd to look for input */
    /* size of bitmap to watch is one more than value of fdIn */
    return(select(fdIn+1, &bvfdr, 0, 0, &tv));
}

```

```

int readercount = 0;          /* number of readers currently reading */
int readermutex;            /* semaphore mutex for reader count */
int dbaccess;               /* semaphore to control access to database */

main()
{
    readermutex = semcreate(1); /* mutex for reader count */
    dbaccess = semcreate(1);   /* mutex for database */
    CreateProcess(reader);     /* create a reader process */
    CreateProcess(writer);     /* create a writer process */
}

reader()
{
    while (TRUE) {
        semwait(readermutex); /* get access to readercount */
        readercount++;        /* increment count */
        if (readercount == 1) /* if first reader ... */
            semwait(dbaccess); /* gain access to database */
        semsignal(readermutex); /* done with count */
        /* read database */
        semwait(readermutex); /* get access to readercount */
        readercount--;        /* decrement count */
        if (readercount == 0) /* if last reader ... */
            semsignal(dbaccess); /* relinquish access to database */
        semsignal(readermutex); /* done with count */
        /* use data read */
    }
}

writer()
{
    while (TRUE) {
        /* generate new data */
        semwait(dbaccess); /* gain access to database */
        /* update database */
        semsignal(dbaccess); /* relinquish access to database */
    }
}

```

FIGURE 52.15 Solution to the readers/writers problem with semaphores. Based on statements of the algorithm in Tanenbaum (2008). (From Tanenbaum, A., *Modern Operating System*, 3rd edn., Prentice Hall, Upper Saddle River, NJ, 2008.)

readers are allowed to access the database simultaneously, but a writer must have exclusive access to the database before performing any updates for consistency. A practical example of this problem is an airline reservation system with many readers and an occasional update of the information.

Figure 52.15 shows a solution to this problem for multiple reader and writer processes with semaphores. The solution allows multiple readers access to the database at a time. A writer process can gain access only after all reader processes have relinquished the database. The solution gives priority to reader processes, who can gain access to the database even if a writer process is already requesting access to the database. Solutions giving more balanced priority to each type of process can also be constructed as discussed in (Flynn and McHoes 2011).

52.3.3.2 Dining Philosophers Problem

The dining philosophers problem was proposed and solved by Dijkstra (1971). It consists of five philosophers sitting at a round table. Philosophers each have a bowl of rice in front of them and there is a chopstick in between each bowl (alternately, the problem is described using plates of spaghetti and forks).

FIGURE 52.16 Illustration of the dining philosophers problem.

The problem is illustrated in Figure 52.16 with the philosophers' bowls labeled A–E and the chopsticks 1–5. These philosophers have two functions in life: think, requiring no interaction with colleagues, and eat, requiring the philosopher to pick up the chopstick on the left and right.

This classic synchronization problem has potential for both deadlock and starvation (literally!). The straightforward solution for a philosopher to eat is to first pick up the left chopstick and then the right chopstick. However, if all philosophers pick up their left chopstick at the same time, they will all deadlock when they go to pick up their right chopstick. A simple modification to this approach is for the philosophers to put down the left chopstick if the right chopstick is not available, wait for some time, and try again. However, there is still a chance that the philosophers will operate in lock step and no philosophers will acquire both chopsticks. This condition is called *livelock* and occurs when attempts by two or more processes (philosophers) to acquire a resource (the left and right chopsticks) run indefinitely without any process succeeding. The dining philosophers problem will be used as a guide in the following discussion on deadlock and starvation.

52.3.4 Deadlock and Starvation

Deadlock occurs when a set of processes using shared resources are permanently blocked trying to gain access to those resources. Classic papers on this topic are Coffman et al. (1971) and Holt (1972). Zobel and Koch (1988) contains an annotated bibliography on the subject. Deadlock can occur with synchronization such as when two processes each need to gain access to two separate critical regions for execution. If one process gains access to the first critical region and the other process gains access to the second critical region, then these two processes will be in deadlock when they attempt to acquire the other needed critical region.

There are four principles used for dealing with the issue of deadlock in operating systems. These principles are prevention, detection, avoidance, and recovery and are summarized in Isloor and Marsland (1980). Solutions to the deadlock problem exemplifying these principles are described in the following. Each of these solutions prevents deadlock by precluding one or more of the four conditions for deadlock given in Section 52.2. The solutions are characterized as being conservative or liberal depending on the degree of concurrency they allow.

The most liberal solution is to allocate requested resources to processes if the resources are available. This approach was given as an initial solution when introducing the dining philosophers problem.

As was shown, it can lead to deadlock and requires that a deadlock detection process be periodically invoked. Deadlock detection involves detecting the circular wait condition through any algorithm for detecting cycles in directed graphs. Once deadlock occurs, a deadlock recovery method must be invoked either to take away resources from a victim process or to terminate the process altogether. In the dining philosophers problem, a recovery method would be to take away a chopstick from one of the philosophers.

At the other extreme, the most conservative deadlock prevention solution is *serialization*. This deadlock prevention approach guarantees no deadlock by allowing only one process to acquire resources at a time. In the dining philosophers problem, this approach means that only one philosopher is allowed to eat at any time. The approach prevents any concurrency and can lead to starvation if a philosopher is constantly passed over in obtaining chopsticks.

Another solution that allows more concurrency but still prevents deadlock is *one-shot allocation*. This approach requires that a process obtain all of its resources at once. Using this approach, a dining philosopher must obtain both chopsticks at the same time. It avoids deadlock by preventing the hold and wait condition. This solution prevents deadlock but not starvation. It also requires that a process obtain all of its resources at the same time even if it does not currently need all of them.

A still more liberal solution that prevents deadlock is *hierarchical allocation*. This solution requires that all resources have a number associated with them as in Figure 52.16. Hierarchical allocation prevents deadlock by requiring that processes can acquire only resources with a higher number than any resource it currently holds. Thus, in Figure 52.16, each philosopher must first acquire the left chopstick and then the right except for Philosopher E, who must first acquire the right chopstick. This solution is still conservative and requires processes to acquire resources not necessarily in the order they are needed but in the order resources are numbered. It avoids deadlock by preventing the circular wait condition.

As opposed to deadlock prevention, deadlock avoidance policies do not prevent deadlock a priori but monitor the allocation requests as they are made so as not to allow deadlock to occur. A solution using this approach is the *bankers algorithm* (also called the advanced claim algorithm) introduced in Dijkstra (1968). This solution is the most liberal that avoids deadlock but requires that each process know the maximum number from a class of resources that it may request at any time during execution. The algorithm performs as a banker giving out loans of money in that any resource requests are granted only if they

1. Do not exceed the total number of resources in a class
2. Do not exceed the maximum number of resources for that process
3. Lead to a *safe state* where a sequence of resource deallocations and allocations can allow all processes to complete without deadlock

52.4 Research Issues and Summary

The research issues in synchronization and IPC correspond to the movement toward multithreaded systems running in multiprocessor/core environments. The adoption of traditional synchronization primitives for these environments and the exploration of better primitives is leading to work on hybrid approaches for synchronization. This work has also extending to distributed environments.

Research work continues on extending synchronization primitives and defining new problems. The issue of performance is a key area as researchers seek to minimize the cost of busy waiting in shared memory multi-processors/cores by using virtual memory to reduce memory access costs. Other research is investigating optimal tradeoff between the use of busy waiting for a lock versus suspending the thread or process. Performance is also a research issue for IPC mechanisms in client/server systems as they execute in intra- and inter-machine environments.

An ongoing research issue is correctness, particularly as the synchronization problems of modern operating systems become more complex. Ad hoc synchronization and its associated problems continue

to exist (Xiong et al. 2010). Using language constructs to better encapsulate the synchronization details is being explored, but this approach can lead to tradeoffs with performance. Tools for detecting synchronization errors are also an ongoing area of research.

In summary, synchronization and IPC are fundamental to multiprogrammed operating system design. Many primitives to solve fundamental problems such as mutual exclusion and producer/consumer exist ranging from software only approaches, to special hardware instructions, to primitives constructed by the operating system and programming languages. Many of the primitives are equivalent in terms of their semantics, and one can be implemented in terms of another. Examples include implementing monitors with semaphores or message passing with shared memory and semaphores. Modern operating systems are using hybrid approaches, which adaptively switch between techniques according to the run-time operating environment.

Glossary

- Busy waiting:** Situation in synchronization when a process continuously polls the status of a condition variable.
- Critical region:** Set of instructions for a process that access data shared with other processes. Only one process may execute its critical region at a time.
- Deadlock:** Condition when a set of processes using shared resources or communicating with each other are permanently blocked.
- Interprocess communication (IPC):** Communication between two (or more) processes directly aware of each other.
- Livelock:** Condition when attempts by two or more processes to acquire a resource run indefinitely without any process succeeding.
- Mailbox:** An operating system abstraction containing buffers to hold messages. Messages are sent to and received from the mailbox by processes.
- Monitor:** Programming language construct providing abstract data types and mutually exclusive access to a set of guard procedures.
- Mutual exclusion:** A synchronization problem requiring that two or more concurrent activities do not simultaneously access a shared resource.
- Priority inversion:** Situation where a lower priority process affects access to a resource by a higher priority process.
- Race condition:** Situation where multiple processes access and manipulate shared data with the outcome dependent on the relative timing of these processes.
- Semaphore:** Synchronization primitive consisting of an identifier, a counter, and a queue where processes waiting on a semaphore are blocked and placed on the queue; processes signaling a semaphore may unblock and remove a process from the queue, and the counter maintains a count of waiting processes.
- Spin lock:** Mutual exclusion mechanism where a process spins in an infinite loop waiting for the value of a lock variable to indicate availability.
- Starvation:** Condition when a process is indefinitely denied access to a resource while other processes are granted access to the resource.
- Synchronization:** Situation when two or more processes coordinate their activities based upon a condition.

Further Information

Many good text books on operating systems, such as those by Silberschatz et al. (2012), Tanenbaum (2008), and Stallings (2012) exist, which describe problems, issues, and solutions for synchronization and IPC. The book *Principles of Concurrent and Distributed Programming* by M. Ben-Ari (1990)

contains a number of problems and worked out solutions for both concurrent and distributed programming. *Algorithms for Mutual Exclusion* by M. Raynal (1986) presents a comprehensive treatment of solutions for the mutual exclusion problem. Andrews and Schneider (1983) provide a survey of processes, synchronization, and interprocess communication.

The Association for Computing Machinery (ACM) Special Interest Group on Operating Systems (SIGOPS) publishes *Operating Systems Review* four times a year. This publication contains work on a variety of operating system topics including synchronization. This group also sponsors the biennial *ACM Symposium on Operating Systems Principles* that cover the latest developments in the field of operating systems. Its proceedings are published in an issue of *Operating Systems Review*. Another ACM publication, the *ACM Transactions on Computer Systems* is good source for relevant work.

The USENIX Association sponsors a number of conferences on operating system-related topics. A general technical conference is sponsored each year. Two conferences, the *Symposium on Operating Systems Design and Implementation (OSDI)* and *Workshop on Hot Topics in Operating Systems (HOTOS)* are specific to operating system issues.

53.1 Introduction

Disciplined concurrent programming can improve the structure and performance of computer programs on both uniprocessor and multiprocessor systems. As a result, support for *threads*, or lightweight processes, has become a common element of new operating systems and programming languages.

A thread is a sequential stream of instruction execution. A thread differs from the more traditional notion of a heavyweight process in that it separates the notion of execution from the other state needed to run a program (e.g., an address space). A single thread executes a portion of a program, while cooperating with other threads that are concurrently executing the same program. Much of what is normally kept on a per-heavyweight-process basis can be maintained in common for all threads in a single program, yielding dramatic reductions in the overhead and complexity of a concurrent program.

Concurrent programming has a long history. The operation of programs that must handle real-world concurrency (e.g., operating systems, database systems, and network file servers) can be complex and difficult to understand. Dijkstra (1968) and Hoare (1974, 1978) showed that these programs can be simplified when structured as cooperating sequential threads that communicate at discrete points within the program. The basic idea is to represent a single task, such as fetching a particular file block, within a single thread of control, and to rely on the thread management system to multiplex concurrent activities onto the available processor. In this way, the programmer can consider each function being performed by the system separately and simply rely on automatic scheduling mechanisms to best assign available processing power.

In the uniprocessor world, the principal motivations for concurrent programming have been improved program structure and performance. Multiprocessors offer an opportunity to use concurrency in parallel programs to improve performance, as well as structure. Moderately increasing a uniprocessor's power can require substantial additional design effort, as well as faster and more expensive hardware components. But once a mechanism for interprocessor communication has been added to a uniprocessor design, the system's peak processing power can be increased by simply adding more processors. A shared-memory multiprocessor is one such design in which processors are connected by a bus to a common memory.

Multiprocessors lose their advantage if this processing power is not effectively utilized. If there are enough independent sequential jobs to keep all of the processors busy, then the potential of a multiprocessor can be easily realized: each job can be placed on a separate processor. However, if there are fewer jobs than processors, or if the goal is to execute single applications more quickly, then the machine's potential can only be achieved if individual programs can be parallelized in a cost-effective manner. Three factors contribute to the cost of using parallelism in a program:

- *Thread overhead*: The work, in terms of processor cycles, required to create and control a thread must be appreciably less than the work performed by that thread on behalf of the program. Otherwise, it is more efficient to do the work sequentially, rather than use a separate thread on another processor.
- *Communication overhead*: Again in terms of processor cycles, the cost of sharing information between threads must be less than the cost of simply computing the information in the context of each thread.
- *Programming overhead*: A less tangible metric than the previous two, programming overhead reflects the amount of human effort required to construct an efficient parallel program.

High overhead in any of these areas makes it hard to build efficient parallel programs. Costly threads can only be used infrequently. Similarly, if arranging communication between threads is slow, then the application must be structured so that little interthread communication is required. Finally, if managing parallelism is tedious or difficult, then the programmer may find it wise to sacrifice some speedup for a simpler implementation. Few algorithms parallelize well when constrained by high thread, communication, and programming costs, although many can flourish when these costs are low.

Low overhead in these three areas is the responsibility of the thread management system, which bridges the gap between the physical processors (the suppliers of parallelism) and an application (its consumer). In this chapter, we discuss the issues that arise in designing a thread management system to support low-overhead parallel programming for shared-memory multiprocessors. In the next section, we describe the functionality found in thread management systems. Section 53.3 discusses a number of thread design issues. In Section 53.4, we survey three systems for shared-memory multiprocessors, Windows NT (Custer 1993), Presto (Bershad et al. 1988), and Multilisp (Halstead 1985), focusing our attention on how they have addressed the issues raised in this chapter.

53.2 Thread Management Concepts

53.2.1 Address Spaces, Threads, and Multiprocessing

An address space is the set of memory locations that can be generated and accessed directly by a program. Address space limitations are enforced in hardware to prevent incorrect or malicious programs in one address space from corrupting data structures in others. Threads provide concurrency within a program, while address spaces provide failure isolation between programs. These are orthogonal concepts, but the interaction between thread management and address space management defines the extent to which data sharing and multiprocessing are supported.

The simplest operating systems, generally those for older style personal computers, support only a single thread and a single-address space per machine. A single-address space is simpler and faster since

it allows all data in memory to be accessed uniformly. Separate address spaces are not needed on dedicated systems to protect against malicious users; software errors can crash the system but at least are localized to one user, one machine.

Even single-user systems can have concurrency, however. More sophisticated systems, such as Xerox's Pilot (Redell et al. 1980), provide only one address space per machine, but support multiple threads within that single-address space. Because any thread can access any memory location, Pilot provides a compiler with strong type checking to decrease the likelihood that one thread will corrupt the data structures of another.

Other operating systems, such as Unix, provide support for multiple-address spaces per machine, but only one thread per address space. The combination of a Unix address space with one thread is called a Unix *process*; a process is used to execute a program. Since each process is restricted from accessing data that belong to other processes, many different programs can run at the same time on one machine, with errors confined to the address space in which they occur. Processes are able to cooperate by sending messages back and forth via the operating system. Passing data through the operating system is slow, however; only parallel programs that require infrequent communication can be written using threads in disjoint address spaces.

Instead of using messages to share data, processes running on a shared-memory multiprocessor can communicate directly through the shared memory. Some Unix systems allow memory regions to be set up as shared between processes; any data in the shared region can be accessed by more than one process without having to send a message by way of the operating system. The Sequent Symmetry's DYNIX and Encore's UMAX (Encore 1986) are operating systems that provide support for multiprocessing based on shared memory between Unix processes.

More sophisticated operating systems for shared-memory multiprocessors, such as Microsoft's Windows NT and Carnegie Mellon University's Mach operating system (Tevanian et al. 1987), support multiple-address spaces *and* multiple threads within each address space. Threads in the same address space communicate directly with one another using shared memory; threads communicate across address space boundaries using messages. The cost of creating new threads is significantly less than that of creating whole address spaces, since threads in the same address space can share per-program resources. Figure 53.1 illustrates the various ways in which threads and address spaces can be organized by an operating system.

53.2.2 Basic Thread Functionality

At its most basic level, a thread consists of a program counter (PC), a set of registers, and a stack of procedure activation records containing variables local to each procedure. A thread also needs a control block to hold state information used by the thread management system: a thread can be *running* on a processor, *ready-to-run* but waiting for a processor to become available, *blocked* waiting for some other thread to communicate with it, or *finished*. Threads that are ready-to-run are kept on a *ready-list* until they are picked up by an idle processor for execution. There are four basic thread operations:

- *Spawn*: A thread can create or spawn another thread, providing a procedure and arguments to be run in the context of a new thread. The spawning thread allocates and initializes the new thread's control block and places the thread on the ready-list.
- *Block*: When a thread needs to wait for an event, it may block (saving its PC and registers) and relinquish its processor to run another thread.
- *Unblock*: Eventually, the event for which a blocked thread is waiting occurs. The blocked thread is marked as ready-to-run and placed back on the ready-list.
- *Finish*: When a thread completes (usually by returning from its initial procedure), its control block and stack are deallocated, and its processor becomes available to run another thread.

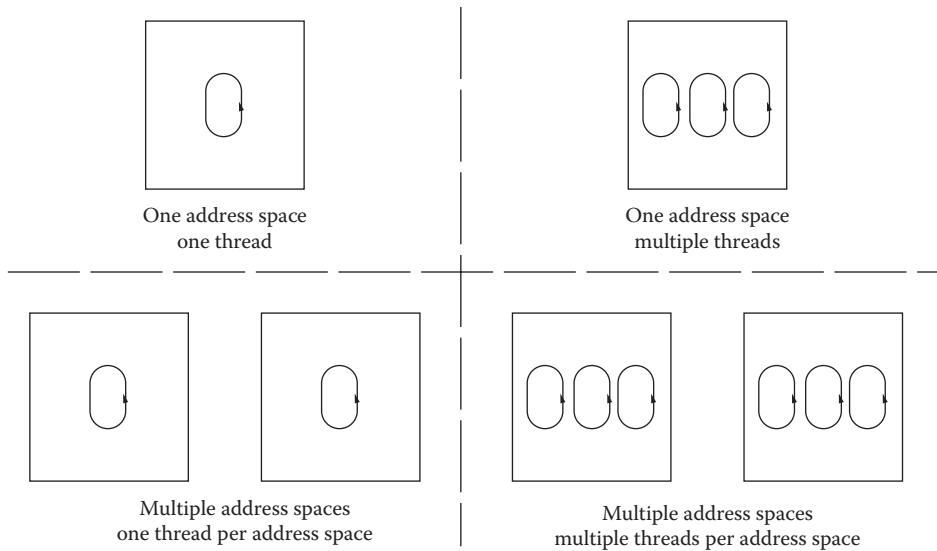

FIGURE 53.1 Threads and address spaces. MS-DOS is an example of a one address space, one thread system. A Java run-time engine is an example of one address space with multiple threads. The Unix operating system is an example of multiple-address spaces, with one thread per address space. Windows NT is an example of a system that has multiple-address spaces and multiple threads per address space.

When threads can communicate with one another through shared memory, *synchronization* is necessary to ensure that threads do not interfere with each other and corrupt common data structures. For example, if two threads each try to add an element to a doubly linked list at the same time, one or the other element may be lost, or the list could be left in an inconsistent state. *Locks* can solve this problem by providing mutually exclusive access to a data structure or region of code. A lock is acquired by a thread before it accesses a shared data structure; if the lock is held by another thread, the requesting thread blocks until the lock is released. (The code that a thread executes while holding a lock is called a *critical section*.) By serializing accesses, the programmer can ensure that threads only see and modify a data structure when it is in a consistent state. When a program's work is split among multiple threads, one thread may store a result read by another thread. For correctness, the reading thread must block until the result has been written. This data dependency is an example of a more general synchronization object, the *condition variable*, which allows a thread to block until an arbitrary condition has been satisfied. The thread that makes the condition true is responsible for unblocking the waiting thread.

One special form of a condition variable is a *barrier*, which is used to synchronize a set of threads at a specific point in the program. In the case of a barrier, the arbitrary condition is: Have all threads reached the barrier? If not, a thread blocks when it reaches the barrier. When the final thread reaches the barrier, it satisfies the condition and *raises* the barrier, unblocking the other threads.

If a thread needs to compute the result of a procedure in parallel, it can first spawn a thread to execute the procedure. Later, when the result is needed, the thread can perform a *join* to wait for the procedure to finish and return its result. In this case, the condition is: Has a given thread finished? This technique is useful for increasing parallelism, since the synchronization between the caller and the callee takes place when the procedure's result is needed, rather than when the procedure is called.

Locks, barriers, and condition variables can all be built using the basic block and unblock operations. Alternatively, a thread can choose to *spin-wait* by repeatedly polling until an anticipated event occurs, rather than relinquishing the processor to another thread by blocking. Although spin-waiting wastes processor time, it can be an important performance optimization when the expected waiting time is less

than the time it takes to block and unblock a thread. For example, spin-waiting is useful for guarding critical sections that contain only a few instructions.

53.3 Issues in Thread Management

This section considers the issues that arise in designing and implementing a thread management system as they relate to the programmer, the operating system, and the performance of parallel programs.

53.3.1 Programmer Issues

53.3.1.1 Programming Models

The flexibility to adapt to different programming models is an important attribute of thread systems. Parallelism can be expressed in many ways, each requiring a different interface to the thread system and making different demands on the performance of the underlying implementation. At the same time, a thread system that strives for generality in handling multiple models is likely to be well suited to none.

One general principle is that the programmer should choose the most restrictive form of synchronization that provides acceptable performance for the problem at hand. For coordinating access to shared data, messages are a more restrictive and, for many kinds of parallel programs, are a more appropriate form of synchronization than locks and condition variables. Threads share information by explicitly sending and receiving messages to one another, as if they were in separate address spaces, except that the thread system uses shared memory to efficiently implement message passing.

There are some cases where explicit control of concurrency may not be necessary for good parallel performance. For instance, some programs can be structured around a single-instruction multiple-data (SIMD) model of parallelism. With SIMD, each processor executes the same instruction in lockstep, but on different data locations. Because there is only one PC, the programmer need not explicitly synchronize the activity of different processors on shared data, thus eliminating a major source of confusion and errors.

Perhaps the simplest programmer interface to the thread system is none at all: the compiler is completely responsible for detecting and exploiting parallelism in the application. The programmer can then write in a sequential language; the compiler will make the transformation into a parallel program. Nevertheless, the compiled program must still use some kind of underlying thread system, even if the programmer does not. Of course, there are many kinds of parallelism that are difficult for a compiler to detect, so automatic transformation has a limited range of use.

53.3.1.2 Language Support

Threads can be integrated into a programming language; they can exist outside the language as a set of subroutines that explicitly manage parallelism; or they can exist both within and outside the language, with the compiler and programmer managing threads together.

Language support for threads is like language support for object-oriented programming or garbage collection: it can be a mixed blessing. On one hand, the compiler can be made responsible for common bookkeeping operations, reducing programming errors. For example, locks can automatically be acquired and released when passing through critical sections. Further, the types of the arguments passed to a spawned procedure can be checked against the expected types for that procedure. This is difficult to do without compiler support.

On the other hand, language support for threads increases the complexity of the compiler, an important factor if a multiprocessor is to support more than one programming language. Further, the concurrency abstractions provided by a single parallel programming language may not do quite what the programmer wants or needs, making it necessary to express solutions in ways that are unnatural or inefficient.

A reasonable way of getting most of the benefits of language support without many of the disadvantages is to define both a language and a procedural interface to the thread management system. Common operations can be handled transparently by the compiler, but the programmer can directly call the basic thread management routines when the standard language support proves insufficient.

53.3.1.3 Granularity of Concurrency

The frequency with which a parallel program invokes thread management operations determines its *granularity*. A *fine-grained* parallel program creates a large number of threads, or uses threads that frequently block and unblock, or both. Thread management cost is the major obstacle to fine-grained parallelism. For a parallel program to be efficient, the ratio of thread management overhead to useful computation must be small. If thread management is expensive, then only *coarse-grained* parallelism can be exploited.

More efficient threads allow programs to be finer grained, which benefits both structure and performance. First, a program can be written to match the structure of the problem at hand, rather than the performance characteristics of the hardware on which the problem is being solved. Just as a single-threaded environment on a uniprocessor can prevent the programmer from composing a program to reflect the problem's logical concurrency, a coarse-grained environment can be similarly restrictive. For example, in a parallel discrete-event simulation, physical objects in the simulated system are most naturally represented by threads that simulate physical interactions by sending messages back and forth to one another; this representation is not feasible if thread operations are too expensive.

Performance is the other advantage of fine-grained parallelism. In general, the greater the length of the ready-list, the more likely it is that a parallel program will be able to keep all of the available processors busy. When a thread blocks, its processor can immediately run another thread provided one is on the ready-list. With few threads though, as in a coarse-grained program, processors idle, while threads do I/O or synchronize with one another.

The performance of a fine-grained parallel program is less sensitive to changes in the number of processors available to an application. For example, consider one phase of a coarse-grained parallel program that does 50 CPU min worth of work. If the program creates five threads on a five-processor machine, the phase finishes in just 10 min. But if the program runs with only four processors, then the execution time of the phase *doubles* to 20 min: 10 min with four processors active followed by 10 min with one processor active. (Preemptive scheduling, which could be used to address this problem, has a number of serious drawbacks, which are discussed subsequently.) If the program had originally been written to use 50 threads, rather than 5, then the phase could have finished in only 13 min, a reasonable degradation in performance.

Of course, one could argue that the programmer erred in writing a program that was dependent on having exactly five processors. The program should have been parameterized by the number of processors available when it starts. But, even so, good performance cannot be ensured if that number can vary, as it can on a multiprogrammed multiprocessor. We consider further the issues of multiprogramming in the next section.

53.3.2 Operating System Issues

53.3.2.1 Multiprogramming

Multiprogramming on a uniprocessor improves system performance by taking advantage of the natural concurrency between computation and I/O. While one program waits for an I/O request, the processor can be running some other program. Because the processor and I/O devices are kept busy simultaneously, more jobs can be completed per unit time than if the system ran only one program at a time.

A multiprogrammed multiprocessor has an analogous advantage. Ideally, periods of low parallelism in one job can be overlapped with periods of high parallelism in another job. Further, multiprogramming

allows the power of a multiprocessor to be used by a collection of simultaneously running jobs, none of which by itself has enough parallelism to fully utilize the multiprocessor.

53.3.2.2 Processor Scheduling

Processor scheduling can be characterized by whether physical processors are assigned directly to threads or they are first assigned to jobs and then to threads within those jobs. The first approach, called *one-level* scheduling, makes no distinction between threads in the same job and threads in different jobs. Processors are shared across all runnable threads on the system so that all threads make progress at relatively the same rate. In this case, threads from all jobs are placed on one ready-list that supplies all processors, as shown in Figure 53.2. Although this scheme makes sense for a uniprocessor operating system, it has some unpleasant performance implications on a multiprocessor.

The most serious problem with one-level scheduling occurs when the number of runnable threads exceeds the number of physical processors, because preemptive scheduling is necessary to allocate processor time to threads in a fair manner. With preemption, a processor can be taken away from one thread and given to another at any time. In a sequential program, preemption has a well-defined effect: the program goes from the running state to the nonrunning state as its one thread is preempted. The effect of preemption on the performance of a sequential program is also well defined: if n CPU-intensive jobs are sharing one processor in a preemptive, round-robin fashion, then each job receives $1/n$ th of the processor and is slowed down by a factor of n (modulo the preemption and scheduling overhead).

For a parallel program, though, the effects of untimely processor preemption on performance can be more dramatic. In the previous section, we saw how a coarse-grained program can be slowed down by a factor of two when the number of processors is decreased from five to four. That program exemplified a problem that occurs more generally with preemption and barrier-based synchronization. The program had an implicit barrier, which was the final instruction in the phase. Until all threads reached that instruction, the program could not continue. When one processor was removed, it took twice as long to reach the barrier because not all threads within the job could make progress at an equal rate.

Preemptive multiprocessor scheduling also affects program performance when locks are used, but for a different reason than with barriers. Suppose a thread holding a lock while in a critical section is unexpectedly preempted by the operating system. The lock will remain held until the thread is rescheduled. As threads on other processors try to acquire the lock, they will find it held and be forced to block. It is even possible that, as more threads block waiting for the lock to be freed, the number of that job's runnable threads drops to zero and the application can make no progress until

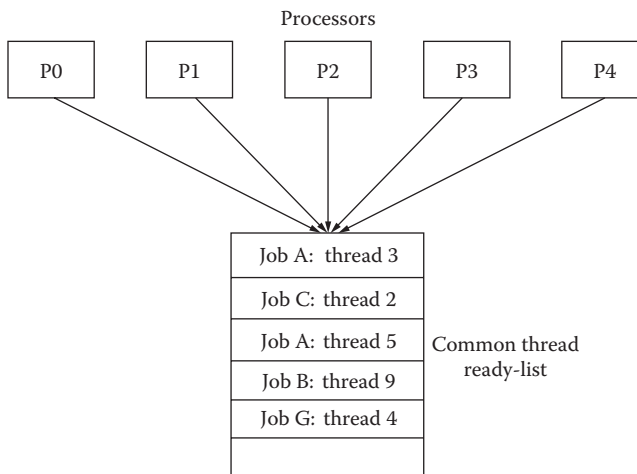

FIGURE 53.2 One-level thread scheduling.

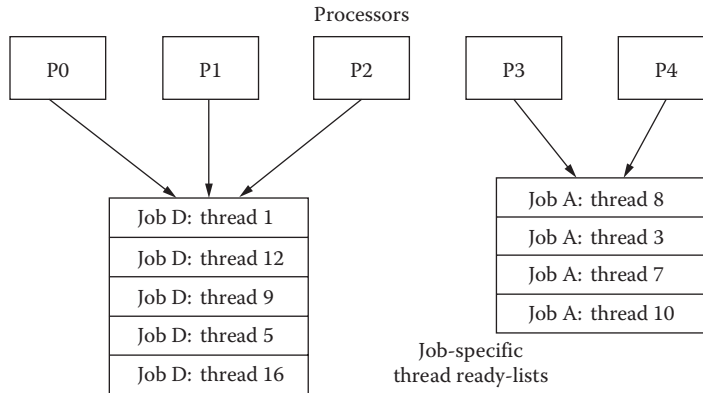

FIGURE 53.3 Two-level thread scheduling.

the preempted thread is rescheduled. The overhead of this unnecessary blocking and unblocking slows down the program's execution.

In the previous section, we saw how fine-grained parallelism can improve a program's performance by increasing the chance that a processor will find another runnable thread when its current thread blocks. Unfortunately, a fine-grained parallel program that packs the ready-list interacts badly with the behavior of a one-level scheduler. In particular, when a program's thread blocks in the kernel on an I/O request, the parallelism of the program can only be maintained if the kernel can schedule another of the program's threads in place of the one that blocked. This benefit, though, comes at the cost of increased preemption activity and diminished overall performance.

The problems of one-level scheduling are addressed by two-level schedulers. With a two-level scheduler, processors are first assigned to a job, and then threads within that job are executed only on the assigned processors. Each job has its own ready-list, which is used only by the job's processors, as shown in Figure 53.3. Thread preemption may no longer be necessary with a two-level scheduler since a preempted thread will only be replaced by another thread from the same job. Further, for long intervals, a processor runs only threads from the same application, and so the cost of switching between threads is kept low.

In a two-level scheduling system, processors can be allocated to jobs either statically or dynamically. A static two-level scheduler never changes the number of processors given to a job from its initial allocation; if some of those processors are needed by another job, the operating system must preempt all of the job's processors. A dynamic scheduler can adapt the number of processors assigned to each job according to changing conditions.

Dynamic two-level scheduling can give better performance, because it overlaps periods of poor parallelism in one job with periods of high parallelism in another. One difficulty with a dynamic scheduler is that it requires more information from an application describing the current processor requirements. As a result, though, dynamic scheduling can also more easily handle changes in the number of running jobs. For example, when a job finishes, its processors can be reallocated to a running job whose parallelism is increasing. To avoid the problems of one-level scheduling, though, it is crucial that the operating system coordinate with each application when it needs to preempt processors (e.g., to avoid preempting a processor when it would seriously affect performance). A dynamic scheduler always has the option, when it needs processors and no application has any available, of reverting to a static policy.

53.3.2.3 Kernel- versus User-Level Thread Management

Processor scheduling controls the allocation of processors to jobs. The operating system must be responsible for processor scheduling because processors are a hardware resource and shifting a processor from

one job to another involves updating per-processor address space hardware registers. Spawning a thread so that it runs on an already allocated processor, however, does not require modifying privileged state. Thus, thread management and scheduling within a job can be done entirely by the application instead of by the operating system. In this case, thread management operations can be implemented in an application-level library. The library creates virtual processors using the operating system's processor scheduling interface and schedules the application's threads on top of these virtual processors.

Unlike processor allocation, where a single systemwide scheduling policy can be used, thread scheduling policies benefit from being application specific. Some applications perform well if their threads are scheduled according to some fixed policy, such as first-in–first-out or last-in–first-out, but others need to schedule threads according to fixed or even dynamically changing priorities. For example, consider a parallel simulation where each simulation object is represented by its own thread. Different objects become sequential bottlenecks at different times in the simulation; the amount of parallelism can be increased by preferentially scheduling these objects' threads.

It is difficult to provide sufficient thread scheduling flexibility with kernel-level threads. While the kernel could define an interface that allows each application to select its thread scheduling policy, it is unlikely that the system designer could foresee all possible application needs.

Thread management involves more than scheduling. A trade-off exists between user- and kernel-level thread management. A user-level implementation provides more flexibility and better performance; implementing threads in the kernel guarantees a uniformity that eases the integration of threads with system tools.

The downside of having many custom-built thread management systems is that there is no standard thread. By implication, a kernel-level thread management system defines a single, systemwide thread model that is used by all applications. Operating systems that support only one thread model, like those that support only one programming language, can more easily provide sophisticated utilities, such as debuggers and performance monitors. These utilities must rely on the abstraction and often the implementation of the thread model, and a single model makes it easier to provide complete versions of these tools since their cost can be amortized over a large number of applications. Peripheral support for multiple models is possible, but expensive.

A standard thread model also makes it possible for applications to use libraries or canned software utilities. In the same sense that a standard procedure calling sequence sacrifices speed for the ability to call into separately compiled modules, a standard thread model allows one utility to call into another since they both share the same synchronization and concurrency semantics.

It is important to point out that two-level scheduling does not imply that threads are implemented at the application level; the job-specific ready queues shown in Figure 53.3 could be maintained either within the operating system or within the application. Also, a user-level thread implementation does not imply two-level scheduling, even though threads *are* being scheduled by the application. This implication only holds in the absence of multiprogramming or in cases where processors are explicitly allocated to jobs. For example, a user-level thread implementation built on top of Unix processes that share memory suffers from the same problems relating to preemption and I/O as do one-level kernel threads because both are scheduled in a job-independent fashion.

53.3.3 Performance

The performance of thread operations determines the granularity of parallelism that an application can effectively use. If thread operations are expensive, then applications that have inherently fine-grained parallelism must be restructured (if that is even possible) to reduce the frequency of those operations. As the cost of thread operations begins to approach that of a few procedure calls, several issues become performance critical that, for slower operations, would merely be second-order effects.

Simplicity in the thread system's implementation is crucial to performance (Anderson et al. 1989). There is a performance advantage to building multiple thread systems, each tuned for a single type of application.

Even simple features that are needed by only some applications, such as saving and restoring all floating point registers on a context switch, will markedly affect the performance of applications that do not need the functionality. Each context switch takes only tens of instructions; a feature that adds even a few more instructions must have a large compensating advantage to be worthwhile. For example, the ability to preemptively schedule threads within each job makes the thread management system more sluggish at several levels, because preemption must be disabled (and then re-enabled) whenever scheduling decisions are being made. These scheduling decisions are on the critical path of all thread management operations.

Although kernel-level thread management simplifies the generation and maintenance of system tools, it increases the baseline cost of all thread management operations. Just trapping to the operating system can cost as much as the thread operation itself, making a kernel implementation unattractive for high-performance applications. Further, the generality that must be provided by a kernel-level thread scheduler hurts the performance of those applications needing only basic service. Kernel-level threads are less able to cut corners by exploiting application-specific knowledge. With a user-level thread system, the thread management system can be stripped down to provide exactly the functions needed by an application and no more. User-level thread operations also avoid the cost of trapping to the kernel.

Other performance issues have less to do with what a thread system does than with how it goes about doing it. For example, using a centralized ready-list can limit performance for applications that have extremely fine-grained parallelism. The ready-list is a shared data structure that must be locked to prevent it from being modified by multiple processors simultaneously. Even if the ready-list critical sections consist only of simple enqueue and dequeue operations, they can become a sequential bottleneck, since there is little other work involved in spawning/finishing or blocking/unblocking a thread. For an application with thread overhead of 20% of the total execution time, and half of that overhead is spent accessing the ready-list, then its maximum speedup (the time of the parallel program on P processors divided by the time of the program on one processor) is limited to 10.

The bottleneck at the ready-list can be relieved by giving each processor its own ready-list. In this way, enqueueing and dequeueing of work can occur in parallel, with each processor using a different data structure. When a processor becomes idle, it checks its own list for work, and if that list is empty, it scans other processors' lists so that the workload remains balanced.

Per-processor ready-lists have another nice attribute: threads can be preferentially scheduled on the processor on which they last ran, thereby preserving cache state. Computer systems use caches to take advantage of the principle of *locality*, which says that thread's memory references are directed to or near locations that have been recently referenced. By keeping references close to the processor in fast cache memory, the average time to access a memory location can be kept low. On a multiprocessor, a thread that has been rescheduled on a different processor will initially find fewer of its references in that processor's cache. For some applications, the cost of fetching these references can exceed the processing time of the thread operation that caused the thread to migrate.

The role of spin-waiting as an optimization technique changes in the presence of high-performance thread operations. If a thread needs to wait for an event, it can block, relinquishing its processor, or spin-wait. A thread must spin-wait for low-level scheduler locks, but in application code, a thread should block instead of spin if the event is likely to take longer than the cost of the context switch. Even though context switches can be implemented efficiently, reducing the need to spin-wait, a hidden cost is that context switches also reduce cache locality.

53.4 Three Modern Thread Systems

We now outline three modern thread management systems for multiprocessors: Windows NT, Presto, and Multilisp. The choices made in each system illustrate many of the thread management issues raised in the previous section.

TABLE 53.1 Basic Operations of Thread Management Systems

Basic	Windows NT	Presto	Multilisp
Spawn	Thread_create; thread_resume	Thread::new; Thread::start	(Future...)
Block	Thread_suspend	Thread::sleep	Touch unresolved future
Unblock	Thread_resume	Thread::wakeup	When future is resolved
Finish	Thread_terminate	Thread::terminate	Resolve this future

The thread management primitives for each of these systems are shown in Table 53.1. The table is organized to indicate how the primitives in one system relate to those in the others, as well as those provided by the basic thread interface outlined in the Basic Thread Functionality section.

Windows NT is an operating system designed to support Microsoft Windows applications on uni-processors, shared-memory multiprocessors, and distributed systems. Windows NT supports multiple threads within an address space. Its thread management functions are implemented in the Windows NT kernel. Since NT's underlying thread implementation is shared by all parallel programs, system services such as debuggers and performance monitors can be economically provided.

Windows NT's scheduler uses a priority-based one-level scheduling discipline. Because Windows NT allocates processors to threads in a job-independent fashion, a parallel program running on top of the Windows NT thread primitives (or even a user-level thread management system based on those primitives) can suffer from anomalous performance profiles due to ill-timed preemptive decisions made by the one-level scheduling system.

Presto is a user-level thread management system originally implemented on top of Sequent's DYNIX operating system, but later ported to DEC workstations. DYNIX provides a Presto program with a fixed number of Unix processes that share memory. The Presto run-time system treats these processes as virtual processors and schedules the user's threads among them. Presto's thread interface is nearly identical to Windows NT's.

Presto is distinguished from most other thread systems in that it is structured for flexibility. Presto is easy to adapt to application-specific needs because it presents a uniform object-oriented interface to threads, synchronization, and scheduling. The object-oriented design of Presto encourages multiple implementations of the thread management functions and so offers the flexibility to efficiently accommodate differing parallel programming needs.

Presto has been tuned to perform well on a multiprocessor; it tries to avoid bottlenecks in the thread management functions through the use of per-processor data structures. Presto does not provide true two-level scheduling, even though the thread management functions (e.g., thread scheduling) are implemented in an application library accessible to the user; DYNIX, the base operating system, schedules the underlying virtual processors (Unix processes) any way that it chooses. Although a Presto program can request that its virtual processors not be preempted, the operating system offers no solid guarantee. As a result, kernel preemption threatens the performance of Presto programs in the same way as it does Windows NT programs.

Although Windows NT and Presto are implemented differently, the interfaces to each represent a similar style of parallel programming in which the programmer is responsible for explicitly spawning new threads of execution *and* for synchronizing their access to shared data. This style is not accidental, but reflects the basic function of the underlying hardware: processors communicating through shared memory. One criticism often made of this style is that it forces the programmer to think about coordinating many concurrent activities, which can be a conceptually difficult task.

Multilisp demonstrates how thread support can be integrated into a programming language in order to simplify writing parallel programs. In Multilisp, a multiprocessor extension to LISP, the basic concurrency mechanism is the *future*, which is a reference to a data value that has not yet been computed. The *future* operator can be included in any Multilisp expression to spawn a new thread that computes the value of the expression in parallel. Once the value has been computed, the future *resolves* to that value.

In the meantime, any thread that tries to use the future's value in an expression automatically blocks until the future is resolved. The language support provided by Multilisp can be implemented on top of a system like Windows NT or Presto using locks and condition variables.

With Multilisp, the programmer does not need to include any synchronization code beyond the future operator; the Multilisp interpreter keeps track of which futures remain unresolved. By contrast, using the Windows NT or Presto thread primitives, the programmer must add calls to the appropriate synchronization primitives wherever the data are needed. Multilisp, like Presto, uses per-processor ready-lists to reduce contention in scheduling operations.

53.5 Summary

This chapter has examined some of the key issues in thread management for shared-memory multiprocessors.

Shared-memory multiprocessors are now commonplace in both commercial and research computing. These systems can easily be used to increase throughput for multiprogrammed sequential jobs. However, their greatest potential—as yet not fully realized—is for accelerating the execution of single, parallelized programs.

As programmers make use of finer-grained parallelism, the design and implementation of the thread management system becomes increasingly crucial. Modern thread management systems must address the programmer interface, the operating system interface, and performance optimizations; language support and scheduling techniques for multiprogrammed multiprocessors are two areas that require further research.

54.1 Introduction

Virtual memory is one of the engineering triumphs of the computer age. In the 1960s, it became a standard feature of nearly every operating system and computer chip. In the 1990s, it became also a standard feature of the Internet and the World Wide Web (WWW). It was the subject of intense controversy after its introduction in 1959; today, it is such an ordinary part of infrastructure that few people think much about it.

Early programmers had to solve a memory *overlay problem* as part of their programming work. Early computers had very small amounts of random access memory (RAM) because storage technology was so expensive. Programmers stored a master copy of their programs (and data) on a secondary storage system—then a drum, today a disk—and pulled pieces into the RAM as needed. Deciding which pieces to pull and which parts of RAM to replace was called “overlaying.” It was estimated that most programmers spent half to two-thirds of their time planning overlay sequences. As a reliable method of automating, virtual memory had the potential to increase programmer productivity and reduce debugging by severalfold. Virtual memory was invented to automate solutions to the overlay problem.

Virtual memory was taken into the large commercial operating systems of the 1960s to simplify the new features of time-sharing and multiprogramming. The RAMs were considerably larger, sometimes allowing individual programs to be fully loaded. Virtual memory provided three additional benefits in these systems: it isolated users from each other, it allowed dynamic relocation of program pieces within RAM, and it provided read–write access control to individual pieces. These benefits were so for fault tolerance (Denning 1976) that virtual memory was used even when there was sufficient RAM for every program. Thus, the story of virtual memory is not simply a story of progress in automatic storage allocation; it is a story of machines helping programmers to protect information, reuse and share objects, and link software components.

The first operating system with virtual memory was the 1959 Manchester Atlas operating system (Fotheringham 1961, Kilburn et al. 1962). They called their virtual memory a “one-level store.” They simulated a large memory—sufficient to hold an entire program—by moving fixed-size pages of a large file on disk in and out of a small RAM. The system appeared as a large, slower RAM to its users. The term “virtual memory” soon superseded the original name because of an analogy to optics: a virtual image in a mirror or lens is an illusion, made from traces of a real object that is actually somewhere else.

54.2 Early Virtual Memory Systems

Electronic digital computers have always had memory hierarchies consisting of at least two levels (Figure 54.1):

1. The main memory, often called RAM, is directly connected to the central processing unit (CPU). RAM is fast and can keep up with the CPU. RAM is volatile; loss of power erases its contents. RAM is expensive.
2. The secondary memory is connected to RAM by a subsystem that implements “up” and “down” moves of blocks of data. It was originally rotating drums, and today it is usually rotating or solid state disks. It is persistent, meaning that data are written as magnetic or optical patterns that do not disappear until explicitly erased. It is much cheaper than RAM.

FIGURE 54.1 Two-level memory hierarchy. A processor executes a program from main memory. The entire program is held in the secondary memory (DISK), and segments of it are copied to the main memory (RAM) for processing. The overlay problem is to partition the program into segments and schedule their moves up and down the hierarchy. The manual work to construct a program’s overlay sequence doubles or triples the programming time from when no overlays are needed.

Today's disk technology is about a thousand (10^3) times cheaper per bit than RAM and about a million (10^6) times slower. These differentials make it a challenge to find a good trade-off between main and secondary storage. The goal is enough RAM to run programs at close to CPU speed and sufficient permanent storage for all data.

The secondary storage system can include other technologies such as solid state disks, CD/DVD recorders and players, flash memory sticks, tape backups, and remote Internet storage (such as dropbox.com). These non-disk secondary devices are not usually part of the virtual memory system.

Data on RAM or disk are organized into blocks of contiguous bytes. The blocks are units of storage and transfer between the memory levels. Many systems use all blocks of the same fixed size, called *pages*. A few systems allow blocks of different sizes, in which case they are called *segments*.

54.2.1 Address Mapping

The original purpose of virtual memory was to solve the burdensome overlay problem by automating the movement of pages between memory levels. The 1959 Atlas computer system at the University of Manchester was the first working prototype (Fotheringham 1961, Kilburn et al. 1962). The heart of this system was a radical innovation: a distinction between *address* and memory *location*. An address was the name of a byte, and a location was the physical storage holding the byte. This distinction enabled designers to provide programmers a large address space (AS) even though the system had a smaller amount of RAM. Programmers could then design software as if all the code and data fit into a single, contiguous AS.

This distinction led the Atlas designers to three inventions: (1) They built an *address translator*, hardware that automatically converted each address generated by the CPU to its current memory location. (2) They devised *demand paging*, an interrupt mechanism triggered by the address translator that moved a missing page from secondary memory to RAM. (3) They built the first *replacement algorithm*, a procedure to detect and move the least useful pages back to secondary memory.

Despite the success of the Atlas memory system, the literature of 1961 records a spirited debate about the feasibility of automatic storage allocation in general-purpose computers. By that time, Cobol, Algol, Fortran, and Lisp had become the first widely used higher level programming languages. These languages made storage allocation harder because programs were larger, more portable, more modular, and their dynamics more dependent on their input data. Through the 1960s, there were dozens of experimental studies that sought to either affirm or deny that virtual memory systems could do a better job at storage allocation than any compiler or programmer (Denning 1970). The matter was finally laid to rest—in favor of virtual memory—by an extensive study of system performance by an IBM research team led by David Sayre (Sayre 1969).

54.2.2 Multiprogramming

Convinced that virtual memory was the right way to go, the makers of major commercial computers adopted it in the 1960s. Virtual memory was in the IBM 360/67, CDC 7600, Burroughs 5500/6500, RCA Spectra/70, and Multics for the GE 645. By the mid-1970s, the IBM 370, DEC VMS, DEC TENEX, and Unix also had virtual memory.

All these systems used multiprogramming, a mode in which several programs simultaneously reside in RAM. Multiprogramming was intended for better CPU utilization and throughput: if a program stops for input-output, the CPU can switch to another program.

Virtual memory married nicely with multiprogramming. It gave a clean way to logically partition the RAM among multiple programs, preventing them from interfering with one another. This worked because the address translator in the CPU used a distinct mapping table for each program; the mapping table pointed only to the pages of that program's AS. The address translator also recognized access codes, thus protecting read-only pages from being overwritten.

54.2.3 Thrashing

But these design choices exacted an unexpected price. The first multiprogrammed virtual memory systems succumbed to an unexpected and most unwelcome surprise: *thrashing*. Thrashing was a condition of near-total performance collapse when the multiprogramming level became too high (Denning 1968). The performance collapse worked as follows. The system would be operating well, with good throughput. Occasionally, the activation of one additional program pushed the system over an edge into a state with extremely low throughput. Engineers soon determined that in this state, every job was waiting in the disk queue for a page to be moved; and when its page was moved, every job very quickly rejoined the queue with a new request. The engineers called this state “paging to death.” They did not understand the conditions that triggered it or how to design a load control that would prevent it.

The solution to thrashing lay with a new model of program behavior, called the *working set (WS) model* (Denning 1968). This model hypothesized that every program had a WS, a dynamic subset of pages that it needed in RAM for efficient execution; and that most of the time, the WS did not change much from one page reference to the next. Thrashing would be impossible as long as every program has its WS loaded in RAM. The operating system would not activate any new program whose WS could not fit into the unused part of RAM.

A series of early experiments confirmed the WS hypothesis and gave engineers insights on how to retrofit their multiprogrammed virtual memory systems to avoid thrashing. It also stimulated a long line of experiments and models seeking to understand why computations would exhibit locality, the principle behind the working-set behavior. By the late 1970s, these investigations had produced deep understanding of the principle of locality and had confirmed that working-set memory controllers would achieve throughput close to the theoretical optimum (Denning 1980).

New studies by Adrian McMenamin in 2011 for Linux reconfirmed the locality behavior of programs in modern systems and the efficacy of WS memory management (McMenamin 2011).

54.3 Cache Systems

The address mapping principle of virtual memory attracted hardware designers as well as software designers. In 1965, Maurice Wilkes proposed the *slave memory*, a small high-speed store included in the CPU to hold a small number of most recently used words from RAM (Wilkes 1965). Like virtual memory, slave memory used address translation, demand loading, and usage-based replacement. Wilkes argued that designing translation, loading, and replacement strategies is easier when the memory hierarchy is two forms of RAM: moving small blocks is efficient because of smaller speed differences. By exploiting the principle of locality, a small slave memory eliminates many data transfers between CPU and main memory, allowing the CPU to run much faster with hardly any increase of memory cost.

This idea became popular among hardware designers. IBM introduced a cache memory in 1968 as part of its 360/85 machine. IBM and others placed small caches in the CPU, enabling the CPU to run faster because it could bypass many accesses to RAM. Modern chips incorporate two levels of cache—L1 operates at register speed and simulates a large set of registers, while L2 operates at a slower speed and bypasses many references to RAM. Cache memory is now a standard principle of computer architecture (Hennessey and Patterson 1990).

The term *caching* is often used to mean that a small set of data are moved to a location close to the CPU, enabling the CPU to run fast on that set, bypassing delays in accessing the data at a larger distance away. Data and instructions cached in the CPU enable faster CPU execution. Files cached in disk controllers enable fast re-access to recently used files. Web pages cached on local servers enable faster re-display and bypass the longer access times in the Internet.

54.4 Object Systems

In the 1960s, virtual memory was seen as a method to make programming easier and more secure:

1. Programmers can write their code without having to worry about overlays, which are done automatically by the system.
2. Programmers can share memory without fear of interference from other programs.

If it ended here, this story would already have guaranteed virtual memory a place in history. But the designers of the 1960s saw even more possibilities to adapt virtual memory to make programming more productive and secure. They added two new programming objectives:

3. Programmers can share, reuse, or recompile any program module without requiring changes to any other program module.
4. Programmers can define abstract data types by specifying a package consisting of a hidden internal data structure to represent an object's state and procedures to access an object's state.

The first new objective was met by a *segmented AS*, an extension of the original linear AS. The second new objective was met by *capability-based architecture*, which later morphed into *object-oriented programming*. Both extended the basic virtual memory in important ways.

In 1965, the designers of Multics at MIT believed that programmer communities develop around interactive, time-shared computing systems, and that members of these communities want to share separately compiled program modules that can be linked together on demand (Dennis 1965, Organick 1972). Link-on-demand was a significant departure from the more common practice of using a linking loader (or makefile program) to bind component files to together into an AS.

In a computer with 32 bit addresses, an AS can contain up to 2^{32} addresses. Multics added a second dimension that selected one of 2^{32} ASs, called segments. Thus, a Multics CPU address consisted of a pair of 32 bit addresses (s, x) denoting segment s , offset x .

In Multics, a program encountering a symbolic reference to a variable X within a segment S would be interrupted by a *linkage fault*. The linkage fault handler would convert the S to a segment number s and the X to a linear offset x . After the conversion, the program would not encounter the same linkage fault again.

The Multics virtual memory demonstrated innovations in sharing, reuse, access control, and protection. Many of its innovations, however, did not find their way beyond Multics; programmers were content with one private, linear AS and a handful of open files. As will be discussed, the WWW (Berners-Lee 2000) changed this: programs and documents contain *hypertext links*: symbolic pointers to other objects that are not linked until the program references them for the first time.

In 1966, Jack Dennis and Earl Van Horn published a landmark paper that initiated a new line of computer architectures: machines that helped programmers create protected managers of classes of objects. They anticipated what is now called object-oriented programming. They were especially concerned that objects be freely reusable and shareable and, at the same time, be protected from unauthorized internal access. They proposed an extension of virtual memory that used two levels of mapping instead of one to get to an object. The first level maps an object name to a persistent global identifier, called a *capability*, for the object. The second level maps the capability to the object's location. Capabilities acted as tickets granting access to their objects. You could share an object by giving another person a copy of your capability for the object. Capability addressing offered an elegant solution to the problem of sharing and reusing modules.

Several commercial and academic capability systems were built in the 1970s: notably the Plessey 250, IBM System 38, Cambridge CAP, Intel 432, SWARD, and Hydra. These systems implemented capabilities as long addresses (for example, 64 bits), which the hardware protected from alteration (Fabry 1974, Myers 1982, Wilkes and Needham 1979). The reduced instruction set computer, coupled with programming languages with type checking, made capability-managing hardware obsolete by the mid-1980s.

But software-managed capabilities, now called *handles*, are indispensable in modern object-oriented programming systems, databases, and distributed operating systems (Chase et al. 1994). The same conceptual structure reappeared in a proposal to manage objects and intellectual property in the Internet (Kahn and Wilensky 1995). It is a powerful structure indeed.

54.5 Virtual Memory in Other Systems

Some people wonder why virtual memory, which was so popular and ultimately successful in the operating systems of the 1960s and 1970s, was not present in initial versions of several new technologies of the 1980s:

- Personal computers (PCs)
- Highly parallel supercomputers
- Distributed memory computers
- WWW

These technologies emerged from new communities that initially had no contact with the earlier generation of operating systems or rebelled against that generation. PC developers, for example, distanced themselves from mainframe companies because they wanted computing affordable to an individual home user. They did not have the memory capacity or knowhow to implement a full operating system and often believed they could do much better with extreme simplicity. After a few years, however, they rediscovered the same programming issues that motivated the early operating system designers. They started to use locality and virtual memory to improve their productivity and build faster machines.

For PCs, the pundits of the microcomputer revolution proclaimed that PCs would not succumb to the diseases of the large commercial operating systems; the PC would be simple, fast, and cheap. Bill Gates once said that no user of a PC would ever need more than 640 K of main memory. His first Microsoft operating system, DOS (1982), did not include most of the common functions, such as multiprogramming and virtual memory. Eventually, the PC makers (Apple, Microsoft, and IBM) added multiprogramming and virtual memory to their operating systems. They were able to do this because the major chip makers had not lost faith; Intel offered virtual memory and cache in its 80386 chip in 1985; Motorola did likewise in its 68020 chip. Apple offered multiprogramming in its MultiFinder and virtual memory in its System 6 operating system. Microsoft offered multiprogramming in Windows 3.1 and virtual memory in Windows 95. IBM offered multiprogramming and virtual memory in OS/2.

A similar pattern appeared in the early development of distributed-memory multicomputers beginning in the mid-1980s. These machines allowed for a large number of computers, sharing a high-speed interconnection network, to work concurrently on a single problem. Around 1985, Intel and N-Cube introduced the first hypercube machines consisting of 128 component microcomputers. Shortly thereafter, Thinking Machines produced the first commercial supercomputer of this genre, the Connection Machine, with as many as 65,536 component computer chips. These machines soon challenged the traditional supercomputer by offering the same aggregate processing speed at a much lower cost (Denning and Tichy 1990). Their designers initially eschewed virtual memory, believing that address translation and page swapping would seriously detract from the machine's performance. But they quickly encountered new programming problems in synchronizing processes on different chips and exchanging data among them. The ordinary method of passing a message to another chip involved three copy operations: first from the sender's local memory to a local buffer, then across the network to a buffer in the receiver, and finally to the receiver's local memory. With virtual memory, the same transfer takes one copy, invoked at the time of reference. Virtual memory significantly decreased communication costs in these machines. Tannenbaum (1995) describes a variety of implementation issues under the topic of distributed shared memory.

The WWW, started in 1989 by Tim Berners-Lee, sought to link together all information in the world. It accomplished this by creating a virtual AS for objects in the WWW. The name of an object is given by its *uniform resource locator* (URL). The Web protocols (such as hypertext transfer protocol [HTTP] and

domain name service [DNS]) map URLs to hosts and files in the Internet. The mapping operations are performed only when someone tries to use a URL by clicking a mouse on it. The URL differs from a standard virtual address map because it is possible that a URL points to a nonexistent object or possibly to a new object given the same name as a previously deleted object. To avoid the problem of URLs becoming invalid when the object's owner moves it to a new machine, Kahn and Wilensky proposed that objects be named by global persistent handles; handles are translated with a two-level mapping scheme first into a URL, then into the machine hosting the object (Denning and Kahn 2010, Kahn and Wilensky 1995). The handle scheme recalls the Dennis-Van-Horn capability system of the 1960s, but now with worldwide, decentralized mapping systems. The Java language allowed URLs to address programs as well as documents; when a Java interpreter encounters the URL of another Java program, it brings a copy of that program to the local machine and executes it as an applet. These technologies, now seen as essential for the Internet, vindicate the view of the Multics designers in 1965—that many large-scale computations will consist of many processes roaming a large space of shared objects.

In the Internet, some objects such as Web pages or Web sites become very popular and attract many links. People using the links can create a high demand for a site, causing a queue of backlogged requests and thus a significant delay to a user wanting a fast access to the site. Even though the Internet architecture is relatively flat—the access time (“ping time”) to most sites is typically 20–30 ms—queueing at popular sites can cause very slow response times much longer than 30 ms. Caching solves this problem. A cache server can be placed in a cluster of users where it collects their recent web page requests; it can satisfy many repeat requests locally without going to the main site and its long queue. The company Akamai has become a leader in this performance-enhancing technology for the Internet.

From time to time over the past 50 years, various people have argued that virtual memory is not really necessary because advancing memory technology would soon permit us to have all the RAM we could possibly want. Each new generation of users has discovered that its ambitions for processing, memory, and sharing led it to virtual memory. It is unlikely that today's predictions of the passing of virtual memory will prove to be any more reliable than similar predictions made every year since 1960. Virtual memory accommodates essential patterns in the way people use computers to communicate and share information. It will still be used when we are all gone.

54.6 Structure of Virtual Memory

Let us now examine the structure of virtual memory systems. We will begin with the simplest form, a paging system, which was historically the first form.

Virtual memory was originally designed to solve the overlay problem in systems with two levels of memory. In 1959, the time of the first virtual memory, main memory (RAM) access times were about 10^{-6} s (1 μ s) and secondary memory (drum) access times were about 10^{-2} s (10 ms), giving a speed ratio of about 10^4 . A single-page fault (up-move) would force the CPU be idle for about 10^4 instructions, a stiff penalty. The designers, therefore, sought replacement policies that would minimize the number of page faults. The situation is worse today, with RAM access times around 10^{-9} s and disk around 10^{-3} , for a speed ratio of 10^6 . These speed ratios do not make virtual memory very attractive for those who believe that its primary purpose is to move pages up and down the hierarchy.

All virtual memories are based on the principle of distinguishing addresses from locations, and providing a dynamic map that translates an address to its storage location. The map can be updated whenever the location changes.

Every program and its data must fit inside a virtual AS, which is a sequential set of addresses that the CPU can generate. If addresses are k bits long, the AS consists of 2^k bytes, designated $0, 1, \dots, 2^k - 1$. Thus, 16 bit addresses can span a space of 65,536 bytes. Today, 32 bit addresses are common, spanning spaces of about 4 gigabytes.

It would be too costly to build a mapping table that mapped individual bytes to their locations. With 32 bit addresses, such a table would require 4 gigabytes of memory. A system with 64 running user

programs would require around a terabyte of memory just for the 64 mapping tables. The size of mapping tables is significantly reduced by dividing AS into equal size blocks, called *pages*, and the RAM into same-size blocks, called *frames*. The table maps pages to frames. If the page size were 1024 bytes (10^{10}), the mapping table would be smaller by a factor of 1024. Such tables are feasible.

The mapping is organized as follows. A *page table* contains entries of the form, one for each page:

$$(P, U, M, A, B)$$

where

- *P* is a *presence bit* set to 1 when the page is in RAM
- *U* is a *use bit* set to 1 when the page is read or written
- *M* is a *modified bit* set to 1 when the page is written
- *A* is an *access code* indicating read or write permission
- *B* is the *base address* of the page in RAM

A virtual address of the CPU is encoded as

$$(i, x)$$

meaning page *i*, line *x*. This address is translated to a memory address by adding the displacement *x* to the page's base address *B*.

With the help of Figure 54.2, let us walk through the components of a paged virtual memory. The circled numbers in the figure flag four key elements. Every virtual AS has its own page table; by

FIGURE 54.2 Structure of paged virtual memory system. The four numbered elements are discussed in the text.

default there are no shared pages. The CPU register AS points to page table the CPU uses for address mapping on behalf of the process it is currently running.

54.6.1 Element 1: Providing the Virtual Address to the Memory Mapping Unit

The memory mapping unit (MMU) is a hardware component that translates virtual addresses to memory locations. A virtual address is a linear offset into the AS. The high order bits of the virtual address in register VA are interpreted as a page number and the low order bits as a line number. An example will show how this works. Assume a page size of $2^{10} = 1024$ bytes in a system with 32-bit addresses. In this case, the virtual AS will contain $2^{22} = 4$ million pages. In a 32-bit address, the 22 high-order bits are page number and 10 low order bits are the line number in the page. Thus, address 8044 will be on page 7, line 876, because $8044 = (7)(2^{10}) + 876$.

54.6.2 Element 2: Mapping the Address

The MMU's job is to map the incoming virtual address to a memory location. The MMU looks up the frame for the current page in the page table. In our example, the page table has one entry per page for a total of 2^{22} entries. If page 7 is in frame 50, the base field B of the page table entry for page 7 will contain 50, which we can write as $PT[d,7].B = 50$. The MMU decomposes the target address 8044 into the two components (7,876), retrieves 50 from page table entry 7, and then presents the location address (50,876) to the RAM.

The P -bit of a page table entry records whether the page is present in RAM. If page 7 is not present, its P -bit will be 0. In that case, the MMU cannot map the virtual address. Instead, it halts with an error condition called *page fault*. The page fault condition triggers an interrupt, which passes control to an operating system routine called *page fault handler* (PFH). The operation of PFH will be discussed shortly at step 4.

54.6.3 Element 3: Checking the Translation Lookaside Buffer

The translation lookaside buffer (TLB) is a small set of high-speed associative registers attached to the MMU. Its purpose is to enable the MMU to bypass the page table lookup as often as possible. Without it, the virtual memory would run at half the rated RAM speed because every virtual address requires two RAM accesses.

A typical register in TLB contains the three components

$$(i, A, B)$$

where

- i is the page number (the tag in the TLB)
- A is the access code from the page table
- B is the frame number from the page table

Before accessing the page table, the MMU checks the TLB for an entry tagged as page i . If it finds such an entry, it immediately retrieves the access code A and the frame number B without having to look them up in the page table. If it does not find an entry for i , it proceeds with the normal page table lookup as described earlier and also creates a new TLB entry reflecting that access. The new entry replaces the least recently used (LRU) TLB entry.

Experience shows that with a relatively small TLB—from 32 to 128 registers—the MMU can achieve a sufficiently high hit rate in the TLB that the average slowdown for page table lookups is 1%–3% (Hennessey and Patterson 1990).

54.6.4 Element 4: Managing the RAM Contents

The operating system maintains a complete copy of a program's AS on the disk. The operating system also specifies a RAM allocation as a maximum number of pages from the AS. Thus, RAM contents are a subset of disk contents.

A page fault is an exceptional condition generated by the MMU when it encounters a missing page ($P = 0$). The operating system interrupts the running program and instead runs a special routine called PFH, which follows these steps:

1. Locates the needed page in the secondary memory
2. Uses a replacement policy to select a frame of main memory to put that page in
3. Empties that frame
4. Copies the needed page into that frame
5. Updates the page table entry to reflect these changes
6. Restarts the interrupted program, this time, allowing it to complete its reference

The replacement policy (step 2) has a significant effect on performance of a virtual memory system. Replacement policies generally try to predict which pages are most likely to be reused in the immediate future and protect them from replacement. Because recently used pages tend to be the most likely to be reused soon, the replacement policy identifies the pages with $U = 0$ as candidates for replacement. Among those, it favors one with $M = 0$ because an unmodified page does not need to be copied back to disk.

While no replacement policy can give a perfect prediction of the future, many years of experience and experiment have led to the consensus that the LRU policy is best when RAM allocations are fixed, and the WS policy is best when RAM allocations can vary (Denning 1980, McMenamin 2011).

54.6.5 Summary

Virtual memory makes address translation transparent to the programmer. Since the operating system maintains the contents of the map, it can alter the correspondence between pages and frames dynamically. A program can now be executed on a wide range of system configurations, from small to large main memories, without recompiling it.

54.7 Cache Memories

The caching principle used in the TLB was first proposed by Wilkes (1965) as a direct hardware method for speeding up memory accesses for pages already loaded in RAM (Figure 54.3). The cache contains a set of "slots," each the size of a page. A tag associated with a slot indicates which frame of RAM is copied in that slot. When the MMU of the processor generates location address (b,x) —meaning frame b line x —the cache hardware searches all of the tag registers in parallel for a match on b . If there is a match, it addresses byte x of that slot. If not, the hardware copies frame b into a slot, sets the slot's tag to b , and then addresses byte x of that slot (see Hennessey and Patterson 1990).

Note how the virtual memory mapping principle has been applied to components of the virtual memory system itself. The TLB is a cache of recent (page and frame) paths; a match bypasses the page table lookup. The slot-cache holds copies of recently used RAM frames; a match bypasses the RAM access. The TLB and cache access times are much faster than the corresponding RAM times. The virtual system will demonstrate significant accelerations with these caches, even when they are a small fraction of their maximum potential size. The costs of cache are small compared to full memory size.

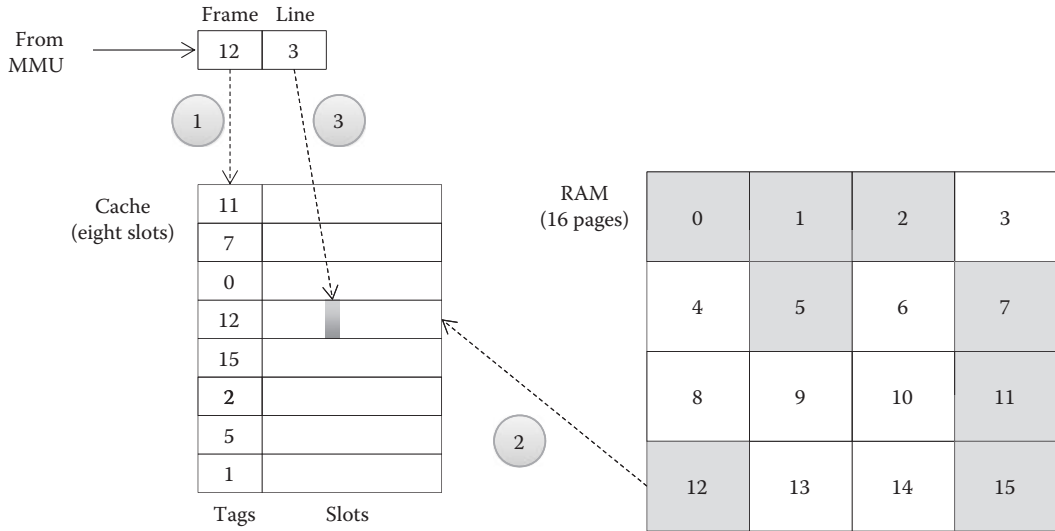

FIGURE 54.3 In a cache memory, the slots hold copies of RAM frames, and the tags indicate which frame is in a slot. The cache hardware searches the tag registers in parallel for a match on the addressed page (1). If no match is found, a page is loaded into the least recently used cache slot (2). Then, the line number selects a byte of that page (3). The search can be accelerated by dividing the tags into 2^m sets, using the m low-order bits of the frame number to select the set, and restricting the parallel search to that set (the figure is drawn for $m = 0$.) This partitions the frames equally among the sets and thereby limits the number of slots into which a given frame may be placed. In the worst case, when 2^m equals the number of cache slots, the set size is 1, and each block can be loaded into one slot only.

54.8 Multiprogramming

Multiprogramming is a mode of operation in which the RAM is shared simultaneously by multiple jobs. The set of pages a job has in RAM is called its resident set (or partition). The resident sets of all loaded jobs partition the RAM into disjoint subsets of frames.

Multiprogramming was originally introduced in the operating systems of the 1960s as a means to improve the utilization of a CPU: When a job stops to wait for an event, such as reading a file from a disk, the CPU can switch to another job ready to go. In the 1990s, multiprogramming was extended to allow each user to start and load multiple jobs in RAM. Users could switch among active programs such as word processor, spreadsheet, mail, and browser. Because virtual memory confines each process to its assigned AS, it provides an elegant and flexible way of partitioning a multiprogrammed memory.

Multiprogramming can be done with fixed or variable partitions. Fixed partitions are easier to implement but variable partitions offer much better performance. With variable partitions, the operating system can adjust the size of the partition so that the rate of page faults stays within acceptable limits. The operating system can transfer space from processes with small memory needs to processes with large memory needs. Variable partitions often improve over fixed even when the variation is random (Denning 1980). System throughput will be near optimal when the virtual memory guarantees each active process just enough space to hold its WS (Denning 1980).

54.9 Performance and the Principle of Locality

We can discuss performance of virtual memory systems in terms of decisions about loading and replacing pages. Loading refers to the actions that bring a page into main memory. Most systems load pages only on demand because they have no reliable method of predicting future page use. Because the time

to load a page is usually 6 orders of magnitude higher than the time to access a loaded page, a few bad predictive guesses are more expensive than simply waiting for page faults. However, in some cases, enough is known about future references that pages can reliably be loaded ahead of time; for example, an application doing a long, linear scan of a database.

Replacement refers to the actions of removing pages from RAM. Each removal has a cost because most pages will be recalled into RAM by future page references. Because this is an ongoing process—removal followed by recall—replacement is a major determinant of virtual memory performance.

The main metrics of system performance are *throughput* and *response time*. Throughput is measured as jobs or transactions completed per second and response time as the average number of seconds to complete a job or transaction after submission.

The main metric of memory usage is *space-time*, which is the total number of page-seconds accumulated by a job while it holds RAM. Space-time is a like “rent” paid by a job for memory usage. There is a relation between throughput and space-time. It is called the space-time law and works as follows. If C jobs complete in T seconds, the throughput is $X = C/T$. When the total memory is M bytes, the total space-time available in the system is MT , and therefore the space-time per job is $Y = MT/C = M/X$. Thus, $M = XY$. This invariant relation is fundamental: it says that minimizing space-time is the same as maximizing throughput for a given amount of main memory. For this reason, the ideal of a replacement policy is minimizing the space-time of each job.

When a job holds RAM, it circulates among servers of the system for pieces of service it needs to complete. These servers include disks, directories, network requests, printing devices, and more. Each service delay accumulates some space-time toward the job’s total. The delays caused by page faults are only a subset of all the delays contributing to space-time. Still, reducing the number of page faults will reduce a job’s total space-time.

The parameters of system usage outside of virtual memory are normally unaffected by paging within the virtual memory. Therefore, the minimum space-time occurs when the page faults are minimum. The ideal policy—let us call it MIN—replaces the page that will not be used again for the longest time (Belady 1966). This policy causes the intervals between page faults to be as long as possible, which minimizes total number of page faults.

MIN requires advance knowledge of the future. Because such knowledge is not usually available, replacement policies use past observations to predict future references. The predictions are necessarily imperfect.

The LRU replacement policy predicts that time until next reference to a page is same as time since last reference. Although not as good as MIN, LRU has been found to be quite robust over a range of programs, typically doing as well or better than other common policies, such as first-in-first-out (Belady 1966). LRU is often used in caches. A simple memory scan approximates LRU well: a pointer cycles through all the pages in the job’s resident set, skipping over those with usage bit $U = 1$ (and resetting to $U = 0$), until it finds an unused page.

If we remove the constraints that memory size is fixed and that replacements occur only at page-fault times, we can do better than MIN. The ideal variable-space policy—let us call it VMIN—operates as follows (Prieve and Fabry 1974). After each page reference, VMIN looks ahead to the moment of the next reference to that page: if the time to that reference exceeds a threshold T , VMIN immediately replaces the page; otherwise, it retains the page in memory until that next reference. As T gets larger, VMIN retains more pages and generates fewer page faults. Thus, the parameter T trades off the amount of memory used against the amount of paging generated. The reason no other policy can do as well is that VMIN minimizes space-time at every reference: VMIN retains a page only if the cost of recovering it by page-fault at the next reference exceeds the cost of retaining it.

The WS model gives a good approximation to VMIN (Denning 1968, 1970, 1980). A process’s WS is defined as the set of pages referenced in a window of size T references looking backwards from the current time. The WS replacement policy guarantees that every page of the WS is in RAM.

Under WS replacement, a page reference causes a page fault only if the time since prior reference to that page exceeds T . In other words, WS replacement generates exactly the same faults as VMIN. The difference between WS and VMIN is due solely to the extra space-time generated by WS for retaining pages for T seconds when the time until next reference exceeds T . The space-time “overshoot” is worst during a change of locality: VMIN unloads the pages of the current locality set prior to the change to the new locality set, while WS keeps the former locality set in memory for a while after the change. Many researchers looked at ways to reduce this overshoot, but none gave much benefit. The WS policy is about as close to optimal as can be found among non-lookahead replacement policies.

The WS policy works especially well suited for multiprogramming. All jobs use a common window size T . The scheduler admits waiting processes to the RAM, one at a time, until the RAM space is filled with WSs. The global window size T can be adjusted empirically until it maximizes system throughput. System throughput may improve further by using a customized window size for each running process—but the space-time improvement is at most 5%–10% (Denning 1980).

Working-set memory management became popular because it prevented a system instability called *thrashing* (see Figure 54.4). Many early virtual memory systems attempted to extend the LRU policy to the entire memory by keeping track of the reference times of all pages in RAM. Extended this way, LRU is subject to thrashing because the normal cycles of the scheduler cause a process’s pages to look old by before it gets its next time slice. Extended LRU does not have a built-in load limit like the WS policy. Thrashing can be avoided by limiting the multiprogramming level either by a fixed limit or by a working-set policy. The working-set policy generally leads to more stable performance with higher throughput.

These replacement policies all do well because of the *principle of locality*. This principle says that a computation tends to reference the same pages in the immediate future as it referenced in the immediate past.

FIGURE 54.4 The system throughput is depicted as a function of the multiprogramming level N , which is the number of active programs in RAM. When N is too large, programs have too little space for their working sets. This drives the paging rates up, turns the disk into the bottleneck, and dramatically slows down the system. The slowdown is called thrashing. The WS policy is ideal; it holds N near the throughput peak but does not allow it to fall off the thrashing cliff.

In fact, computations tend to reference from the same subset of pages over extended intervals. The memory usage of a computation can be represented as a sequence

$$(L_1, P_1), (L_2, P_2), \dots, (L_k, P_k), \dots$$

where

L_i is a “locality set”

P_k is the length of time the computation uses only that set (P_k is called the phase time)

Abrupt changes in locality sets at phase transitions are the norm. This principle accounts for the success of WS policies: the backward looking window T is usually much smaller than the phase times, and thus the WS sees the current locality set most of the time. In this way, WS reveals the pages that need to stay in RAM in the immediate future (Denning 1980).

Over the years, it became clear that locality is a deep principle of computing. It accounts for the universal success of caches in every form, whether as part of a virtual memory, a Web browser, or an edge server in the Internet. By 1980, we knew that locality is a product of the way the human mind works—notably its tendencies to pay attention to the same things for a while and to divide big problems into smaller pieces for separate solution (Denning 1980).

In 2010, Moshe Vardi cited some new thinking on the question, “What is an algorithm?” (Vardi 2012). He cites a work of Yuri Gurevich, who defines an algorithm as a description of an abstract state machine, where states can be any data structure, and each operation can cause only a bounded change of state. By limiting the effect of an operation to a local set, this definition pulls the principle of locality into a fundamental definition of computation. Without locality, there is no computation. Locality has long been accepted as a fundamental principle of memory behavior, but it has never been so clearly linked to effective computation. By definition, every computation exhibits locality; some form of backward window can observe the pages of the current locality set and exempt them from replacement.

54.10 Object-Oriented Virtual Memory

Many computing environments offer abstractions and functions that require virtual addressing, but which are not easily accommodated by paging. These include

- Program objects—arrays, procedures, structures, and objects
- System objects—processes, message buffers, files, directories, and streams
- Concurrent processes (threads) with varying permissions sharing the same AS
- Modular programs
- Very large ASs containing many objects shared among many users

The designers of early virtual memories anticipated these uses with segmented and capability-based virtual memories (Dennis 1965, Dennis and Van Horn 1966, Fabry 1974). The resulting storage systems are called object-oriented virtual memories. The Internet, an example of the last bullet, was not anticipated in the 1960s, but the addressing principles discovered then contributed to solutions of its addressing problems.

The earliest form of object-oriented virtual memory was the segmented AS. It appeared as a collection of named blocks (segments) of various sizes. Each segment was a container for a program object. In the Burroughs B5000 and later series, for example, the Algol compiler created program segments containing procedures and data segments containing array rows (Organick 1973). The compiler generated virtual addresses of the form (i, x) , meaning segment i , line x . The size of each segment was explicitly recorded in the mapping table, so that the mapper could reject out-of-bounds addresses x .

Multics went further than the Burroughs Algol compiler. It let the programmer define the segments. In Multics PL/I, operands had symbolic two-part names $S.X$; the operating system used a

linkage fault to invoke a routine that mapped a symbolic name to its corresponding virtual segment number s and line number x (Organick 1972).

54.10.1 Two-Level Mapping

In recognition that paging led to much simpler virtual memory structures, Multics combined segmentation with paging. It allowed each segment to be divided into pages. The offset into a segment was subdivided into a page and line number. It used a *two-level map* as follows to resolve an address (s,x) :

1. The segment number s selects a *segment table* entry, which points to a page table for the segment. There is one segment table for each AS.
2. The offset x decomposes into a page number and line number, which are mapped through the page table as before. There is one page table for each segment.

The two-level mapping scheme makes it easy to share segments. Users simply share the segment's page table. Users sharing a segment are likely to get different local segment numbers for their segment tables; but all those segment table entries point to the *same* page table. When it moves a page, the operating system records the new location in the page table. Instantly, all users sharing the page are mapped correctly to the new location. There is no need for the operating system to locate all the users and update their segment mapping tables.

Inspired by Dennis and Van Horn (1966), Robert Fabry formalized the two-level mapping scheme to allow any number of users to share any number of objects in large systems (Fabry 1974). Fabry's addressing principle is summarized in Figure 54.5. The key idea is that the first level of mapping takes a segment number i to a system handle h ; the second level takes a handle to a descriptor of the storage

FIGURE 54.5 The two-level mapping scheme replaces a page table with two tables. The capability list $CL[d]$ explicitly lists objects accessible in domain d . Each entry in CL consists of a tag, an access code, and a handle. The tag identifies the type of object (such as file or directory), the access code the type of access allows (such as read or write), and the handle is the unique global system name for the object. The descriptor table DT is a list of descriptors for every object in the system. This example shows a standard segment with base b and length k . A handle h is passed through a hash function to localize it within the DT for fast mapping. Although the full addressing sequence 1-2-3-4 requires several RAM accesses, the key elements of the path, (T,A,B,L) , can be cached in the TLB for fast future lookup.

space holding the object (Fabry used the terms “capability,” where we now say “handle”). All information about the location of an object is recorded in the descriptor; any changes instantly affect anyone trying to use the object.

54.10.2 Protection of Handles and Objects

In the two level mapping system, a program that holds a handle can access the object regardless of whether it has permission to do so. In other words, having a handle confers permission to access the object.

Because the mere fact of holding a handle was like having super-user privilege to the designated object, the designers of early capability addressing systems thought that handles had to be heavily protected by the hardware from alteration. They saw no other way to prevent someone from manufacturing a handle pointing to someone else’s files or to prevent an erroneous program from corrupting a handle. Some early commercial systems such as Plessey 250 or IBM 360/38 used hardware protection for capabilities. The Cambridge CAP system, a research project, also used hardware protection but concluded that hardware protection led to unwieldy complexity in the operating system (Wilkes and Needham 1979). Eventually, operating system structures were discovered that hid handles from users, thus prevent tampering or alteration, without special hardware protection. For example, file and directory handles are stored in directories, where the user can invoke them by giving their symbolic names; but the handles themselves never enter the user’s virtual AS.

One of the fundamental requirements of an operating system is that users cannot interfere with each other. That means, by default, they cannot see each other’s ASs. The virtual memory system plays an integral role in meeting this requirement. The images of ASs are always in disjoint regions of main memory. This property of virtual memory is called *logical partitioning*.

With simple virtual memory (Figure 54.2), a processor can address only the pages listed in its page table. With extended virtual memory (Figure 54.5), a processor can address only the objects listed in its capability list. In either case, unlisted objects are inaccessible. In effect, the operating system walls each process off, giving it no chance to read or write the private objects of any other process.

The mapping mechanisms further restrict individual accesses to those permitted by the access codes in the mapping tables. Thus, a read-only page or segment cannot be modified, or a read-only directory cannot be searched.

54.10.3 Protection of Procedures

One of the biggest vulnerabilities of systems is that procedures can be called incorrectly. The normal call puts the CPU instruction pointer to a designated “entry point” of the procedure. But a buggy or malicious calling program can transfer to some other location in the procedure, causing erroneous operation or bypassing security checks at the procedure’s entry. The designers of early capability systems therefore provided *protected entry*, a method to guarantee that a procedure call could only start the CPU at the authorized entry point.

It is straightforward to structure a capability system to provide a protected entry operation (Dennis and Van Horn 1966, Wulf et al. 1974). An instruction “ENTER i ” works only if object i (in the caller’s domain $d1$) is an enter capability. An enter capability points to the capability list of a new domain $d2$. Object “0” in every domain’s capability is the domain’s entry procedure. The effect of the enter instruction is to call the entry procedure of the target domain, simultaneously making its capability list the current capability list used by the CPU. The caller’s domain and instruction pointer are saved on the stack and restored when the called procedure returns (Figure 54.6).

These structures have important benefits for system fault tolerance. Should a process run amok, it can damage only its own objects: a program crash does not imply a system crash. An untrusted program can be encapsulated in a domain whose capability list contains only the objects it needs to execute;

FIGURE 54.6 Protected entry into a protection domain is easily implemented in a capability system. The user in domain $d1$ has a domain enter capability (tag e) with enter permission (en) that points to another domain $d2$. By convention the first entry in every domain (object “0”) is a procedure (tag p) with execute permission (ex) to be automatically invoked when the domain is called. The instruction “ENTER i ” causes a procedure call on object “0” in the new domain, and the capability list of the new domain becomes the current capability list.

any erroneous or malicious actions cannot access or damage anything outside this encapsulated domain. Systems that support this structure have found it effective against Trojan horses and other malware.

These benefits are so important that many systems use virtual memory even if they have sufficient RAM to eliminate overlaying.

54.11 Distributed Shared Memory

Starting in the mid-1980s, Sequent, Intel, Thinking Machines, N-Cube, and then later IBM, Cray, Kendall Square, and a few others introduced commercial multicomputers. These machines allowed for a large number of computers, sharing a high-speed interconnection network, to work concurrently on a single problem. Multicomputers soon began to challenge the traditional supercomputer by offering the same aggregate processing speed at a much lower cost (Denning and Tichy 1990).

In the mid 1990s, new operating systems like Beowulf provided the means to distribute tasks among ordinary computers registered as a cluster on a network. A large problem can be divided into numerous small problems for the cluster to solve, and their respective answers combined back into an answer to the original problem. Clusters provide supercomputer-grade processing power by mobilizing a large number of ordinary computers.

These new architectures introduced a host of new programming problems having to do with synchronizing the processes on the different computers and exchanging data among them. Because these systems offered no common AS among all of the component computers, their programmers could share data only by copying it between machines. That causes high message overhead.

Much of the overhead can be eliminated if the multicomputers all share an AS. Now data can be passed from one computer to another simply by passing the virtual address. The cost of moving a single pointer is much less than copying the entire object from one AS to another.

A virtual memory organized in this way is often referred to as *distributed shared memory* because the shared AS is composed from the RAMs of the individual computers (Tannenbaum 1995). Examples of such systems today include OpenSSI and MOSIX.

54.12 World Wide Web: A Global Name Space

The WWW allows an author to embed, anywhere in a document, a link to any file in the Internet. The link contains a URL, which is the symbolic name of a file. By clicking the mouse on a URL string, the user triggers the operating system to map the URL to the file and then bring a copy of that file from the remote server to the local workstation for viewing.

A URL is a string of the form *hostname/pathname*, where *hostname* identifies an Internet host, and *pathname* the name of a file in that host's directory system. Since hostnames and pathnames are unique, the URL names a single object anywhere in the Internet. Tim Berners-Lee invented URLs for the WWW. They define a scheme for naming objects that can be shared anywhere in the Web. The HTTP maps a hostname to its IP address (using the DNS) and sends a read-request message containing the pathname to that machine.

The URL system has a drawback that often causes problems: the URL names are not persistent. For example, if an owner deletes a file, any URL pointing to it will, by design, no longer function. However, if that owner creates a different file of the same name later, anyone holding the old URL will now get a copy of the new file. This means that a URL cannot be guaranteed to point to the same file as it did when a user first acquired it. Many service providers, notably publishers, want a naming system that uniquely identifies each published object and guarantees that the unique identifier will never point to another object.

The handle system (*handle.net*) was invented in 1995 by Robert Kahn to provide persistent names for objects. The most well known use of the handle system is with *digital object identifiers* (DOIs) that are of the form *A/B*, where *A* is a numerical string assigned by a DOI registrar to a publisher, and *B* is a unique numerical string assigned by the publisher (Denning and Kahn 2010). For example, the author's paper about WSs (Denning 1968) has DOI 10.1145/363095.363141, where "10.1145" is ACM's unique identifier assigned by the DOI Foundation, and "363095.363141" is a number chosen by ACM to distinguish that paper from every other that ACM has ever published, or ever will. ACM provides a server that translates DOI's to the current URLs of the papers. Thus, invoking the Web address "http://doi.acm.org/10.1145/363095.363141" will get a copy of the paper. ACM can change the URLs, but no matter where ACM actually stores the paper the DOI will always find it.

The handle system (including DOI's) is functionally similar to the handles described earlier in the extended, object-oriented virtual memory. The difference is that no attempt is made to hide the handles from users.

54.13 Conclusion

Virtual memory systems are used to meet one or more of these needs:

- *Automatic storage allocation*: Solving the overlay problem that arises when a program exceeds the size of the computational store available to it. Furthermore, it includes the problems of relocation and partitioning arising with multiprogramming.
- *Logical partitioning*: Each process is given access to a limited set of objects, its protection domain. The operating system enforces the rights granted in a protection domain by restricting references to the memory regions in which objects are stored. Processes cannot access objects beyond those listed in its local mapping tables.
- *Access control*: Within a protection domain, the operating system enforces further restrictions by permitting only the types of reference stated for each object (for example, read, write, or apply a function). These constraints are easily checked by the hardware in parallel with the main computation.

- *Encapsulation and protected entry*: Any untrusted software can be encapsulated in its own protection domain. Any unauthorized action will be automatically blocked by the access controls. It will be impossible to attempt access to any object outside the protection domain.
- *Modular programs*: Programmers should be able to combine separately compiled, reusable, and shareable components into programs without prior arrangements about anything other than interfaces and without having to link the components manually into an AS.
- *Object-oriented programs*: Programmers should be able to define managers of classes of objects and be assured that only the manager can access and modify the internal structures of objects (Myers 1982). Objects should be freely shareable and reusable throughout a distributed system (Chase et al. 1994, Tannenbaum 1995). (This is an extension of the modular programming objective.)
- *Data-centered programming*: Computations in the WWW tend to consist of many processes navigating through a space of shared, mobile objects. Objects are bound to a computation on demand.
- *Parallel computations on multicomputers*: Scalable algorithms that can be configured at run time for any number of processors are essential to mastery of highly parallel computations on multicomputers. Virtual memory joins the memories of the component machines into a single AS and reduces communication costs by eliminating some of the copying inherent in message passing.

Virtual memory, once the subject of intense controversy, it is now so ordinary that few people think much about it. Its original purpose—automating solutions to the overlay problem—is today less important than its extended purposes for sharing and access objects in large name spaces. The success of virtual memory is tied directly to the principle of locality, which is a fundamental principle of computation itself. Virtual memory is an enduring technology.

Key Terms

- Access control**: A means of allowing access to an object based on the type of access sought, the accessor's privileges, and the owner's wishes.
- Address fault**: An error that halts the mapper when it cannot locate a referenced object in main memory; it invokes an interrupt, whose handler corrects the condition by loading the missing object.
- Address map**: A table that associates an object (or page) number with the main memory locations containing the object.
- Address space**: The set of all addresses that a processor can issue while processing a program.
- Bounds fault**: An error that halts the mapper when it detects that the offset requested into an object exceeds the object's size; it invokes an interrupt that terminates the program.
- Capability**: A systemwide unique identifier for an object; the bits of a capability are protected from alteration.
- Context-switch**: An operation that switches the CPU from one process to another by saving all of the CPU registers for the first and replacing them with the CPU registers for the second.
- CPU**: Central processing unit or processor.
- Data-centered view**: A view of computing that emphasizes navigation of many concurrent processes within a large space of objects.
- Handle**: A systemwide unique identifier for an object, like a capability without the system guarantee of integrity.
- Location**: A memory register with its own address.
- Logical partitioning**: A property of virtual memory, whereby the address spaces of different jobs are mapped into disjoint regions of memory.
- Main memory**: The highest level of the memory hierarchy; all CPU memory references are directed to main memory; CPU can access objects only when they are loaded in main memory.

- Memory hierarchy:** A system of memory devices of different speeds and capacities; allows for trading off between capacity and speed, and between volatility and persistence.
- Memory space:** The set of all hardware addresses of memory locations in RAM available to a given address space.
- Modular programming:** Programs are divided into parts that can be shared, reused, and recompiled without affecting other parts of the system as long as the interfaces to modules are unchanged.
- Object-oriented addressing:** A form of virtual addressing in which object numbers are mapped to memory regions and internal object references are mapped to offsets within an object's memory region.
- Object-oriented programming:** A form of programming in which data are organized into classes of objects, each with a specific set of functions that can be applied to the objects.
- Page:** a fixed size unit of storage and transfer in a memory hierarchy.
- Page frame:** A contiguous block of memory locations used to hold a page.
- Paging:** A method of virtual memory in which address space and memory space are paged.
- Partition:** A division of memory space into disjoint subsets of pages for each address space.
- PC:** Personal computer.
- Permissions:** Access rights granted by an object's owner and represented as bits in the object's access code.
- Process:** An abstraction of the execution of a program, usually represented as the sequence of values of its CPU state as the program traces through its instruction sequence.
- Processor-centered view:** A view of computing that emphasizes the work of a processor.
- Protection fault:** An error condition detected by the address mapper when the type of request is not permitted by the object's access code.
- Response time:** The time from when a command is submitted to a computer until the computer responds with the result.
- RAM:** Random access memory.
- RISC:** Reduced instruction set computer (e.g., PowerPC, Sun SPARC, DEC Alpha, and MIPS).
- Secondary memory:** Lower, large capacity level of a memory hierarchy, usually a set of disks.
- Segmentation:** An approach to virtual memory when the mapped objects were variable-size memory regions rather than fixed-size pages.
- Slave memory:** A hardware cache attached to a CPU, enabling fast access to recently used pages and lowering traffic on the CPU-to-main-memory bus.
- Space-time:** The accumulated product of the amount of memory and the amount of time used by a process.
- Thrashing:** A condition of performance collapse in a multiprogramming system when the number of active programs gets too large.
- Throughput:** The number of jobs (or transactions) per second completed by a computer system.
- TLB:** Translation lookaside buffer, a cache that holds the most recently followed address paths in the mapper.
- Two-level map:** A two-tiered mapping scheme; the upper tier converts local object numbers into system unique handles, and the second tier converts handles to the memory regions containing the objects essential for sharing.
- URL:** Uniform resource locator (in the WWW).
- Working set:** The smallest subset of a program's pages that must be loaded into main memory to assure acceptable processing efficiency; changes dynamically.
- Working-set (WS) policy:** A memory allocation strategy that regulates the amount of main memory allocated to a process, so that the process is guaranteed a minimum level of processing efficiency.
- World Wide Web (WWW):** A set of servers in the Internet and an access protocol that permits fetching documents by following hypertext links on demand.

55.1 Introduction

The memory on a computer is organized into a hierarchy of storage. This storage ranges from small and fast to large and slow. Figure 55.1 shows a typical hierarchy. It is composed of two main parts: the primary store and the secondary store.

The main components of this hierarchy are the following:

1. The first level of the primary store is the *cache memory hierarchy*. It is often contained on the same chip as the central processing unit (CPU) or on other nearby chips that can be connected to the CPU with a minimum of delay. Because it must be able to run at close to the speed of the CPU, with access times of as little as a few nanoseconds, cache memory is typically small, rarely exceeding a few megabytes (Mbytes). The cache is never used for permanent storage; it holds values that are actively being processed by the CPU.
2. The second level of the primary store is the *main memory* on the computer. It currently runs with access times of 40–80 ns that may delay a CPU running at 3 GHz by 200–300 instruction cycles. The size of main memory ranges from a few gigabytes (Gbytes) up to several terabytes (Tbytes). Like the cache, main memory is not used for permanent storage; it holds the active part of running programs. Inactive parts of running programs are swapped out of the main memory to secondary store when the main memory becomes full. Thus, the size of a program is not constrained to the size of the main memory.
3. The first level of the secondary store is often built from flash memory. Flash memory is a nonvolatile computer storage chip that can be electrically erased and reprogrammed. NAND flash memory is the type usually used for secondary storage because it is higher density than other types of flash memory. NAND must be read and written in pages much like the sectors on a disk. Unlike disks, it must be erased in large blocks of pages before these pages can be rewritten with new data. Because flash

FIGURE 55.1 Computer memory hierarchy.

memory avoids the mechanical delay of disks, it can typically access data about a hundred times faster than a disk (though it is still a hundred to a thousand times slower than main memory).

4. The second level of the secondary store is usually built from one or more disk drives. These disk drives are usually connected directly to the computer, though they may be located across a fast network on a central storage server. Disks are used for intermediate to long-term data storage. Access time for a fast disk is currently about 4–5 ms; thus, a CPU that needs to access data that is on disk will have to wait thousands of instruction cycles. Modern multitasking operating systems will suspend a program that awaits a disk access and run another program. Sometimes after the disk access has completed, the program that requested the data will begin to run again.

This chapter is concerned with the secondary part of the storage hierarchy; Chapters 18 and 54 discuss primary storage and its management. In particular, disks may be used as a temporary store when the main memory becomes full. This chapter considers the secondary storage solely from the perspective of its use as long-term storage media. The first half of this chapter will briefly discuss the hardware used to support secondary storage; Chapter 18 describes the storage hardware in much greater detail. The second half of the chapter will discuss filesystem software used to access and manage secondary storage.

55.2 Secondary Storage Devices

Many types of hardware are used to support secondary storage. This section will describe the most commonly used devices—solid-state disks (SSDs), magnetic disks, digital video disk (DVD) disks, and tape.

55.2.1 Solid-State Disks

A SSD is a data storage device that uses solid-state memory to store persistent data. By contrast, a traditional magnetic disk is an electromechanical device containing spinning disks and movable read/write heads. SSDs use the same interface as magnetic disk drives, thus easily replacing them in most applications. SSDs are typically less susceptible to physical shock, are silent, have lower access time and latency, but are more expensive per Gbyte.

SSDs contain no moving parts and most use NAND-based flash memory that retains memory even without power. NAND flash memory is organized in blocks that are a few Mbytes in size. Each of these blocks is made up of pages that are a few Kbytes in size. Each page can be read or written independently. Once written, a page must be erased before it can be written again. Erasure can only be done at a block level; erasing a block causes all the pages contained in that block to be erased. Flash memory can only be erased and rewritten a few hundred thousand times before it wears out and ceases to work.

Lower priced drives usually use multilevel cell (MLC) flash memory, which is slower and less reliable than single-level cell (SLC) flash memory. For MLC flash memory, a problem called lower page corruption can occur when MLC flash memory loses power while programming an upper page. The result is data written previously and presumed safe can be corrupted if the memory is not supported by a super capacitor covering for a sudden power loss. Another property of MLC flash memory is that the pages within a block must be written sequentially rather than being able to be written in a random order. These problems do not exist with SLC flash memory. Current controllers can mitigate the speed

and reliability issues of MLC memory by using more robust error-correcting codes and by using greater over-provisioning (more excess capacity) with which the wear-leveling algorithms can work.

The key components of an SSD are the controller and the flash memory to store the data. The controller incorporates the electronics that bridge the NAND memory components to the host computer. The controller is an embedded processor that executes firmware-level code and is an important factor of SSD performance. Some of the functions performed by the controller include the following:

- *Logical to physical block mapping:* Unlike the magnetic disks that the SSD is emulating, it cannot overwrite an already written block until the page holding that block has been erased. Because erasure must be done in blocks of pages, the only practical way to overwrite a page is to write a new copy elsewhere.

The SSD needs to maintain a mapping from the logical block numbers being presented to it by the host to the physical block numbers in which those logical blocks are being stored. This mapping table needs to be updated each time a block is over-written and its physical location is changed. The mapping table must be stored in the nonvolatile memory of the drive so that it can be recovered after a crash or power failure as it would otherwise be impossible to recover the contents of the SSD. For performance reasons, the active part of the mapping table is kept in a dynamic-memory cache. The SSD needs either a capacitor or some form of battery to maintain data integrity such that the data in the cache can be flushed to the drive when power is dropped. Some filesystems are beginning to maintain this table for the SSD as part of their operation; this integration of the filesystem with the SSD is described in more detail in the next section.

- *Error correction:* Flash memory is prone to error, especially as it begins to approach the end of its write cycles. Each page needs to have error-correcting codes associated with it so that these errors can be detected and corrected. When the number of errors gets close to the maximum number that the error-correcting code can correct, the page must be retired from use by recording it in a bad-block table.
- *Garbage collection:* When the SSD controller finds that it is running out of unwritten pages, it must create new ones. Because erasure must be done in blocks, it must find a block whose pages have mostly been freed. The remaining valid pages in the block must be copied to free pages in another block. Once the valid pages are copied out, the block can be erased, and all its pages are then available for future write requests.

This extra writing that must be done to clear out a block before erasing is called write amplification. This multiplying effect increases the number of writes required over the life of the SSD that shortens the time it can reliably operate. The increased writes also consume bandwidth to the flash memory, which mainly reduces random write performance to the SSD. Many factors affect the write amplification of a SSD; some can be controlled by the user and some are a direct result of the data written to and usage of the SSD.

The SSD knows about the blocks it has freed owing to their being replaced by an over-write. To operate efficiently, it needs to know when blocks are no longer being used by the filesystem such as when an application deletes a file. Most filesystems today provide a TRIM command to inform a SSD that blocks of data are no longer in use by the filesystem and can be erased. While TRIM is frequently spelled in capital letters, it is not an acronym; it is merely a command name.

- *Wear leveling:* Because each page can only be written a finite number of times, pages that are approaching their write limit need to be switched to hold with static or infrequently changing data. Pages with low usage counts, because they have been holding static or infrequently changed data, need to be switched to hold more frequently changing data. The goal is to have as nearly equal write usage as possible. Ideally, the switching of high and low use pages can be done as a side effect of the garbage collection and the new block placement.
- *Read scrubbing and read disturb management:* Pages that are not read for months and pages that are read frequently begin to develop errors. The SSD controller must periodically read every page and rewrite any that have error rates that are close to what the error-correcting code can correct.

- *Encryption*: Eliminating data on a magnetic disk can be done by over-writing it. Eliminating data on an SSD is much more difficult since any attempt to over-write it will leave the old data in place and place the replacement data elsewhere. Unless the drive provides a specific function to erase all the memory in the drive, there is no reliable way to ensure that any particular piece of data has been removed. Thus, many SSD drives provide the ability to encrypt all the data written to the drive and to decrypt it when it is read back. If the encryption is done on a file-by-file basis, a file can be reliably deleted by destroying its associated key.
- *Read and write caching*: As with magnetic disks, SSD drives usually provide cache memory to hold recently read pages and to as a staging area for data to be written to improve their response rates.

The performance of the SSD can scale with the number of parallel NAND flash chips used in the device. A single NAND chip is slow because of a narrow (8/16 bit) asynchronous input/output (I/O) interface and the additional high latency of basic I/O operations. Typically, it takes about 25 ms to fetch a 4 Kbyte page from the array to the I/O buffer on a read, about 250 ms to commit a 4 Kbyte page from the I/O buffer to the array on a write, and about 4 ms to erase a 1 Gbyte block. When multiple NAND devices operate in parallel inside a SSD, the bandwidth scales and the high latencies can be hidden, as long as enough outstanding operations are pending and the load is evenly distributed between devices. The 2012 generation of SSD controllers deliver about 500 Mbyte per second read/write speeds.

55.2.2 Magnetic Disks

Data are transferred between the main memory and the disk by a disk controller. Most disk controllers transfer data between the disk and main memory using direct memory access. The CPU issues a command specifying the range of main memory addresses to be written or read and the disk sectors to or from which they should be transferred. The controller is responsible for issuing a seek command to the disk if necessary, waiting for the desired sectors to rotate under the head, transferring the data between the specified main memory locations, and interrupting the CPU to signal that the transfer has been completed.

To improve performance, disk controllers often provide a *track cache*, which holds the contents of the track containing the currently requested sector. For example, consider a file that fits on one track of a disk. Suppose the disk controller has been requested to read the first part of the file, but when the seek completes, the head is sitting over the middle of the file half a rotation away from its beginning. Instead of waiting for the disk to rotate the beginning of the file into position, the controller immediately begins reading the track into its cache. As the beginning of the file passes under the head, it is transferred into the main memory as requested, and the CPU is notified of its completion. Following the end of the requested data transfer, if there are no further requests awaiting the controller, it reads the remaining quarter of the track into its cache. Since files are often read sequentially, the controller will probably be asked to read the next quarter of the file. Instead of having to wait for the disk to rotate back into position, it can satisfy this request from its cache. Thus, after one disk revolution, the controller can produce any part of the file with no rotational delay. Since the controller can transfer data from its cache to main memory much faster than data are delivered by the disk, the disk cache produces an even greater performance gain than just that measured by eliminating rotational delay.

Using a cache to speed up disk writes is a bit more difficult. If the controller completes a seek half a rotation ahead of the spot that requests the write, there is nothing useful that it can do; it must wait for the requested position to rotate into place. Normally, the controller waits until the write completes before issuing a completion interrupt to the CPU. Typically, a millisecond or so of CPU processing occurs before it issues the next write request. If the next write request contiguously follows the previous write, then the disk head will have just missed the start of the block and will incur nearly an entire rotation's delay reaching the correct starting point. When writing a large contiguous file, the controller will consistently be delayed by a full rotation on each block, which leads to poor throughput. One approach

to correcting this problem is to transfer the requested block into the controller cache and then issue the completion interrupt before the block has been placed entirely on the disk. In this study, the CPU can prepare and issue the next request for the controller while the previous block is being written. With the new request in hand, the controller can start its transfer to the disk without loss of a revolution.

This approach has a serious failing if the controller does not have a nonvolatile cache. Many applications, such as databases, depend on the completion interrupt to let them know that critical data such as a transaction log have been stored in a location that will survive a system failure. If the data are only in the volatile controller cache and the system fails before the cache is written to disk, then the database will be unable to recover. Thus, early completion interrupts must be used only if the controller cache uses nonvolatile memory and has software to restart it and write out any incomplete blocks after a system failure.

A much better alternative is to use a technique called tag queuing. In this study, several requests are given to the disk controller, each of which is identified with a unique tag. When a request has been written to the disk, an interrupt is generated that presents the tag of the completed transfer to the system. Tag queuing allows the disk to write contiguously without the need to depend on premature and possibly incomplete I/O. Thus, applications can reliably know that their data are on stable store.

The capacity of disks has been rising steadily; single disks today hold a few Tbytes of data. Unfortunately, disks are still able to transfer data from only one location at a time. As the amount of data on the disk grows, this serialized access has become more and more of a bottleneck. To compensate, some systems deliberately use smaller capacity disks to increase the total number of disks on the system, which allows more parallel data access.

55.2.3 Redundant Array of Independent Disks (RAID)

The biggest problem with magnetic disks is dealing with their inevitable failures. Because the heads fly only microns above the disk surface and because of the need to dissipate the heat that this small gap produces, even the best designed disks have a lifetime of only 5–7 years. On a large file server containing hundreds of disks, a disk failure is a common event. Traditionally, recovery from such failures were handled by use of a tape backup system. Every few weeks, a complete copy of each disk would be made on tape. Each day, a backup would be made of everything that had changed since the last complete copy had been made. When a disk failed, it would be replaced with a new disk; then the contents of the complete copy, followed by all the daily changes, would be made to complete the recovery process.

There are three problems with this approach:

1. *Capacity limits:* As the capacity of disks has increased, the amount of data that must be backed up on tape has exploded. The large server above would have many Tbytes of disk space connected to it. Even with the high density tapes available today, it would take hundreds of tapes to back it up. The server would require several tape drives running continuously just to keep up with the backups.
2. *Data loss:* At best, most systems can only schedule backups once per day. If the disk crashes shortly before it is scheduled for its daily backup, everything that was done that day will be lost. For many businesses, losing even a few hours of work is unacceptable.
3. *Recovery delay:* Replacing a disk and recovering its contents from backup tapes takes several hours. During the recovery period, the disk is completely unavailable. This recovery delay is often unacceptable for time critical applications.

Two approaches have been taken to avoid these problems. The first of these approaches is a brute force solution called *mirroring*. The number of disks on the system is doubled. Disks are paired off and each pair keeps a copy of its partner. Thus, each time an application does a write, the changed data are written to both disks in the pair. Reads may be done from either disk since they both contain the same data. If one disk in the pair fails, the other disk can continue servicing requests without interruption.

When the failed disk is replaced, its initial contents are copied in from its operating partner. Although it may take an hour or two to do the replacement and contents copy, users are unaware of the delay since they are running from the remaining good drive. In addition, no data are lost since there is no dependence on backup tapes for recovery. Mirroring has traditionally been used for time or business critical data, such as that handled by banking and airline reservation systems, where the extra cost can be justified.

The second approach to avoiding the tape backup problem is to collect several disks together and use one of them to store a parity of the others. Such an organization is referred to as a redundant array of independent disks (RAID) (Patterson et al., 1988; Chen et al., 1994). A typical RAID cluster will contain five disks. Four of the disks contain data and the fifth contains a parity of the data on the other four. Each time data are written to any of the other four disks, a new parity must be computed and written to the fifth disk. In practice, the parity is not stored entirely on one disk as it would become the bottleneck when trying to write to one of the other four disks. Instead, each disk in a five disk RAID cluster would be divided so that 20% stores parity and 80% stores data that would be covered by parity on the other four disks. A more robust version of RAID maintains two sets of parity that allows it to suffer two disk failures without losing any data.

Recovery from disk failure in a RAID cluster is not as transparent as it is with mirroring. Access to the RAID cluster can continue, but at approximately half of its regular access rate, while the broken disk is replaced and rebuilt. The replacement disk is initialized by reading the other four disks in the cluster and computing what value should be put onto the new disk. In data communications, parity can be used to detect errors, but not to correct them. That is because in data communications, the receiver does not know which bit is in error. Parity can be used for error correction for a RAID cluster because the cluster knows which disk failed. Thus, it can recompute the correct value for the failed disk using the data on the other drives. Failure recovery on a RAID cluster typically takes a few hours.

Once the recovery is complete, the cluster returns to the state it was in just before the disk failed. Thus, RAID clusters solve two of the three tape backup problems. They avoid the need for daily backups and they avoid losing data when they fail. While access to the data is slow during the recovery period, that period is typically about half the time required for a tape recovery. A RAID cluster is considerably cheaper than a mirroring strategy since there is only a 25% redundancy of hardware rather than a 100 percent redundancy. Thus, the RAID cluster usage is increasing in less time-critical environments.

Even with RAID clusters, the need for backups is not completely eliminated. Full backups need to be taken and stored off-site for recovery if a major catastrophe such as a fire destroys the disks in a machine room. Backups are also needed to recover from user errors where an important file is accidentally deleted. Neither of these problems can be handled by RAID clusters.

Mirroring can handle the catastrophic failure if the mirror disks are kept in physically separate locations. For genuine safety, the mirrors should be in different buildings that are at least several miles apart. Buying space on a cloud server is often a less expensive alternative than maintaining a second facility. The communication costs of the high-bandwidth network connection that is required sometimes makes a long distance mirroring solution unacceptably expensive. A less expensive alternative is to make periodic tape backups and transport the tapes to the distant location for archival storage.

Distance mirroring does not provide recovery from user errors where an important file is accidentally deleted. As described in the next section of this chapter, modern filesystems provide the ability to take a *snapshot* of the filesystem. Logically, the snapshot represents a frozen copy of the filesystem as it existed at the time that the snapshot was taken. If a user accidentally deletes a file, they can copy a replacement for it from a recent snapshot.

55.2.4 DVD Disks

The ubiquitous DVD plays a small but important role in computer systems today (Asthana, 1995). Its primary use is as a software distribution medium where it has replaced tapes and floppy disks. It has the benefits of being cheap, reliable, and easily mass produced. It has the random access features of

a magnetic disk that makes it much more convenient than a tape. Because the software is often used directly from the DVD rather than being loaded onto the system disk, large software packages can be used on systems that are otherwise short of disk space. Even with all these benefits, the use of DVDs as a software distribution medium is declining as software is increasingly being downloaded directly from the Internet.

The DVD disks are more compact to store than tapes. Like tapes, all user writable DVDs can only hold data reliably for 5–8 years. Factory pressed (read-only) DVDs are expected to hold data reliably for 50–100 years.

55.2.5 Tapes

Tapes are used for archival and backup storage. The access time to get to the start of and begin reading a file stored on a robotically managed tape system is several minutes. If a human operator must get involved, the access time takes longer. Historically, actively running programs directly manipulated data on tapes. Today, most applications arrange to have data read from tapes onto disk before beginning to access that data. Tapes are used primarily to archive data that is not currently accessed.

Tapes remain the most commonly used form of archival storage though they are being increasingly replaced by cloud storage solutions. Early tape technology used 12 in. reels of half-inch tape that stored a little over 100 Mbytes of data. Current tape technology uses DLT cartridges that store Tbytes of data. The rule of thumb has been that the largest tapes hold about the same amount of data as the largest disks.

Data transfer to and from tapes tends to be slower than data transfer to and from disks. Random access to tapes is much slower than disks. Even modern DLT drives take about a minute to seek from one end of a tape to the other. The big benefit of tapes is that they are a tenth the cost of disks per Gbyte of storage. Furthermore, by installing a robotic tape system with a capacity of several hundred tapes, it is possible to create a file store capable of storing hundreds of Tbytes of data. While the access time to the data may be a minute or two, it is far cheaper than storing a similar amount of data on disk.

In practice, tape store is generally used as the final repository for data. Recently accessed data are stored on disk where it is more readily available. When the disks become full, the least recently accessed data are copied to tape and deleted from the disk. If it is later needed, it is reloaded onto the disk displacing other less recently accessed data. To maintain reasonable access times, most systems arrange to have enough disk space to keep data disk resident for up to a year.

55.3 Filesystems

Most applications that users run on their computer do not write data directly onto the disk. The operating system provides an interface called a filesystem that organizes the data into files. The filesystem converts the file from the user abstraction as an array of bytes to the structure imposed by the underlying physical medium and is responsible for deciding where the file contents should be placed on the disk. The filesystem provides several important services:

- *Protection*: Most filesystems allow users to control access to their files. At a minimum, they can restrict access to themselves, a defined group of other users, or all other users of the system.
- *Organization*: Data in each file can be manipulated independently of data in other files. Data may be added or deleted from one file without affecting the data contained in other files. In particular, the user need not be concerned that one file might run into another file on the disk as they would if they were directly placing the data on the disk themselves.
- *Multiple access*: Modern filesystems allow multiple files to be accessed at the same time and even allow separate programs to consistently access the same file. Consistent access means that if one application writes a file while another is reading the same part of the file, the reader will see the file either before the write has been started, or after it has finished, but not in a partially written state.

- *Space management:* The filesystem tracks the used and free space on the disk. When any file in the filesystem needs to grow, the filesystem finds an appropriate sized piece of free space and allocates it to the file. As long as there is free space left on the disk, the filesystem is prepared to allocate it to any file within the filesystem that wants to grow or to create a new file and allocate the space to that new file.

In addition, a filesystem is expected to optimize the use of disk bandwidth. Thus, it must not only find space to allocate to files, but it must try to find space that is contiguous or at least rotationally close together to minimize the time that it takes to read and write the file. Issues of space management are discussed in the subsequent sections.

55.3.1 Directory Structure

Most filesystems allow files to be grouped together into directories. These directories may then be further grouped together into other directories. The files and directories are usually grouped together in a tree hierarchy; Figure 55.2 shows a typical filesystem hierarchy. The rounded boxes represent directories; the square boxes represent files. The top of the tree is referred to as the *filesystem root*. Files are accessed by giving the set of names of directories from the root of the tree down to the desired file, separated by slashes; this name is called the *pathname*. Unix-like systems such as Linux, Solaris, and FreeBSD use forward slashes; Windows uses back slashes. For example, access to the file *mydata* in Figure 55.2 would use the pathname */users/myhome/mydata* (IEEE, 1994).

Many filesystems maintain a current working directory for the user. Instead of having to always specify a file by its complete pathname, the system keeps track of which directory the user is currently referencing and does all filename translation relative to that directory. The user initially specifies a current directory using a complete pathname. Using the filesystem shown in Figure 55.2, the user might request that the current directory be set to */users/myhome*. Thereafter, the reference to the file *mydata* can be used without specifying its entire path since it is resident in the current directory.

55.3.2 Describing a File on Disk

To allow both multiple file allocation and random access, most systems use a data structure similar to that shown in Figure 55.3 to describe the contents of a file. This structure includes

- Access permission for the file
- The file's owner
- The time the file was last read and written
- The size of the file in bytes

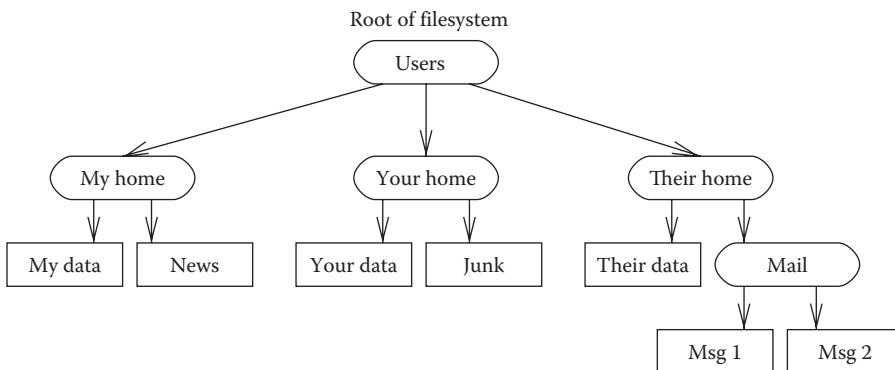

FIGURE 55.2 A set of files and directories.

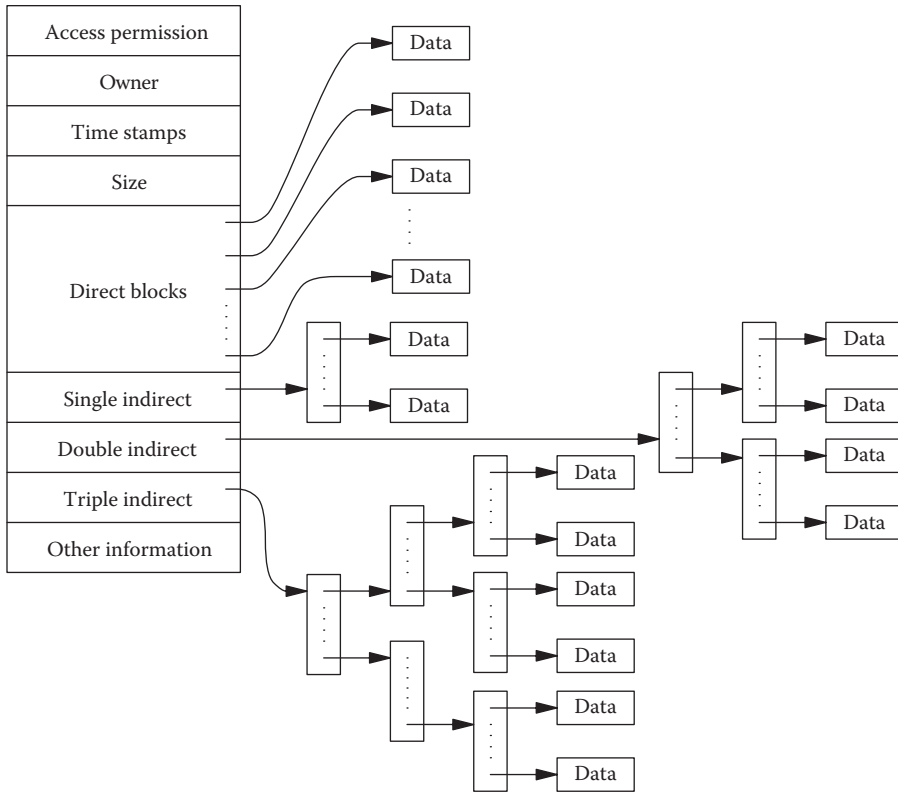

FIGURE 55.3 Extensible data structure used to describe a file.

Notably missing in this structure is the filename. Filenames are usually maintained in directories rather than in this structure because a file may have many names, or links, and the name of a file may be large (often up to 255 bytes in length).

The file structure also contains an array of pointers to the blocks in the file. The system can convert from a *logical block* number to a *physical block* number by indexing into this array using the logical block number. A null array entry shows that no block has been allocated and will cause a block of zeros to be returned on a read. On a write of such an entry, a new block is allocated, the array entry is updated with the new block number, and the data are written on that physical block of the disk.

Since the filesystem must support many files and most files that it stores are small, the file structure has a small array of pointers for efficient use of space. The first few array entries are allocated in the file structure itself. For typical filesystems, these array entries allow the first 400 Kbytes of data to be located directly using a simple indexed lookup.

For somewhat larger files, Figure 55.3 shows how the file structure contains a pointer to a single *indirect block* of pointers to data blocks. To find the hundredth logical block of a file, the system first fetches the block identified by the indirect pointer, then indexes into it by 100 minus the number of direct pointers, and fetches that data block.

For files that are larger than a few Mbytes, this single indirect block is eventually exhausted. These files must resort to using a double indirect block, which is a pointer to a block of pointers to pointers to data blocks. For files of multiple Gbytes or Tbytes, the system uses a triple indirect block, which contains three levels of pointers leading to the data block.

Although indirect blocks appear to increase the number of disk accesses required to reach a block of data, the overhead for this transfer is typically much lower. Most filesystems maintain a memory-based

cache of recently read disk blocks. The first time that a block of indirect pointers is needed, it is brought into the filesystem cache. Further accesses to the indirect pointers find the block already resident in memory; thus, they require only a single disk access to reach the data.

The filesystem handles the allocation of new blocks to files as they grow. Simple filesystem implementations, such as those used by early microcomputer systems, allocate files contiguously, one after the next, until the files reach the end of the disk. As files are removed, gaps occur. To reuse this freed space, the system must compact the disk to move all the free space to the end. Files can be created only one at a time; to increase the size of a file (other than the last one on the disk), it must be copied to the end and then expanded. For the more complex file structure just described, the locations of the data blocks in each file are given by its block pointers. Although the filesystem may cluster the blocks of a file to improve I/O performance, the file structure can reference blocks scattered anywhere throughout the disk. Thus, multiple files can be written simultaneously, and all the disk space can be used without the need for compaction.

55.3.3 Filesystem Input/Output

The filesystem implementation converts the file from the user abstraction as an array of bytes to the structure imposed by the underlying physical medium. Consider a typical medium of a magnetic disk with fixed-sized sectoring. Although the user may wish to write a single byte to a file, the disk supports reading and writing only in multiples of sectors. In this study, the system must read the sector containing the byte to be modified, replace the affected byte, and write the sector back to the disk. This operation of converting a random access within an array of bytes to reads and writes of disk sectors is called *block I/O*.

First, the system breaks the user's request into a set of operations to be done on logical blocks of the file. Logical blocks describe block-sized pieces of a file. The system calculates the logical blocks by dividing the array of bytes into filesystem-sized pieces. Thus, if a filesystem's block size is 8192 bytes, logical block 0 would contain bytes 0–8191, logical block 1 would contain bytes 8,192–16,383, and so on.

Figure 55.4 shows the flow of information and work required to access the file on the disk. The abstraction shown to the user is an array of bytes. These bytes are collectively described by a file descriptor that refers to some location in the array. The user can request a write operation on the file by presenting the system with a pointer to a buffer, with a request for some number of bytes to be written. Figure 55.4 shows that the requested data need not be aligned with the beginning or end of a disk sector. Furthermore, the size of the request is not constrained to a single disk sector. In the example shown, the user has requested data to be written to parts of logical blocks 1 and 2.

The data in each logical block are stored in a physical block on the disk. A physical block is the location on the disk to which the system maps a logical block. A physical disk block is constructed from one or more contiguous sectors. For a disk with 4096 byte sectors, an 8192 byte filesystem block would be built from two contiguous sectors. Although the contents of a logical block are contiguous on disk, the logical blocks of the file need not be laid out contiguously.

Returning to our example in Figure 55.4, we now know which logical blocks are to be updated. Since the disk can transfer data only in multiples of sectors, the filesystem must first arrange to read in the data for any part of the block that is to be left unchanged. The system must arrange an intermediate staging area for the transfer. This staging is done through one or more *system-cache buffers*.

In our example, the user wishes to modify data in logical blocks 1 and 2. The operation iterates over five steps:

1. Allocate a system-cache buffer.
2. Determine the location of the corresponding physical block on the disk.
3. Request the disk controller to read the contents of the physical block into the system-cache buffer and wait for the transfer to complete.

FIGURE 55.4 The block I/O system.

4. Do a memory-to-memory copy of the next piece of the data from the user's I/O buffer to the appropriate portion of the system-cache buffer.
5. Write the block to the disk.

Since the user's request is incomplete, the process is repeated with the next logical block of the file. The system fetches logical block 2 and is able to complete the user's request. Had an entire block been written, the system could have skipped step 3 by simply writing the data to the disk without first reading the old contents. This incremental filling of the write request is transparent to the user's process, because that process is blocked from running during this entire operation. It is also transparent to other processes since the file is locked by this process; any attempted access to the file by any other process will be blocked until this write has completed.

55.3.4 Disk Space Management

The role of the filesystem code is not only to organize the data on a disk but also to minimize the time that it takes to read and write that data. There are two important measurements of access time. The first is the time that it takes to access the data contained within a particular file. The second is the time that it takes to access the data contained within a collection of files that are accessed together.

Examples of collections of files accessed together include files that are collected together in a spool area such as those destined to be sent to a printer or those being batched to be sent as a collection of electronic mail messages. Another example might be a collection of files that make up the components of a spreadsheet, a document, or a program. Directories provide a strong clue that a set of files will be accessed together. Thus, many filesystems will try to allocate all the files contained within a directory in close physical proximity to each other on the disk. If they are accessed together, the disk will not need to make long or multiple seeks to get from one to the next.

Most filesystems put their greatest effort into optimizing the layout of individual files. The default assumption is that the files will be accessed sequentially starting at their beginning. Certain files, such as those that contain a large database, may have randomly scattered accesses. The optimal layout for such files is dependent on their access patterns, which may be known only to the database or application program, or that may not be known at all. For such files, the filesystem may allow the database or application to direct the layout of the file. Alternatively, it may simply lay the file out sequentially and assume that the database or application will attempt to cluster related information within the file to minimize the time it takes to seek between file locations.

For a sequentially accessed file, the usual strategy is to allocate a contiguous piece of space on the disk on which it is stored. When a disk is first put into service, doing sequential allocation for files is easy. The filesystem has a large area of contiguous physical free space and allocates pieces out of that space for each new file. Unfortunately, this allocation approach quickly uses up all the physically contiguous space. As old files are deleted, they return the space that they were using. However, this unused space will be randomly scattered throughout the disk. Eventually, the disk will become completely fragmented with no large contiguous pieces of space remaining, thus making it impossible for the filesystem to allocate new files contiguously.

Filesystems often use defensive algorithms to reduce the rate of fragmentation of the free space on the disk. A key to reducing fragmentation is to observe that most of the files within a filesystem are small. When a new file is created, the filesystem can assume that it will be small. Instead of allocating its initial disk space in a large contiguous area of the disk, the file will be allocated in a smaller fragment that may have been freed when another small file was deallocated. If the file turns out to be small as expected, then it will nicely fit in the small space that it was initially allocated. If it continues to grow, then the filesystem can move it to a fragment left by a somewhat larger file. Only when the file grows large, it is finally relocated to the large contiguous space that the filesystem has now been able to hoard. By only allowing large files to be allocated in the large contiguous space, the filesystem is better able to ensure that some large contiguous space will be available when it is needed.

Moving files around on the disk can be a potentially slow and expensive operation if the file must be read and rewritten every time that the filesystem wants to move it. To reduce the relocation cost, the filesystem will attempt to defer writing the file until it has determined its final location on the disk. The deferral is done by holding blocks of the file in system-cache buffers until its size can be determined (see Figure 55.4). The steps involved in allocating space to a file are as follows:

- When the first block is written, a system-cache buffer is allocated. A single block-sized piece of free disk space is found, the address of that piece of disk space is assigned to the system-cache buffer, but the buffer is not written to the disk.
- If the file continues to grow, a second system-cache buffer is allocated. The filesystem finds a two block-sized piece of free space, frees the single block-sized piece of space originally assigned to the file, and assigns the addresses of the new larger block to the two buffers. As before, neither buffer is written to the disk.
- This process continues until the file has grown to the maximum sized block allowed (typically the size of a disk track) or the file has ceased to grow at which point the buffers are written to their final destination.

If the system-cache buffers are needed for another purpose, or the application explicitly requests that the file be stored on disk (for example, it is a transaction log that must be in stable storage before the application can proceed), the system-cache buffers always have a location to which they can be written. The only implication of doing the write early is the loss of performance that comes from writing the data to disk more than once.

This algorithm has the additional benefit that it allows even slowly growing files to be written contiguously. If a file, such as one holding accounting records, grows at the rate of a few Kbytes per hour, it will be relocated to larger contiguous blocks periodically. In this study, the relocation usually involves

reading and rewriting the data, since the turnover in system-cache buffers causes them to be flushed before the new disk addresses for the data are assigned. Since the reallocation occurs only a few times per hour, the added I/O overhead does not adversely affect system performance.

To ensure successful layouts, a filesystem must have a quick method for finding contiguous and nearby free blocks on the disk and then allocating them. The most common data structure used for describing the free disk blocks is an array of bits. The blocks on the disk are sequentially numbered; the corresponding bit in the array is set to 1 if the block is being used and 0 if it is free. Block allocation involves setting the bits corresponding to the blocks being allocated; block deallocation involves clearing the bits corresponding to the blocks being freed. Finding other nearby blocks can be done by looking for 0 bits in the array near the location of the most recently allocated block in the file. Clusters of blocks can be identified by looking for strings of 0 bits in the array.

The free disk block array is large for a big disk. Exhaustive searches of the array (for example, when the disk is nearly full and there are few free blocks remaining) would slow filesystem performance unacceptably. Consequently, most filesystems maintain auxiliary data structures that summarize the contents of subranges of this bit array. Such summaries include the number of free blocks and the maximum sized contiguous piece within each subrange of the bit map. When looking for a block or a cluster of blocks, the filesystem first scans the summary information to find a subrange of the bit map that has the necessary free space. Once it finds the needed space, the filesystem can narrow its search to that subrange of the bit map rather than searching the whole space.

An alternative to using an array of bits is to describe the free space using a more complex data structure such as a B+ tree. For example, a B+ tree is used for this purpose in the XFS filesystem (Sweeney et al., 1996). A B+ tree can also be used to locate the blocks for the file rather than using the indirect block scheme shown in Figure 55.3. B+ trees are described in Chapter 3 on data structures.

55.3.5 Filesystem Crash Recovery

Logging long has been used in database systems to provide recovery after a system failure (Date, 1995). The database periodically does a *checkpoint* of its on-disk data structures to ensure that they are in a consistent state. Following the checkpoint, the database keeps a log of every change that it commits. The log is usually written serially onto a disk that is dedicated to the log. Thus, the log can be written quickly since the disk head is always within no more than a rotational delay from the next location to be written.

If the system fails, the log does a *roll forward* operation on the database to bring it back to consistency. The roll forward works by going through the log and ensuring that all the changes that it lists are reflected in the on-disk database state. The time required to recover the database after a system failure is bounded by the frequency of checkpoints. By checkpointing the database and resetting the log every few minutes, the recovery time for a disk failure can be kept to a few minutes or less.

The idea of using a log to recover a database has also been applied to filesystems. Like a database, the filesystem periodically checkpoints its state. It then writes all changes after that point both to its log and to the filesystem itself. When the log becomes full or a time limit is reached, the filesystem checkpoints itself again and resets its log. As with the database, the log is rolled forward after a system failure to ensure that all the changes made since the checkpoint are reflected in the filesystem. The log only needs to record modifications to the filesystem. While it has no effect on the speed with which data can be read from the filesystem, logging does introduce additional overhead when files are written. However, if the log is stored on a separate disk from the rest of the filesystem, writing to the log is seldom the limiting function on the speed with which data are placed into the filesystem. For systems that require high write performance, the logging disk can be replaced with nonvolatile memory.

Although a log provides fast recovery after a system failure, it does not provide the data recovery of mirroring or RAID that can recover from catastrophic disk failure. The reason that logging does not help with catastrophic disk failure is that data may be lost from parts of the disk that the filesystem thinks are stable and hence did not enter in the log.

55.3.6 Non-Overwriting Filesystems

Traditional filesystem design makes updates by overwriting old versions of the data with new versions. If an application such as an editor writes new contents to a file, the new contents are written into the same space as was previously occupied by the old contents. The benefit of this design is that related files reside near each other on the disk even if they are written at different times. The drawback of this design is that the filesystem may be inconsistent during times when data destined for the disk is still in the main memory waiting to be written. Thus, some mechanism such as logging is necessary ensure that the filesystem can be recovered after a crash.

A more recent filesystem design has taken the approach of never overwriting existing data in the filesystem. Any time an update is made to a file, the changes are accumulated in memory. When a preset interval (usually less than 30 s) or a threshold of changes is reached, all the new data are written to free space on the disk. When all the changes have been written, the filesystem does one last checkpoint write to commit itself to its new state. As part of doing the filesystem checkpoint, the space formerly used by the files that have been updated is released for future use.

The filesystem always moves from one consistent state to the next and is never in an inconsistent state that needs to be recovered after a crash. After a crash, the filesystem can begin operating from its last consistent state. Such filesystems still need a log for use after a crash. Although they do not need it to recover the filesystem, they do need it to recover the changes that occurred since the last checkpoint. After a crash, the filesystem begins from its last checkpoint, all the changes in the log are applied to it, and a new checkpoint is taken to commit those changes.

A drawback of the non-overwriting filesystem design is that the data for related files no longer resides together on the disk. Instead, the files are laid out on the disk in the order in which they were written; if two related files are written at different times, they will likely be far apart from each other on the disk. Thus, reading those files at the same time will take longer than it would on a conventional filesystem. Furthermore, files that are written over time (such as system activity logs) will have their data scattered over the disk. Reading such files will be considerably slower than reading such a file on a traditional filesystem that will put all its data together in one place. These slow access patterns can be mitigated by using a large main-memory cache to hold frequently or commonly accessed data.

The ability to take a snapshot has become a popular filesystem feature. Snapshots are typically compact as they reference the filesystem on a copy-on-write basis. So, the snapshot only needs to retain copies of the disk blocks that are modified. As the contents of most filesystems change slowly, the extra space required to hold a snapshot is small.

A major benefit of non-overwriting filesystems is that they can quickly take snapshots. Because existing data are never overwritten, the filesystem need only to take a checkpoint and then not release the previously used data until the snapshot is deleted. The commit record written to create the checkpoint is saved as the access point for the snapshot. When the snapshot is deleted, the commit record and space associated with it can be released. Because the commit records are small and there is no need to check for over-writing of filesystem blocks, a non-overwriting filesystem can cheaply retain tens or hundreds of snapshots.

Taking a snapshot in a traditional over-writing filesystems is time consuming and requires significant space since it must record every block in use at the time of the snapshot. Every time data are written to the filesystem, it must check every snapshot to see if it will overwrite a block in that snapshot and save a copy of the old contents when such an overwrite is made. Thus over-writing filesystems limit the number of snapshots that they will retain to avoid using up too much space and slowing down filesystem performance.

Non-overwriting filesystems work particularly well with SSDs. Because they never overwrite any existing data, the SSD seldom needs to change the mapping of logical blocks to physical blocks. The only time a remapping is needed is when blocks are moved as part of garbage collection or wear leveling.

Some filesystems are now beginning to integrate more tightly with the SSD. Wear leveling is managed by the filesystem as part of its block allocation strategy. Blocks with low write counts are allocated to files and filesystem metadata structures that are expected to be short-lived, while blocks with high write counts are allocated to files and filesystem metadata structures that are expected to be long-lived.

Garbage collection is also coordinated with the filesystem. When the SSD selects a block for garbage collection, it notifies the filesystem of the blocks that will be moved. The filesystem updates its internal pointers to reference the new locations. Once the filesystem has committed these updates, the SSD can erase the selected block.

When a non-overwriting filesystem can support wear leveling and the block remapping associated with garbage collection, the SSD no longer needs to maintain the logical to physical mapping table. The removal of this extra level of indirection and the need for its maintenance dramatically reduces the cost of the SSD controller as well as improves its performance.

55.3.7 Versioning Systems

Users often want to retain previous versions of files, such as released versions of programs or documents. Usually, they use a revision control utility that maintains a database, which stores and retrieves the selected versions. Most version control systems only keep a complete copy of the original file. Each successive version is then stored as a set of differences from the previous version. Some version control systems operate by storing each version in a separate file, allowing fast and easy access to older versions (since it is just a matter of finding and reading the desired version). However, this method of version control is wasteful of space, especially if the file being versioned is large and the changes between versions are minimal.

The whole file copy version of revision control can be done by the filesystem itself. Each time a file is opened for writing, the contents of the old file are saved instead of being overwritten. The old file is kept around until the filesystem runs out of space. When additional space is needed for new files, the user must either explicitly delete unneeded earlier versions of files or request the filesystem to reclaim the space from the oldest of the earlier file versions.

The user interface for accessing older files may simply provide a list of different versions that are available and allow the user to specify the one that they want. Or it may be more sophisticated, allowing the user travel in time. For example, the user might be able to request all the files making up a particular program as they existed at the release date for the program.

Another variant of versioning involves taking a *snapshot* of the filesystem. When running on a non-overwriting filesystem, it is possible to take a snapshot of a filesystem every few hours during the day. Often, the snapshots are put in a location accessible to the users so that they can go retrieve older versions of their files without the intervention of a system administrator. Thus, if a user wrote a file in the morning and accidentally overwrote it in the afternoon, they could retrieve the original copy from the late-morning snapshot.

Key Terms

Block I/O: The conversion of application reads and writes of records with arbitrary numbers of bytes into reads and writes that can be done based on the block size and alignment required by the underlying hardware.

Checkpoint: The writing of all modified data associated with a filesystem to stable storage (either non-volatile memory or the disk). A checkpoint ensures that all operations completed before the checkpoint will be recovered following a system failure.

- Dirty blocks:** In computer systems, modified, a system usually tracks whether an object has been modified—is dirty—because it needs to save the object’s contents before reusing the space held by the object. For example, in the filesystem, a system-cache buffer is dirty if its contents have been modified. Dirty buffers must be written back to the disk before they are reused.
- Indirect block:** A filesystem data structure composed of an array of pointers to disk blocks used to locate the data blocks associated with a file.
- Logical block:** The sequential fixed-sized pieces of a file. The logical block associated with a given byte offset in a file is calculated by dividing the offset by the filesystem block size. For example, byte 20,000 is located in the third logical block of a file residing on a filesystem with 8 kbyte blocks.
- No-overwrite policy:** The filesystem never rewrites existing data in a file. New data are always written into a new location on the disk.
- Physical block:** The disk sector addresses associated with a logical block of a file. The filesystem finds the contents of a logical block in a file by using the logical block number as an index into an indirect block to find the disk sector address holding the requested data.
- Roll forward:** Used to recover after a system failure. The operation of rerunning the update operations stored in a log file against a filesystem or database to bring it to a consistent state as of the last update completed in the log.
- Snapshot:** A filesystem snapshot is a frozen image of a filesystem at a given instant in time.
- System-cache buffers:** System memory used to hold recently used data. For example, in the filesystem, system-cache buffers are used to hold recently accessed disk blocks.

Further Information

A good overview of filesystems can be found in Chapter 3 of Silberschatz and Galvin (1994).

Most operating systems today use filesystem designs similar to those found in (McKusick and Neville-Neil, 2005). This chapter summarizes information on file layout on disk described in Section 79.2, filesystem naming described in Section 79.3, and the traditional disk space management described in Section 79.9.

A description of the non-over-writing Open Solaris ZFS filesystem can be found in (Solaris, 2012).

Ars Technica has an excellent in-depth article on SSD technology (Hutchinson, 2012).

The Stanford VLSI Group’s CPU database project has a catalog of evolving microprocessor technology (Stanford, 2012).

56.1 Introduction

Since the inception of computers, there has been intense interest in their performance. Other dimensions are reliability [143], which is briefly discussed in the chapter on storage systems, power consumption that arises in the broader context of green computing [1], footprint, ease of operation, etc.

Initial attention was paid to the speed of the *central processing unit (CPU)*, specified in *millions of instructions per second (MIPS)* [2]. The MIPS rating of computer systems is specified with respect to

the VAX 11/780 marketed as a one MIPS computer [3]. The execution speed of a computer depends on the instruction mix, such as Gibson's, but also the sequence of their execution as affected by data and control dependencies (branches) [73]. There is a slowdown when the instructions and data cannot be accessed in one cycle as a result of cache misses [73].

The slow speed of *arithmetic logic units (ALUs)* of early computers led to research in developing and implementing new arithmetic algorithms [63]. Pipelining was introduced to allow a new arithmetic operation to be started per CPU cycle, and this concept was extended to the instruction execution level. For example, the IBM 360/91 decoded one instruction per its 60 nanosecond (ns) cycle, so that at its best it could process 16.7 MIPS [4]. Unlike the IBM 360/85 introduced at about the same time, the 360/91 was not equipped with a cache memory, but rather a sufficient number of instruction registers to hold the inner loop of a program and 16-way memory interleaving for parallel data access.

Early computers were uniprocessors with expensive magnetic core memories. Given the high cost of CPU hardware, multiprogramming was introduced to take advantage of the CPU-I/O overlap in these computers, allowing the CPU to be shared by several jobs. A rule of thumb to determine the *multiprogramming level (MPL)* to fully utilize the CPU is discussed in Section 56.3.5. Multiprogramming is also required by *online transaction processing (OLTP)* to attain a higher *transaction (txn)* throughput at an acceptable mean txn response time.

Multiprocessors and multicomputers have been developed to attain more computing power than uniprocessors. Multiprocessors have been classified as shared everything systems by Stonebraker [107], since resources such as the main memory and disks can be accessed by all processors. There is a performance degradation due to cache interference and also synchronization delays in multiprocessors [70]. In shared disk or data-sharing systems, the processing is shared by two or more computers, which need to coordinate their activities in processing database applications, such as coherency control of database buffers and concurrency control [96]. In the shared-nothing category, there are multicomputers, which share an interconnection network and communicate via message passing or a *distributed shared memory (DSM)* [57].

There are numerous applications requiring lengthy execution times if executed sequentially on a uniprocessor. There is also the issue of timeliness, that a computation needs to be completed by a certain deadline, for example, daily weather forecasting (although long-term forecasts are now available). Fortunately, many such computations exhibit a high degree of parallelism [57], so that their processing can be speeded up by parallel computing [5]. Parallelism is also exploited in *database management systems (DBMSs)* and web search engines to ensure timeliness of responses.

A semblance of parallelism can be attained by pipelining, which overlaps the processing of successive operations in time. Supercomputers in 1970s were highly pipelined vector computers, with Cray-1 being the world's fastest computer at that time. Flynn classified computers in mid-1960s into four categories based on the number of instruction and data streams [6,73]: *single instruction, single data stream (SISD)* [7] computers are uniprocessors. *Single instruction, multiple data stream (SIMD)* computers such as the Illiac IV were an early form of parallel computing, where a control unit issued decoded instructions to 64 *processing elements (PEs)*. This categorization also applies to vector computers, where a single instruction applies to elements of vectors. *Graphics processing units (GPUs)* belong to this category [73]. *Multiple instruction, multiple data stream (MIMD)s* are multicomputers. Several notable early computers are described in [44].

Amdahl in 1967 enunciated Amdahl's law, as an argument against parallel computing to promote IBM's uniprocessors at that time [8]. Given that a fraction $1 - F$ (of the sequential execution time of a program) cannot be parallelized to run at K processors $\text{Speedup} = (1 - F + F/K)^{-1}$, for example, $F = 0.5$ yields at most a speedup of two.

The highest computing power is currently attained by MIMD parallel processors with the *message passing interface (MPI)* [9]. IBM's Deep-Blue computer, which allegedly beat world's chess champion Kasparov in 1997 [10], was followed by the Blue-Genie supercomputer for understanding cellular architectures [11]. Another IBM computer called Watson consisting of 90 servers with 16 TB RAM outplayed human contestants of the TV game show Jeopardy [12]. Japan's 10.51 Petaflops/second (10^{15} floating

point operations per second) K computer was the world's fastest computer until IBM introduced the Sequoia 16.32 Petaflops computer at the Lawrence Livermore National Laboratory in June 2012 [13]. Changes in supercomputer rankings are listed in [14].

Growth in supercomputer performance is limited by reliability and power consumption considerations. It was said in 1970s that the Illiac IV supercomputer failed every 30 s. When the failure was due to one of its 64 PEs, the system was fixed by manually substituting the failed PE with a spare and restarting. Periodic checkpointing was used to save the state of the computation to ensure that completed work preceding a system failure is not lost [15]. The issue of power consumption is partially addressed by placing the supercomputers in areas where cheap hydroelectric power is available.

Current microprocessor speeds are specified in GigaHertz, which is an upper bound to instruction execution rate, assuming one instruction is decoded per cycle. The growth in microprocessor speeds since late 1970s is shown in Figure 1.1 in [73]. The increase in processor speeds has slowed down in recent years, but the fact that the number of transistors per chip can be increased at a faster rate than its speed is exploited in these systems by providing multiple cores (processors and caches), which provide an increase in raw computing power. An extra effort is, however, required to exploit the parallelism provided by multicore systems [73].

Since the cycle time of main memory is much slower than the processor, cache memories operating at processor speeds are provided to improve performance. Although CPU caches are much smaller than the main memory, they attain small miss rates due to spatial and temporal locality of references [53,73,86,106]. Spatial locality is exploited by prefetching, since it is more advantageous to access consecutive disk (resp. main memory) blocks with one disk (resp. memory) access [73]. An efficient implementation of cache coherence and synchronization in multiprocessor systems is critical for performance [57,73]. Several levels of caches referred to as L1, L2, ..., are usually provided. In multiprocessors, L1 caches are dedicated to one processor, while L2 caches are shared by two or more processors [16].

Cache, DRAM (main memories), and (magnetic) disk technologies and their performance are discussed in [75]. *Hard disk drives (HDDs)* are slow due to their mechanical nature, and their impact on system performance and reliability is discussed in the chapter on storage systems. Numerous technologies referred to as *storage class memory (SCM)* are under development, which in addition to flash memories compete in replacing disks or at least serve as their caches. Performance modeling studies of the processor, caches, main memories, and peripheral devices are discussed in a collection of papers in [81]. The standard computer architecture textbook emphasizing system performance [73].

Benchmarks have been developed over the years for evaluating computer system performance [17]. *Standard Performance Evaluation Corporation's* SPEC CPU2006 has a floating point and integer version [18]. SPECfp2000 results for several popular microprocessors are given in Figure 1.15 in [73]. Early database benchmarks are discussed in a handbook edited by Gray [19]. He was instrumental in proposing the debit-credit benchmark, which due to its simple nature suited Tandem's shared-nothing organization [20]. The performance goal for the debit-credit OLTP benchmark in 1985 was one *kilo transactions per second (KTPS)*, which was determined at the point where the mean txn response time stayed below a certain time limit, say 2 s. The metric for batch applications, such as sorting, is elapsed time. Two computer systems are usually involved in benchmarking, with one system generating txns for the *system under test (SUT)*. This benchmark termed TPC-1 was adopted by the *Transaction Processing Council (TPC)*. TPC later introduced other benchmarks for processing ad hoc queries in relational DBMSs, decision support, data mining, and web applications [21].

I/O benchmarks were developed by the *Storage Performance Council (SPC)* to estimate the performance and energy consumption of disk drives with OLTP and database applications generating random and sequential disk accesses for various RAID levels (see chapter on storage systems) [22].

This chapter deals mainly with methods that can be used to evaluate the performance of computer systems at a macro level, for example, txn response time versus throughput. The emphasis is on queueing theory, which has shown its usefulness in performance evaluation of computer systems, but also computer communication networks. Simulation is a much more flexible tool, which can be used when the system

under consideration is analytically intractable. In fact, passive resources such as miss rates in the memory hierarchy can be determined by trace-driven simulation. Finally, performance is evaluated via measurement studies, which can be used for validating analytical and simulation models (see Section 2.2 in [83]).

In what follows, Section 56.2 is a brief introduction to queueing theory. Analysis of Markovian queueing systems with exponential interarrival and service times is discussed in Section 56.3. Non-Markovian queueing systems including M/G/1 and GI/M/1 are discussed in Section 56.4. Several applications of these queueing systems are also provided. Fork-join queueing systems are discussed in Section 56.5. The analysis of *queueing network models* (QNMs) is discussed in Section 56.6. Buffer space management in computer systems is discussed in Section 56.7. The performance of *concurrency control* (CC) methods is analyzed in Section 56.8. Simulation modeling of computer systems is discussed in Section 56.9. Conclusions are presented in Section 56.10.

56.2 Queueing Theory Basics

Queueing systems consist of a single or multiple servers and a queue that holds incoming requests when all servers are busy. Requests are served as soon as a server becomes available, but forced idleness under some circumstances may reduce the mean overall response time, for example, when the overall queue length is short and one of two servers is considerably faster than the other (see Section 56.3.3). Incoming requests are lost when no queue is provided or the queue is full. Such requests may be resubmitted or are lost as in the case of a caller who does not redial after finding the line busy. The probability of requests being rejected due to a full queue is of interest in the design of multistage switches. Requests wait in the queue until they are served according to a scheduling policy, such as *first-come, first-served* (FCFS). Queueing theory mainly deals with estimating the waiting time in queues, which are formed by humans in the more civilized countries of the world.*

According to Kendall's notation, interarrival and service times in queues are denoted by D (deterministic), M (Markovian or exponential), G (general), E_k (Erlang with k exponential stages), H_k (k -way hyperexponential distribution), etc. We use GI/G/m/K/M to represent a queueing system with general independent interarrival time, general service time, m servers, total capacity K to hold requests, and M sources. By default $K = \infty$ and $M = \infty$.

Little's law is a fundamental law in queueing theory, which was well known even before it was proved by him [23]. This law states that the long-term average number of requests in a stable system (L) is equal to the long-term average effective arrival rate (λ) multiplied by the average time requests spend at the system (W) or $L = \lambda W$. A pictorial proof of Little's law is given in [78,80,92].

Arrivals may be from an infinite or finite number of sources. Examples of the former are calls to a telephone switching system, txn arrivals at an OLTP system, and requests to a web server. Quasi-random arrivals apply to the users of a time-sharing system, where a finite number of users generate successive requests following a delay known as think time [80]. The error introduced by approximating a finite number of sources in an M/G/1//N queueing system with M/G/1 is explored in Section 56.4.2.

The Poisson arrival process is associated with exponential interarrival times with *probability distribution function* (PDF) $A(t) = 1 - e^{-\lambda t}$, $t > 0$, and *probability density function* (pdf) $a(t) = \frac{dA(t)}{dt} = \lambda e^{-\lambda t}$.

Poisson arrivals are uniformly distributed over intervals [78], for example, given a time interval $(0, 1)$, n arrivals partition the interval to segments of average length $1/(n + 1)$. This observation was utilized in [134] in determining the mean seek distance according to the scan policy. Generally, we denote the pdf of a continuous *random variable* (r.v.) as $f(x)$, so that for positive r.v.'s $\int_0^{\infty} f(x)dx = 1$ and the PDF is

* John Milton, the English poet, ends his poem "On his blindness" with "They also serve who only stand and wait." At US Congress, money is made by professional "waiters" who are hired by lobbyists to stand in their place for congressional hearings they wish to attend.

$F(t) = \int_0^t f(x)dx$, so that $F(\infty) = 1$. This is not always the case, for example, the pdf of the busy period in M/G/1 is $\int_0^\infty g(y)dy = 1/\rho$, which is smaller than one for $\rho > 1$ (see Section 56.4.1). In the case of discrete r.v.'s instead of the pdf, we have the *probability mass function (pmf)* with $\sum_{k \geq 0} p_k = 1$. The *cumulative distribution function (cdf)* is $P_k = \sum_{j=0}^k p_j$, which tends to one as $k \rightarrow \infty$ [42,143].

The mean, second moment, the variance, and coefficient of variation squared of the exponential distribution are

$$\bar{t}_e = \int_0^\infty [1 - A(t)] dt = \frac{1}{\lambda}, \quad \bar{t}_e^2 = \int_0^\infty t^2 a(t) dt = \frac{2}{\lambda^2}, \quad \sigma_e^2 = \frac{1}{\lambda^2}, \quad c_e^2 = \frac{\sigma_e^2}{(\bar{t}_e)^2} = 1. \tag{56.1}$$

The *Laplace Stieltjes transform (LST)* of a positive r.v. with pdf $f(x)$ and its i th moment is given as follows [78,143]:

$$\mathcal{F}^*(s) = \int_0^\infty f(x) e^{-sx} dx, \quad \bar{x}^i = (-1)^i \frac{d^i \mathcal{F}^*(s)}{ds^i} \Big|_{s=0} = \int_0^\infty x^i f(x) dx. \tag{56.2}$$

For the exponential distribution, the LST, i th moment, the variance, and the coefficient of variation squared are

$$\mathcal{A}^*(s) = \int_{x=0}^\infty (\lambda e^{-\lambda t}) e^{-st} dt = \lambda \int_0^\infty e^{-(s+\lambda)t} dt = \frac{\lambda}{s + \lambda}, \quad \bar{t}_a^i = \frac{i! \lambda}{(s + \lambda)^{i+1}} \Big|_{s=0} = \frac{i!}{\lambda^i}.$$

The exponential distribution has the memoryless property, that is, given an elapsed time t_e , the time to the next arrival remains the same:

$$P[t \leq (t + t_e) | t > t_e] = \frac{P[t_e < t \leq (t + t_e)]}{P[t > t_e]} = \frac{1 - e^{-\lambda(t+t_e)} - (1 - e^{-\lambda t_e})}{e^{-\lambda t_e}} = 1 - e^{-\lambda t}.$$

The memoryless property also holds for the discrete geometric distribution. In tossing a coin given that p is the probability of a head and $q = 1 - p$ the probability of a tail, then the pmf of the number of coin tosses leading to a head and the mean number of tosses is [42,143]:

$$p_k = pq^{k-1} \quad \bar{K} = p \sum_{k \geq 1} kq^{k-1} = p \frac{d}{dq} \sum_{k \geq 1} q^k = \frac{1}{p}. \tag{56.3}$$

An alternate method to determine the moments of a discrete r.v. is to compute its z -transform, take its derivatives, and set $z = 1$:

$$P(z) = \sum_{k \geq 1} p_k z^k = pz \sum_{k \geq 1} (qz)^{k-1} = \frac{pz}{1 - qz}, \tag{56.4}$$

where the sum converges for $|qz| < 1$.

Taking the i th derivatives of $P(z)$'s, we have

$$\overline{K(K-1)\dots(K-i+1)} = \frac{d^i P(z)}{dz^i} \Big|_{z=1} = \sum_{k \geq 0} k(k-1)\dots(k-i+1) p_k z^{k-i} \Big|_{z=1}. \tag{56.5}$$

In the case of the geometric distribution \overline{K} and $\overline{K(K-1)}$ are

$$\overline{K} = \frac{dP(z)}{dz} \Big|_{z=1} = \frac{p}{(1-qz)^2} \Big|_{z=1} = \frac{1}{p}, \quad \overline{K(K-1)} = \frac{d^2P(z)}{dz^2} \Big|_{z=1} = \frac{2pq}{(1-qz)^3} \Big|_{z=1} = \frac{2q}{p^2} \tag{56.6}$$

Consider passengers arriving at random instants at a bus station, where the bus interarrival time pdf is $f(x)$. Of interest in the mean residual time to the next bus arrival (r_1). Renewal theory shows that arrivals tend to occur during longer bus interarrival times with a pdf $f_x(x) = xf(x)/m_1$, whose mean is $\overline{X}_1 = \int_0^\infty x^2 f(x) dx = m_2/m_1$. The forward and backward recurrence times are identically distributed so that the forward recurrence time or the mean residual lifetimes is $r_1 = m_2/(2m_1)$ [78]. In the case of the exponential distribution for bus interarrival times, $r_1 = 1/\lambda$, which is a consequence of its memoryless property. Given that the passenger arrives $1/\lambda$ time units after the arrival of the previous bus, then the bus interarrival time encountered by passengers is $f_x(x) = \lambda^2 x e^{-\lambda x}$, which is the two-stage Erlang distribution with mean $2/\lambda$ [143].

Generally the k -stage Erlang distribution (E_k) consists of $k > 1$ exponential stages with rate $k\mu$, so that $f_E(x) = k\mu(k\mu x)^{k-1} e^{-k\mu x}/(k-1)!$ for $x \geq 0$. The mean, variance, the coefficient of variation squared, the LST, and the LST with an infinite number of stages ($k \rightarrow \infty$) are

$$\overline{x}_E = \frac{1}{\mu}, \quad \sigma_E^2 = \frac{1}{k\mu^2}, \quad c_E^2 = \frac{1}{k} < 1, \quad \mathcal{E}^*(s) = \left(\frac{k\mu}{s+k\mu} \right)^k, \quad \lim_{k \rightarrow \infty} \left(1 + \frac{s}{k\mu} \right)^{-k} = e^{-s/\mu}. \tag{56.7}$$

In fact, $e^{-s/\mu} \Leftrightarrow u_0(x-1/\mu)$, which is a unit impulse at $x = 1/\mu$. It is shown in Figure 4.5 in [78] that the pdf for E_k tends to a fixed value as $k \rightarrow \infty$.

The pdf of the Gamma distribution is given as $f_G(x) = \alpha(\alpha x)^{\beta-1} e^{-\alpha x}/\Gamma(\beta-1)$ for $x > 0$, where the Gamma function $\Gamma(t) = \int_0^\infty x^{t-1} e^{-x} dx$. When t is an integer $\Gamma(t) = (t-1)!$, which is the factorial function. The Gamma distribution in this case is tantamount to an Erlang distribution with t stages. The mean, variance, coefficient of variation squared, and LST for this distribution are

$$\overline{x}_G = \frac{\beta}{\alpha}, \quad \sigma_G^2 = \frac{\beta}{\alpha^2}, \quad c_G^2 = \frac{1}{\beta}, \quad \mathcal{G}^*(s) = \left(\frac{\alpha}{\alpha+s} \right)^\beta. \tag{56.8}$$

The I -way Hyperexponential distribution (H_2) $f_H(x) = \sum_{i=1}^I p_i \mu_i e^{-\mu_i x}$, $x > 0$. For two-way hyperexponential $p_1 = p$ and $p_2 = 1 - p$ with $p \neq 0$ and $p \neq 1$. The mean, second moment, coefficient of variation squared, and the LST of this distribution are

$$\overline{x}_H = \sum_{i=1}^I \frac{p_i}{\mu_i}, \quad \overline{x_H^2} = 2 \sum_{i=1}^I \frac{p_i}{\mu_i^2}, \quad c_H^2 = \frac{\overline{x_H^2}}{(\overline{x}_H)^2} - 1, \quad \mathcal{F}_H(s) = \sum_{i=1}^I p_i \frac{\mu_i}{s + \mu_i}. \tag{56.9}$$

The LST $\mathcal{H}^*(s)$ is a weighted sum of I LSTs for corresponding exponentials. It can be shown easily that $c_H^2 > 1$ for $I = 2$. The CPU service time distribution has been approximated by the hyperexponential distribution as shown in Figure 3.13 in [144].

The exponential and related distributions are popular in that they lend themselves to tractable analytic solutions. The Erlang (resp. hyperexponential) distribution can be used as an approximation to distributions with a coefficient of variation smaller (resp. larger) than one. The Coxian distribution $f_C(x)$ consists of multiple exponentials in tandem similarly to an Erlang distribution, but with a variable number of stages being bypassed. Based on the choice of its parameters, it can attain a coefficient of variation

smaller or larger than one. In the case of the Coxian distribution with r stages with services rates μ_i for $1 \leq i \leq r$, the probability that the i th stage is visited is β_i and $\gamma_i = 1 - \beta_i$ is the probability that an early exit is taken, so that $\gamma_{r+1} = 1$. An Erlang distribution is obtained by setting $\gamma_i = 0, \forall i$. The LST for the Coxian distribution can be specified as follows [78,79]:

$$\mathcal{F}_C^*(s) = \int_{x=0^-}^{\infty} f_C(x) e^{-sx} dx = \gamma_1 + \sum_{i=1}^r \beta_1 \beta_2 \dots \beta_i \gamma_{i+1} \prod_{j=1}^i \left(\frac{\mu_j}{s + \mu_j} \right). \quad (56.10)$$

The integration is started at $x = 0^-$ to capture the discontinuity at $x = 0$, which has probability γ_1 . Given that $\beta_i = q, \gamma_i = 1 - q, \forall i, \gamma_{r+1} = 1$ and $\mu_i = \mu, \forall i$ then the mean, second moment, coefficient of variation squared, and the LST are

$$\bar{x}_C = \sum_{i=1}^r \frac{q^i}{\mu}, \quad \overline{x_C^2} = 2 \sum_{i=1}^r i \frac{q^i}{\mu^2}, \quad c_C^2 = 2 \frac{\sum_{i=1}^r i q^i}{\left(\sum_{i=1}^r q^i \right)^2}, \quad \mathcal{C}^*(s) = 1 - q + \sum_{i=1}^r q^i \left(\frac{q\mu}{s + \mu} \right)^i. \quad (56.11)$$

The pdf of the uniform distribution can be specified as $f_U(x) = (b - a)^{-1}$ for $a \leq x \leq b$. Its mean, variance, coefficient of variation squared, and LST are

$$\bar{x}_U = \frac{a+b}{2}, \quad \sigma_U^2 = \frac{(b-a)^2}{12}, \quad c_U^2 = \frac{1}{3} \left(\frac{b-a}{b+a} \right)^2, \quad \mathcal{F}_U^*(s) = \frac{e^{-bs} - e^{-as}}{s(a-b)}. \quad (56.12)$$

Other arrival processes and service time distributions and methods to generate them are discussed in Sections 6.8 and 11.5.2 in [45], Also, see Chapter 5 by Shedler in [82].

We use a disk drive as an example of a server whose service time is its access time. Disks are in fact a complex queueing system in that the service time of requests is affected by the order in which requests are processed and hence the disk scheduling policy. For accesses to randomly placed small disk blocks, the disk access time is dominated by the positioning time of the read/write head, which is the sum of seek time and rotational latency [75]. The transfer time of small disk blocks is negligible for current disks with very high recording densities.

We consider a disk drive with a mean access time $\bar{x}_{disk} = 5$ milliseconds (ms) with FCFS scheduling. It is intuitively obvious that this disk can process at most $\lambda_{max} = 1/\bar{x}_{disk} = 200$ accesses per second. This also follows from the fact that with an arrival rate λ the utilization of a single server, defined as $\rho = \lambda \bar{x}_{disk}$, is at most one. Note that ρ is also the fraction of time that the server is busy. Ordinarily for $\rho < 1$ the server alternates between idle and busy periods, but with an arrival rate $\lambda > \lambda_{max}$ and $\rho > 1$ the length of the queue increases indefinitely. For $\rho > 1$ the probability that the busy period ends is $1/\rho$ (see Equation 56.38 for $s = 0$ and the discussion that follows). When the system load $\lambda \bar{x} > 1$, the number of servers should be increased such that $\rho = \lambda \bar{x}/m$ is less than one. Attention should be paid to maintaining acceptable mean response time, for example, for $\rho = 0.5$ the mean response time in an M/M/1 queueing system is doubled and it increases 10fold for $\rho = 0.9$ (see Equation 56.14). It is interesting to note that this increase is only fivefold in an M/M/2 queueing system at the same utilization (see Equation 56.20).

Disk access time to randomly placed disk blocks is slow, since it is the sum of seek time, rotational latency, and transfer time [139]. This led to the proposal of the SCAN and *shortest seek time first* (SSTF) disk scheduling policies as improvements to FCFS scheduling in mid-1960s by Denning in [53]. Both are outperformed by the *shortest access time first* (SATF) policy, which was proposed by Jacobson and Wilkes at HP in 1991 to minimize the positioning time, that is, the sum of seek time and latency. SATF's reduction in disk access time with respect to FCFS is $\approx n^{1/5}$ [139], for example, with $n = 32$ enqueued requests $\bar{x}_{SATF} \approx \bar{x}_{FCFS}/2$.

The response time (\tilde{r}) of a queueing system is the sum of waiting (\tilde{w}) and service time (\tilde{x}), that is, $\tilde{r} = \tilde{w} + \tilde{x}$. The mean response time is obtained by taking the expectations of both sides as $R = W + \bar{x}$. The variance of response time (\tilde{r}) is given as the sum of the variances of \tilde{w} and \tilde{x}

$$\sigma_r^2 = E[(\tilde{w} + \tilde{x})^2] - (W + \bar{x})^2 = (\overline{W^2} - W^2) + (\overline{x^2} - (\bar{x})^2) + 2E[\tilde{w}\tilde{x}] - 2W\bar{x} = \sigma_w^2 + \sigma_x^2.$$

The expression $E[\tilde{w}\tilde{x}] = W\bar{x}$, since the waiting time (\tilde{w}) is independent from the service time (\tilde{x}) for FCFS, LCFS (nonpreemptive), and *service in random order* (SIRO) scheduling policies.

The mean waiting time W for M/G/1 queues can be obtained by noting that due to *Poisson Arrivals See Time Averages* (PASTA) [45], arrivals encounter the mean queue length $\bar{N}_q = \lambda W_{FCFS}$ and the equality holds due to Little's law. Also due to PASTA a busy server is encountered with probability ρ , where the mean residual service time of the request in service is $m_1 = \bar{x}^2 / (2\bar{x})$

$$W_{FCFS} = \bar{N}_q \bar{x} + \rho m_1 \Rightarrow W_{FCFS} = \frac{\lambda \bar{x}^2}{2(1-\rho)} = \frac{\rho \bar{x} (1 + c_X^2)}{2(1-\rho)}. \quad (56.13)$$

This equation is known as the Pollaczek-Khinchine (P. K.) formula for mean waiting time. There are two observations: (1) W_{FCFS} increases in proportion to $\rho/(1-\rho)$ and as $\rho \rightarrow 1$ $W \rightarrow \infty$, (2) For a fixed ρ , W_{FCFS} increases with c_X^2 . With respect to W_{FCFS} for the exponential distribution with $c_X^2 = 1$ is halved for a fixed service time with $c_F^2 = 0$ and doubled with a hyperexponential distribution with $c_H^2 = 3$

$$W_{FCFS} = \frac{\rho \bar{x}}{1-\rho}, \quad R_{FCFS} = W_{FCFS} + \bar{x} = \frac{\bar{x}}{1-\rho}. \quad (56.14)$$

The P. K. formula for mean waiting time (W) also holds for LCFS and SIRO policies, but both policies have higher second moments than FCFS [56], as follows:

$$E[w_{LCFS}^2] = \frac{E[w_{FCFS}^2]}{1-\rho}, \quad E[w_{SIRO}^2] = \frac{E[w_{FCFS}^2]}{1-(\rho/2)}.$$

$E[w_{FCFS}^2] = \overline{W^2}$ is given by Equation 56.33 in Section 56.4.1.

A weakness of FCFS scheduling is that all requests, regardless of their service time, encounter the same mean waiting time (W_{FCFS}). *Round-robin* (RR) scheduling allows CPU requests to make progress up to a short time quantum q before the request is preempted and another request is scheduled to run. Shorter requests leave the system after receiving a few quanta. This discrete time queueing model is analyzed in [53], and Chapter 6 in [111] is dedicated to discrete time systems. *Processor sharing* (PS) is an extreme form of RR with $q \rightarrow 0$, which yields $R_{PS}(x) = x/(1-\rho)$ when the service time is x . Given that the service time pdf is $b(x)$, the mean response time for PS is

$$R_{PS} = \int_0^{\infty} \frac{xb(x)dx}{1-\rho} = \frac{\bar{x}}{1-\rho}, \quad W_{PS} = R_{PS} - \bar{x} = \frac{\rho \bar{x}}{1-\rho}. \quad (56.15)$$

Referring to Equation 56.13 it follows $W_{PS} < W_{FCFS}$ for $c_X^2 > 1$, so that PS is the preferred policy when service times are more variable than the exponential.

Foreground/background (FB) scheduling attains even better response times for short requests than RR, since after the time quantum of a CPU expires, longer requests are demoted to lower priority queues, so that shorter requests do not compete with longer requests (see Section 56.4.6 in [79]).

Request priorities can be assigned externally, for example, the processing of OLTP txns at the CPU is given a higher priority than batch jobs. CPU preemptions are possible because they incur a low overhead and that the preemptive resume policy is applicable, so that by saving the state of the computation (the program counter and registers) in main memory, a preempted request may resume from the point it was interrupted. It is inefficient to implement preemptive disk scheduling, since only a preemptive repeat policy is applicable in this case, with the unproductive seek and latency phases being repeated. Preemption is only possible after the completion of a seek and during latency and transfer phases [129]. An efficient implementation of priorities with SATF disk scheduling is attained by multiplying estimated access time of higher priority disk requests by $\alpha \approx 0.625$ [139]. Formulas for M/G/1 queueing systems with priorities are given in Section 56.4.6.

The conditional waiting time for the *shortest processing time (SPT)* first scheduling with job service time PDF $B(x)$ is given in [53,56,78] as

$$W_{SPT}(t) = \frac{\overline{\lambda x^2}}{2 \left[1 - \lambda \int_0^t x dB(x) \right]^2}. \quad (56.16)$$

For small t $W_{SPT}(t) = W_0 = \overline{\lambda x^2}/2$, which is the mean residual service time, since the request is processed as soon as the current request is completed. For large t $W_{SPT}(t) = W_0/(1-\rho)^2 = W_{FCFS}/(1-\rho)$.

Table 3.1 in [79] is a summary of optimal scheduling algorithms. One dimension specifies preemptiveness and the second dimension specifies whether (1) the processing time is known, (2) the processing time distribution is known, and (3) no information about processing time is available. In case (1) SPT (also known as *shortest job first (SJF)*) and *shortest remaining processing time (SRPT)* are applicable depending on preemptiveness. In case (2) *shortest expected processing time (SEPT)* and *shortest expected remaining time time (SERPT)* are applicable, depending on preemptiveness. Finally in case (3) FCFS, LCFS, SIRO, PS, and FB are applicable.

56.3 Analysis of Markovian Models

Queues with Poisson arrivals and exponential service times, referred to as Markovian are undertaken with *continuous time Markov chains (CTMCs)* models [42,45,78,80,143]. Markov chains for queueing systems have discrete states representing the number of requests in the system. Transitions among states are exponentially distributed. The transition rate from each state is the sum of the transitions due to arrivals and completions and the holding time in that state is the inverse of this sum. Systems modeled in this section can be represented by one-dimensional CTMCs known as *birth-death (BD)* processes. Only nearest neighbor transitions are allowed in the more simple queueing systems discussed in Chapter 3 in [78], but this is not so in the case of queueing systems with bulk arrivals and bulk service discussed in Chapter 4 in [78] and Section 56.3.6. The discussions in Chapters 3 and 4 in [78] are referred to as baby queueing theory by Kleinrock [24].

In Section 56.3.1, we use BD models to analyze the performance of M/M/1 queues. In Section 56.3.2, we analyze M/M/1/K queues as an example of a finite capacity system. In Section 56.3.3, we analyze the M/M/m queueing system with $m = 2$ to illustrate the benefits of resource sharing in this context and provide the analytical results for the M/M/m queueing system. In Section 56.3.4, we analyze the performance of an M/M/2 queueing system, whose servers have different service rates. In Section 56.3.5, we analyze the performance of an M/M/1/M queueing system, which has finite sources. In Section 56.3.6, we describe Markovian systems with bulk arrivals and bulk service. The *matrix geometric method (MGM)* is briefly introduced in Section 56.3.7. We postulate FCFS scheduling in this section so that this fact is elided in the notation that follows.

56.3.1 M/M/1 Queueing System

The operation of an M/M/1 queue can be represented by a BD process with states denoted by \mathcal{S}_k , where $k \geq 0$ is the number of requests at the system. The transition $\mathcal{S}_k \rightarrow \mathcal{S}_{k+1}$ with rate λ denotes the arrival of a request or a birth at \mathcal{S}_k and the transition $\mathcal{S}_{k+1} \rightarrow \mathcal{S}_k$ with rate μ denotes the completion of a request or a death at \mathcal{S}_{k+1} . In summary, the arrival rate is λ and the service rate is μ .

The probability that the system is at state \mathcal{S}_k in steady state is denoted by p_k . This also means that for a long time interval T the system is at \mathcal{S}_k for time Tp_k . In other words, p_k is the fraction of time that the system is at \mathcal{S}_k . In equilibrium, the number of transitions in the two directions with increasing and decreasing number of requests are equal, that is, $\lambda Tp_k = \mu Tp_{k+1}$, for $k \geq 0$.^{*} Dividing both sides by T we have $\lambda p_k = \mu p_{k+1}$, for $k \geq 0$. Given the utilization factor $\rho = \lambda/\mu$, $p_k = \rho p_{k-1}$ and $p_k = \rho^k p_0$. The sum $S = \sum_{k \geq 0} p_k = p_0(1-\rho)^{-1}$ for $\rho < 1$. Since the probabilities sum to one, setting $S = 1$ yields $p_0 = 1 - \rho$ and hence $p_k = (1 - \rho)\rho^k$ for $k \geq 0$, which is the modified geometric distribution [143]. The mean number of requests at the system is

$$\bar{N} = \sum_{k \geq 1} k p_k = (1-\rho) \sum_{k \geq 1} k \rho^k = (1-\rho) \rho \sum_{k \geq 1} k \rho^{k-1} = (1-\rho) \rho \frac{d}{d\rho} \sum_{k \geq 1} \rho^k = \frac{\rho}{1-\rho}. \quad (56.17)$$

The second moment of N and its variance can be obtained as follows:

$$\begin{aligned} \overline{N(N-1)} &= \sum_{k \geq 0} k(k-1)p_k = (1-\rho)\rho^2 \frac{d^2}{d\rho^2} \sum_{k \geq 1} \rho^k = \frac{2\rho^2}{(1-\rho)^2}. \\ \sigma_N^2 &= \overline{N(N-1)} + \bar{N} - (\bar{N})^2 = \frac{\rho}{(1-\rho)^2}. \end{aligned} \quad (56.18)$$

The mean response time and mean waiting for M/M/1, which was given as a special case of Equation 56.13 by Equation 56.14 can be obtained by applying Little's law:

$$R_{M/M/1} = \frac{\bar{N}}{\lambda} = \frac{\bar{x}}{1-\rho}, \quad W_{M/M/1} = R_{M/M/1} - \bar{x} = \frac{\rho \bar{x}}{1-\rho}. \quad (56.19)$$

The z -transform for the number in system is

$$P(z) = \sum_{k \geq 0} p_k z^k = (1-\rho) \sum_{k \geq 0} (\rho z)^k = \frac{1-\rho}{1-\rho z},$$

where the sum converges for $|\rho z| < 1$.

56.3.2 M/M/1/K Queueing System with Finite Capacity

An M/M/1/K queue can hold at most K requests, but requests arriving to a full system are lost, so that this queueing system is referred to as *blocked calls cleared (BCC)* in telephony [78]. The state equilibrium probabilities are $p_k = p_0(\lambda/\mu)^k$ for $0 \leq k \leq K$, so that $\sum_{k=0}^K p_k = 1$ yields $p_0 = (1-\lambda/\mu) / (1-(\lambda/\mu)^{K+1})$. The fraction of arrivals lost is p_K and the throughput of processed requests is $\lambda' = \lambda(1-p_K)$. It follows that the server utilization is $\rho = \lambda(1-p_K)/\mu$. In the special case $\lambda = \mu$, applying L'Hospital's rule [95] yields $p_k = 1/(K+1)$ for $0 \leq k \leq K$. For $K = 1$, $p_0 = \mu/(\lambda + \mu)$ and $p_1 = \lambda/(\lambda + \mu)$.

^{*} The concept of equilibrium is illustrated in [78] by a passenger traveling among three cities: C_1 , C_2 , and C_3 . The probability of ending up in C_j at the end of the day after being in C_i in the morning is given by the probability matrix $P = (p_{ij})$ for $1 \leq i, j \leq 3$. This is a discrete time Markov chain and assuming that the passenger is initially at C_i , then he is in one of the cities with probability $\underline{\pi}(1) = \underline{\pi}(0)P$ after 1 day and after n days $\underline{\pi}(n) = \underline{\pi}(0)P^n$ or $\underline{\pi}(n) = \underline{\pi}(n-1)P$. As $n \rightarrow \infty$, the time index can be elided and the set of equations can be expressed as $\underline{\pi} = \underline{\pi}P$, which implies the final state is independent of the initial state.

56.3.3 M/M/m Queuing System and Resource Sharing

Consider an M/M/2 queue with arrival rate λ with two servers each with service rate μ , so that the server utilization is $\rho = \lambda/(2\mu)$. The state equilibrium equations are

$$\lambda p_0 = \mu p_1, \quad \lambda p_k = 2\mu p_{k+1} \text{ for } k \geq 1.$$

It follows from $p_k = 2p_0\rho^k$ for $k \geq 1$ and the fact that probabilities sum to one yields $p_k = (1 - \rho)/(1 + \rho)$ and hence

$$\bar{N}_{M/M/2} = \sum_{k \geq 0} k p_k = \frac{\rho}{1 - \rho^2}, \quad R_{M/M/2} = \frac{\bar{N}}{\lambda} = \frac{\bar{x}}{1 - \rho^2} \quad (56.20)$$

The M/M/2 queueing system with an arrival rate 2λ , has the same server utilization as two (slow) M/M/1 queues with service rates μ , each with arrival rate λ . It is easy to see that $R_{M/M/2} < R_{M/M/1}^{\text{slow}}$, which is because there is the possibility of queueing at one of the servers, while the other server is idle since the jockeying of requests is not provided. We next consider a single fast server with mean service time $\bar{x}_{\text{fast}} = 1/(2\mu)$, and arrival rate 2λ , so that $\rho = \lambda/\mu$. We have $R_{M/M/1}^{\text{fast}} = (1/(2\mu))/(1 - \rho)$, which is smaller than $R_{M/M/2}$. A generalization of this discussion appears in Section 5.1 in [79]. It is important to note that for highly variable service times the M/G/m queueing system is preferable to a single fast M/G/1 queue with the same total processing capacity, which is because with highly variable service times a lengthy requests may get in the way of all other requests in a single queue.

The M/M/ ∞ queueing system has an infinite number of servers so that there is no queueing delay. The state equilibrium equations $\lambda p_k = (k+1)\mu p_{k+1}$ for $k \geq 0$ lead to $p_k = p_0 (\lambda/\mu)^k / k!$ for $k \geq 0$. It follows from $\sum_{k \geq 0} p_k = p_0 \sum_{k \geq 0} (\lambda/\mu)^k / k! = 1$ that $p_0 = e^{-\lambda/\mu}$ and $p_k = e^{-\lambda/\mu} (\lambda/\mu)^k / k!$, which is the Poisson distribution with mean and variance $\bar{N} = \sigma_N^2 = \lambda/\mu$ [42,78,143]. Note that this solution applies to an M/G/ ∞ queue with mean service time $\bar{x} = 1/\mu$, so that $R = \bar{x}$. The transient probability distribution for the M/G/ ∞ queueing system is given by Equation 56.9 in [143] as $P[X(t) = k] = e^{-\lambda t p} (\lambda t p)^k / k!$, where $p = \int_0^t [(1 - G(x))/t] dx$, where $G(x)$ is the PDF for service time. Note that for $t = \infty$, $t p = \int_0^\infty [1 - G(x)] dx = 1/\mu$ [143], which is previously obtained steady-state probability for M/M/ ∞ .

For the M/M/m queueing system, $\rho = \lambda/m\mu$ and p_k can be expressed as follows:

$$p_k = p_0 \frac{(m\rho)^k}{k!}, \quad k \leq m; \quad p_k = p_0 \frac{\rho^k m^m}{m!}, \quad k \geq m; \quad p_0 = \left[\sum_{k=0}^{m-1} \frac{(m\rho)^k}{k!} + \frac{(m\rho)^m}{(1 - \rho)m!} \right]^{-1}. \quad (56.21)$$

The probability of queueing $P[k \geq m] = P_m$, the mean number in the system, and mean response time are

$$P_m = \sum_{k=m}^{\infty} p_k = p_0 \sum_{k=m}^{\infty} \frac{(m\rho)^k}{m! \times m^{k-m}}, \quad \bar{N} = m\rho + \frac{\rho}{1 - \rho} P_m, \quad R = \left[1 + \frac{P_m}{m(1 - \rho)} \right]. \quad (56.22)$$

56.3.4 M/M/2 with Heterogeneous Servers

The analysis of a two-server queue with heterogeneous servers, as given by Example 8.29 in [143], is significantly more complex than an M/M/2 queue. The service rate μ_1 at server 1 is assumed to be higher than the service rate μ_2 at server 2, that is, $\mu_1 > \mu_2$. The utilization factor is $\rho = \lambda/(\mu_1 + \mu_2)$.

The states of the CTMC are specified as (n_1, n_2) , where n_1 is the number of jobs in the queue including any at the faster server and $n_2 \in \{0, 1\}$ indicates whether the slow server is busy or not. Jobs arriving at an empty system are first served by the fast server. The state equilibrium equations are

$$\begin{aligned}\lambda p(0, 0) &= \mu_1 p(1, 0) + \mu_2 p(0, 1) \\ (\lambda + \mu_1) p(1, 0) &= \mu_2 p(1, 1) + \lambda p(0, 0) \\ (\lambda + \mu_2) p(0, 1) &= \mu_1 p(1, 1) \\ (\lambda + \mu_1 + \mu_2) p(1, 1) &= (\mu_1 + \mu_2) p(2, 1) + \lambda (p(0, 1) + p(1, 0)) \\ (\lambda + \mu_1 + \mu_2) p(n, 1) &= (\mu_1 + \mu_2) p(n + 1, 1) + \lambda p(n - 1, 1) \text{ for } n > 1.\end{aligned}$$

The mean number of jobs at the queueing system is

$$\bar{N} = \frac{1}{F(1 - \rho)}, \quad F = \frac{\mu_1 \mu_2 (1 + 2\rho)}{\lambda(\lambda + \mu_2)} + \frac{1}{1 - \rho}. \quad (56.23)$$

This analysis has been utilized to determine the effect of adding a slow computer to fast computer on improving the mean response time. At lower values of λ , the mean response time can be improved by not utilizing the slower computer at all, while at $\lambda > \mu_1$ the slower computer allows higher throughputs up to $\lambda < \mu_1 + \mu_2$ to be attained.

56.3.5 M/M/1//M or Machine Repairman Model

The *machine repairman model* (MRM) considers M machines with exponentially distributed times to failure with rate λ . Machines are repaired by a single repairman with exponentially distributed service time with rate μ . Alternatively there are M users with exponentially distributed think times with mean $Z = 1/\lambda$, which share a computer system with exponentially distributed processing times with mean $1/\mu$. The state equilibrium equations with k requests at the computer system are

$$(M - k)\lambda p_k = \mu p_{k+1} \text{ for } 0 \leq k \leq M - 1.$$

The probabilities are given as follows:

$$p_k = p_0 \prod_{i=0}^{k-1} \frac{(M - i)\lambda}{\mu} = p_0 \left(\frac{\lambda}{\mu}\right)^k \frac{M!}{(M - k)!}, \quad p_0 = \left[\sum_{k=0}^M \left(\frac{\lambda}{\mu}\right)^k \frac{M!}{(M - k)!} \right]^{-1}. \quad (56.24)$$

It follows from Little's result applied to the whole system that

$$M \left(\frac{1}{\lambda} + R \right) = \mu(1 - p_0) \Rightarrow R = \frac{M}{\mu(1 - p_0)} - \frac{1}{\lambda}. \quad (56.25)$$

The normalized mean response time $R_n = R\mu$ versus M has two regions: (1) For small M $R_n \approx 1$, that is, no queueing delay. (2) For large M $R_n \approx M - \mu Z$, that is, R_n increases by one for each additional user. The two lines intersect at $M^* = 1 + \mu Z$, which is known as the saturation number (see Figure 4.27 in [79]). Under the best circumstances users do not encounter queueing delays up to M^* . This model can be used to determine the minimum MPL in order to keep the CPU 100% utilized under perfect conditions, that is, fixed disk and CPU service times. Provided 1 millisecond (ms) of CPU processing entails a 10 ms disk access time requires the MPL to be equal to 11.

User productivity at a time-sharing system is affected by the system response time, that is, user think times have been observed to decrease with subsecond response times. The number of programmer interactions per hour is 180 for a mean response time of $R_1 = 3$ s, but this number is doubled (to 371) when the mean response time is $R_2 = 0.3$ s [25]. It follows from $3600 = 180(R_1 + Z_1)$ that $Z_1 = 17$ and similarly $Z_2 = 9.4$, that is, the mean think time is almost halved with the improved R .

This simple QNM was successfully utilized by Scherr in the analysis of the *compatible time sharing system* (CTSS) at MIT [26,104]. CTSS is a uniprogrammed system, which follows a round-robin policy in processing one program at a time (see Section 56.2). Once the time quantum is expired, the currently active request is preempted and swapped out to a drum, so that the next pending request can be loaded into main memory.

The single server in MRM can be replaced by a state-dependent server representing the computer system using the hierarchical decomposition approach, so that the service rate of the server is $T(k)$, $k \geq 1$ (see Section 56.6.7).

56.3.6 Bulk Arrival and Bulk Service Systems

These systems analyzed in Chapter 4 in [78] are modeled by BD processes with non-nearest neighbor state transitions. We illustrate the analytic solution method required by considering the bulk arrival system, where the probability of i requests per arrival is g_i with a z -transform $G(z) = \sum_{i \geq 1} g_i z^i$. The state equilibrium equations for the number of requests in the system and the associated z -transform is

$$\lambda p_0 = \mu p_1, \quad (\lambda + \mu) p_k = \mu p_{k+1} + \sum_{i=0}^{k-1} p_i \lambda g_{k-i} \quad \text{for } k \geq 1.$$

$$P(z) = \frac{\mu p_0 (1-z)}{\mu(1-z) - \lambda z(1-G(z))} = \frac{p_0}{1 - \frac{\lambda}{\mu} z \frac{1-G(z)}{1-z}}. \quad (56.26)$$

The unknown p_0 can be obtained by noting that $P(1) = 1$. Since the fraction is indeterminate, we apply L'Hospital's rule [95] by differentiating the numerator and denominator with respect to z . This yields $p_0 = 1 - \rho$ with $\rho = \lambda G'(1)/\mu$, where $G'(1)$ is the average bulk size. The reader is referred to [78] for the solution of $M/E_r/1$ queueing system.

We next consider bulk service systems, which can serve up to r requests simultaneously, so that the service rate is $r\mu$ and $\rho = \lambda/(r\mu)$. Service is not delayed if there are $k < r$ requests in the systems and are served at service rate $k\mu$. The state equilibrium equations in this case are

$$\lambda p_0 = \mu \sum_{i=1}^r p_i, \quad (\lambda + \mu) p_k = \mu p_{k+r} + \lambda p_{k-1} \quad \text{for } k \geq 1.$$

The z -transform in this case is given as

$$P(z) = \frac{N(z)}{D(z)} = \frac{\sum_{k=0}^{r-1} p_k (z^k - z^r)}{r\mu z^{r+1} - (1-r\mu)z^r + 1}. \quad (56.27)$$

The denominator $D(z)$ has $r + 1$ roots. Of these $z = 1$ is a root of $N(z)$. It can be shown by Rouché's theorem (see Appendix I in [78]) that $D(z)$ has $r - 1$ roots with $|z| < 1$, which are also roots of $N(z)$, since

$P(z)$ is analytic. There is a single root $|z_0| > 1$, so that $P(z) = [K(1 - z/z_0)]^{-1}$ and $P(1) = 1$ yields $K = 1/(1 - 1/z_0)$. Inverting $P(z)$ we have a modified geometric distribution

$$P(z) = \frac{1 - 1/z_0}{1 - z/z_0} \Leftrightarrow p_k = \left(1 - \frac{1}{z_0}\right) \left(\frac{1}{z_0}\right)^k. \quad (56.28)$$

Queueing systems with Erlang interarrival and exponential service times and Poisson arrivals and Erlang service times, respectively, can be dealt with similarly. Note that $E_r/M/1$ and $M/E_r/1$ queues are special cases of $GI/M/1$ and $M/G/1$ queues and lend themselves to the alternative analysis in Sections 56.4.7 and 56.4.1. A text dedicated to bulk queues is [51].

56.3.7 Brief Note on the Matrix Geometric Method

MGM, developed by Neuts and Lipsky, are a generalization of BD processes with vectors substituting single states. Solution techniques for MGMs are discussed in [45,92]. MGM is used to analyze scheduling policies in mirrored disk systems in [142].

56.4 Analysis of Non-Markovian Queueing Systems

This section is organized as follows. We first provide the analysis of the $M/G/1$ queueing system in Section 56.4.1. The inadequacy of the two moment approximation for $M/G/m$ queueing system is shown in [71], which also proposes upper and lower bounds for its mean waiting time. In Section 56.4.2, we use the mean response time of the $M/G/1//N$ finite population model to assess the error introduced by the $M/G/1$ model with a Poisson arrival process. In Section 56.4.3, Lagrange multipliers are used to minimize the mean response time in accessing data blocks from heterogeneous disks. The *vacationing server model (VSM)* in the context of $M/G/1$ queues is discussed in Section 56.4.4. The application of the VSM to the analysis of the scheduling of readers and writers with a threshold policy is discussed in Section 56.4.5. We next proceed to the analysis of priority queueing in Section 56.4.6. The analysis of the $GI/M/m$ queues is discussed in Section 56.4.7. Request routing to minimize response time is discussed in Section 56.4.8. The analysis of polling systems is discussed in Section 56.4.9, followed by load-sharing in homogeneous distributed systems in Section 56.4.10.

56.4.1 $M/G/1$ and $M/G/m$ Queueing Systems

The queueing system $M/G/1$ is a single server queue with Poisson arrivals with rate λ and general service time with pdf $b(x)$, whose i th moment is x^i and its coefficient of variation squared is $c_X^2 = x^2/(\bar{x})^2 - 1$. The LST of the $b(x)$ is $B^*(s) = \int_0^\infty b(x)e^{-sx} dx$. The analysis of the FCFS scheduling policy to determine the mean (W) and second moment (W^2) of waiting time requires the first two and three moments of service time, respectively.

The distribution of the number in system (p_k) is obtained by specifying the number of requests at the $M/G/1$ queue at departure instants [78]: $q_{n+1} = q_n - \Delta_{q_n} + \nu_{n+1}$, where q_{n+1} and q_n is the number of requests left behind by the $n + 1$ st and n th requests at the system, and ν_{n+1} is the number of arrivals while the $n + 1$ st request was in service, and $\Delta_{q_n} = 0$ if $q_n = 0$ and is otherwise one. The probabilities at departure instants $d_k = P[q_n = k]$ can be obtained by solving the recurrence relation for q_n using z -transforms. Given one step transitions, in a nonsaturated $M/G/1$ system, the number of up and down transitions at arrival and departure instants are equal in the long run. Therefore, the probability of encountering k requests at an arrival instant $r_k = d_k$ and due to PASTA the probabilities at an arrival instant are denoted by r_k , so that $r_k = p_k$ and hence $p_k = d_k$.

It can be shown that the z -transform for the number in the system is

$$Q(z) = V(z) \frac{(1-\rho)(1-z)}{1-V(z)/z}. \quad (56.29)$$

$V(z)$ is the z -transform of number of arrivals during the service time of a single request

$$V(z) = \int_0^{\infty} e^{-\lambda x} \sum_{k=0}^{\infty} \frac{(\lambda x z)^k}{k!} b(x) dx = \int_0^{\infty} e^{-\lambda x(1-z)} b(x) dx = \mathcal{B}^*(\lambda(1-z)).$$

The substitution $V(z) = \mathcal{B}^*(\lambda(1-z))$ in Equation 56.29 yields

$$Q(z) = \mathcal{B}^*(\lambda(1-z)) \frac{(1-\rho)(1-z)}{\mathcal{B}^*(\lambda(1-z))-z}. \quad (56.30)$$

In the case of exponential service times $\mathcal{B}^*(s) = \mu/(s + \mu)$,

$$Q(z) = \frac{1-\rho}{1-\rho z} \Leftrightarrow p_k = (1-\rho)\rho^k, \quad k \geq 0.$$

Inversions of $Q(z)$ to yield p_k for $M/H_2/1$, $M/D/1$, and $M/E_k/1$ are given in Table 7.2 and graphed for $\rho = 0.75$ in Figure 7.4 in [92] (interestingly $p_1 > p_0 = 0.25$ for $M/D/1$).

Similarly to $V(z) = \mathcal{B}^*(\lambda(1-z))$, it can be shown that the following relationship holds between the z -transform for the number of arrivals during the response time of a request, which is also the number of requests left behind by FCFS scheduling. Given $d_k = p_k$ this is also the z -transform of the distribution of the number of requests in the system, hence $Q(z) = \mathcal{S}^*(\lambda - \lambda z)$, where $\mathcal{S}^*(s)$ is the LST of response time pdf. Setting $s = (1-\lambda)z$

$$\mathcal{S}^*(s) = \mathcal{B}^*(s) \frac{s(1-\rho)}{s - \lambda + \lambda \mathcal{B}^*(s)}. \quad (56.31)$$

Given that $\tilde{r} = \tilde{w} + \tilde{x}$ and that the mean waiting time \tilde{x} is independent from the service time (\tilde{x}) for the FCFS policy, we have $\mathcal{S}^*(s) = \mathcal{W}^*(s)\mathcal{B}^*(s)$. It follows that the LST for the waiting time pdf ($w(t)$) in $M/G/1$ is given as [78]

$$\mathcal{W}^*(s) = \int_{t=0^-}^{\infty} w(t)e^{-st} dt = \frac{s(1-\rho)}{s - \lambda + \lambda \mathcal{B}^*(s)}. \quad (56.32)$$

Integration starting with $t = 0^-$ is necessary, because of the possibility of a unit impulse at the origin, that is, the probability that the waiting time is zero is $1 - \rho$. The first and second moment of the waiting time can be obtained by differentiating $\mathcal{W}^*(s)$ once and twice with respect to s and setting $s = 0$

$$\overline{W^i} = (-1)^i \left. \frac{d^i \mathcal{W}^*(s)}{ds^i} \right|_{s=0}, \quad W = \frac{\overline{\lambda x^2}}{2(1-\rho)}, \quad \overline{W^2} = 2W^2 + \frac{\overline{\lambda x^3}}{3(1-\rho)}. \quad (56.33)$$

Takacs recurrence relation can be used to derive higher moments of waiting time as follows [78], where $\overline{W^0} = 1$:

$$\overline{W^k} = \frac{\lambda}{1-\rho} \sum_{i=1}^k \binom{k}{i} \frac{\overline{x^i}}{i+1} \overline{W^{k-i}}. \tag{56.34}$$

A generalization of Little's results is $\overline{N(N-1)} = \lambda^2 \overline{R^2}$, which can be extended to higher moments [78].

In the case of M/M/1 queueing system, $\mathcal{B}^*(s) = \mu/(s + \mu)$ and using tables for inverting LSTs in [42,78,143] we invert $\mathcal{S}^*(s)$ as follows:

$$\mathcal{S}^*(s) = \frac{\mu(1-\rho)}{s + \mu(1-\rho)} \Leftrightarrow s(t) = \frac{1}{R} e^{-t/R}, \tag{56.35}$$

where $R = [\mu(1 - \rho)]^{-1}$ is the mean response time. The LST $\mathcal{S}^*(s)$ for the M/M/1 can be obtained directly by assuming that k requests are encountered by an arrival and unconditioning on p_k

$$\mathcal{S}^*(s) = \sum_{k \geq 0} p_k \left(\frac{\mu}{s + \mu} \right)^{k+1} = \frac{\mu(1-\rho)}{s + \mu} \sum_{\geq 0} \left(\frac{\lambda}{s + \mu} \right)^k = \frac{\mu(1-\rho)}{s + \mu} \frac{1}{1 - \frac{\lambda}{s + \mu}} = \frac{\mu(1-\rho)}{s + \mu(1-\rho)}.$$

The following approximations for the percentiles of M/G/1 response time, proposed by Martin, are quoted in [42]: $R_{90\%} \approx R + \sigma_R$ and $R_{95\%} \approx R + 2\sigma_R$.

The busy period is the duration of the time required to serve jobs starting with an empty queueing system until it is empty again. For $\rho < 1$ M/G/1 queues alternate between busy and idle periods, with mean durations g_1 and $1/\lambda$, respectively. The mean duration of the busy period can be determined easily by noting that $g_1/(\overline{g}_1 + 1/\lambda) = \rho$, which is the fraction of time the server is busy.

The LST of the busy period can be specified noting that each one of the arrivals during the first request entails subbusy periods with the same distribution as the original distribution, as follows:

$$\begin{aligned} E[e^{-sY} | x_1 = x, \tilde{v} = k] &= e^{-sx} [\mathcal{G}^*(s)]^k. \\ E[e^{-sY} | x_1 = x] &= \sum_{k \geq 0} e^{-sx} \frac{(\lambda \mathcal{G}^*(s)x)^k}{k!} e^{-\lambda x} = e^{-x(s + \lambda - \lambda \mathcal{G}^*(s))}. \\ \mathcal{G}^*(s) &= \int_0^\infty e^{-x(s + \lambda - \lambda \mathcal{G}^*(s))} dB(x) = \mathcal{B}^*(s + \lambda - \lambda \mathcal{G}^*(s)). \end{aligned} \tag{56.36}$$

The moments of the busy period can be obtained by taking its derivative

$$g_i = (-1)^i \left. \frac{d^i \mathcal{G}^*(s)}{ds^i} \right|_{s=0}, \quad g_1 = \frac{\overline{x}}{1-\rho}, \quad g_2 = \frac{\overline{x^2}}{(1-\rho)^3}. \tag{56.37}$$

Note that g_2 increases very rapidly with increasing server utilization. For the M/M/1 queue with $\mathcal{B}^*(s) = \mu/(s + \mu)$, the distribution of the busy period is given by a Bessel function of the first kind of order one, which is obtained by solving $\mathcal{G}^*(s) = \mu/(s + \lambda - \lambda \mathcal{G}^*(s) + \mu)$ and inverting the negative root of the quadratic equation

$$\mathcal{G}^*(s) = \frac{1}{\lambda} \left[\mu + \lambda + s - \sqrt{(\mu + \lambda + s)^2 - 4\mu\lambda} \right]. \tag{56.38}$$

The probability that the busy period ends is $\mathcal{G}^*(0) = \int_0^\infty g(y)dy = 1/\rho$. CTMCs have been classified in [78] as positive recurrent, null-recurrent, and transient. In the context of M/G/1 queues, the system is positive recurrent for $\rho < 1$, which implies that the expected time to return to an empty system is finite. For $\rho = 1$, the system is null-recurrent, which means that the probability that the system becomes empty again is one, but the expected time to reach an empty system is infinite. Finally, when $\rho > 1$, the system is transient, which means that with positive probability the system will never empty again.

The z-transform for the number of requests served in a busy period is given in [78], which can be used to determine the mean and variance of the number of requests

$$F(z) = z\mathcal{B}^*(\lambda(1-F(z))), \quad h_1 = (1-\rho)^{-1}, \quad \sigma_h^2 = \frac{\rho(1-\rho) + \lambda^2 \bar{x}^2}{(1-\rho)^3}. \tag{56.39}$$

No exact analysis is available for M/G/m queues, but the well-known two moment approximation for M/G/m can be expressed as [45]

$$W \approx \frac{(1 + c_x^2)}{2m\mu(1-\rho)} P_m, \quad P_m = \frac{(m\rho)^m}{m!(1-\rho)} P_0. \tag{56.40}$$

In the corresponding M/M/m queue, $\mu = 1/\bar{x}$ is the service rate and $P_m = P[k \geq m]$. This formula is exact for M/M/m and M/G/1 queues.

This approximation is shown to be highly inaccurate against simulation results for higher values of c_x^2 in [71]. It is also shown that the lognormal and Pareto distribution with the same three moments have very different mean waiting times. Conjecture 1 in [71] provides the following higher and lower bounds for M/G/m with respect to M/D/m for any finite c_x^2 and $\rho < 1$

$$W_h = (1 + c_x^2)E[W_{M/D/m}], \quad W_\ell = E[W_{M/D/m}] + \frac{\rho - \frac{m-1}{m}}{1-\rho} \frac{c_x^2}{2} \times \left[\rho \geq \frac{m-1}{m} \right].$$

The additional term is added to the first term when the condition in the brackets is true and yields one. A simplified expression for M/D/m is given in [65], where D denotes the fixed service time

$$P[W \leq x] = e^{-\lambda(kD-x)} \sum_{j=0}^{km-1} Q_{km-j-1} \frac{[-\lambda(kD-x)]^j}{j!} \text{ for } (k-1)D \leq x \leq kD. \tag{56.41}$$

Let p_i denote the stationary distribution of i requests in the system

$$p_i = \sum_{j=0}^m p_j \frac{(\lambda D)^j}{i!} e^{-\lambda D} + \sum_{j=m+1}^{i+m} p_j \frac{(\lambda D)^{j+m-j}}{(i+m-j)!} e^{-\lambda D}, \quad \forall i \in \mathbb{N}_0.$$

Let $q_0 = \sum_{j=0}^m p_j$ and $q_i = p_{i+m}$ for $i > 0$, then $Q_j = \sum_{i=0}^j p_i$.

The probability Q_n that there are no more than n requests is difficult to compute since it requires the solution of an infinite set of linear equations [65,141]. A fast Fourier transform (FFT) and a geometric tail approach are proposed in [80a].

Several approximations for GI/G/m queues are listed in Section 2.5 in [79] and Section 6.3.6 in [45].

56.4.2 M/G/1 Approximation to M/G/1//N

We repeat the discussion in [49], based on an analysis by Takacs (see [111] Volume 2), to explore the accuracy of approximating its mean response time (R_N) in an M/G/1//N queueing system with N sources with the mean response time of an M/G/1 queue given by Equation 56.13. This is because of the difficulty of calculating R_N as specified next

$$R_N = \frac{N}{\mu} - \frac{1}{\lambda} + \left[\lambda \sum_{n=0}^{N-1} \binom{N-n}{n} \frac{1}{\mathcal{H}_n} \right]^{-1}, \quad \mathcal{H}_n = \prod_{i=1}^n \frac{\mathcal{B}^*(i\lambda)}{1 - \mathcal{B}^*(i\lambda)}, \quad \mathcal{H}_0 = 1. \quad (56.42)$$

The queueing system M/G/1 overestimates R for the same server utilization ρ . The accuracy of the approximation improves with increasing N as would be expected and is given as $(R/R_N - 1)100\%$. The minimum number of sources to attain a 5% error level increases with the coefficient of variation of the distribution: constant, Erlang-2, exponential, and Hyperexponential-2 (with equal branching probabilities and branch means 0.5 and 1.5) for $\rho = 0.1$ is 2/2/3/4, for $\rho = 0.4$ is 10/16/21/25, and for $\rho = 0.7$ is 61/101/142/188.

The M/G/1//N and M/G/1/K queueing systems are analyzed in Chapters 4 and 5 of Volume 2 in Takagi's three-volume series [111].

56.4.3 Routing to Minimize Mean Response Times

Data allocation to improve response time in the context of heterogeneous servers is considered in this section. Static policies that route requests in proportion to server speeds will balance server utilizations and under Markovian assumptions (exponential service times), the mean response times at server i (R_i) will be proportional to the mean service time at the server $\bar{x}_i = 1/\mu_i$.

The usual criterion is to *minimize (mean) response time (MRP)*, but a more sophisticated policy is to minimize the maximum mean response time policy, which is referred as *minimize maximum (mean response time) policy (MMP)*. The policies considered in this section are static, although dynamic policies such as shortest queue routing are expected to improve performance [91].

Data allocation on disks affects the mean access time. High degrees of access skew are observed among disks in large computer installation, where the utilization of most disks is negligible, see for example, [108]. Data reallocation methods in large file systems are considered in [147]. Striping in RAID (see chapter on storage systems) balances the load in each array, but there is still a need to balance loads across RAID5 arrays [139].

We consider the reallocation of data blocks in a disk array with N heterogeneous disks modeled as M/G/1 queues to minimize the overall mean disk response time. The mean and variance of access time to access data blocks at disk $1 \leq i \leq N$ is $1/\mu_i$ and σ_i^2 , respectively. We assume that disk capacity is not a problem and the data can be reallocated at the level of blocks such that disk access rates λ_i for $1 \leq i \leq N$ can be treated as continuous variables with a fixed sum $\Lambda = \sum_{i=1}^N \lambda_i$ as data blocks are reallocated. The goal of the analysis is to determine the new arrival rates to the N disks also denoted by λ_i for $1 \leq i \leq N$, which will minimize the mean response time over all disks [48].

The mean overall response time, given the mean responses time R_i for $1 \leq i \leq N$, is given as

$$R = \sum_{i=1}^N \frac{\lambda_i}{\Lambda} R_i(\lambda_i), \quad R_i(\lambda_i) = \frac{1}{\mu_i} + \frac{\lambda_i (1/\mu_i^2 + \sigma_i^2)}{2(1 - \lambda_i/\mu_i)}$$

The Lagrange multipliers method [95] is applied in [48] to minimize R with respect to λ_i for $1 \leq i \leq N$ subject to $\Lambda = \sum_{i=1}^N \lambda_i$ and $\lambda_i < \mu_i$ for $1 \leq i \leq N$ [27]. There is no solution if $\Lambda > \sum_{i=1}^N \mu_i$. We define F as follows and set its derivatives with respect to λ_i 's equal to zero to determine their optimum values

$$F = \sum_{i=1}^N \frac{\lambda_i}{\lambda} R_i(\lambda_i) + \alpha \left(\Lambda - \sum_{i=1}^N \lambda_i \right).$$

$$\lambda_i = L_i(k) = \mu_i \left[1 - \sqrt{\frac{\mu_i^2 \sigma_i^2 + 1}{2k\mu_i + \mu_i^2 \sigma_i^2 - 1}} \right] \text{ for } 1 \leq i \leq N \text{ with } k = 2\alpha\Lambda.$$

$L_i(k)$ are increasing functions in k and so is their sum $L(k) = \sum_{i=1}^N L_i(k)$. The value of k satisfying $\Lambda = L(k)$ may yield a solution with some of the λ_i 's negative at slower disks. This violation is resolved by repeating the optimization step but excluding slower disks from the allocation process.

Nonlinear optimization (Lagrangian functions) is used in [112] to optimize the routing of jobs to heterogeneous host computers, which are interconnected by a communication network whose delays satisfy the triangle inequality.

A static routing policy addressing fairness for user level performance measures, that is, mean response time in a multicomputer system with N heterogeneous processors with different speeds is proposed and evaluated in [68]. The criterion used for optimal workload allocation is the one minimizing the maximum expected response time at a subset of N processors to which jobs are routed. MMP equalizes the expected response times at utilized processors emphasizing fairness. Chapter 6 in [74] deals with the fair resource allocation problem.

The response time characteristic of the N heterogeneous processors $R_n(\lambda)$, for $1 \leq n \leq N$ known to the router is a nondecreasing function of λ . For an arrival rate Λ , the router sends a fraction of requests $p_n = \lambda(n)/\Lambda$ to the n th processor. The mean response time of requests is

$$R(\Lambda) = \sum_{i=1}^N R_n(\Lambda p_n(\Lambda)) p_n(\Lambda).$$

Criterion of Optimality for MMP

For a given $\Lambda > 0$, find the probabilities $p_i(\Lambda)$, for $1 \leq i \leq N$, so that the maximum average response time incurred on any system is minimized:

$$\min \max_n \{R_n(\Lambda p_n(\Lambda))\} < \infty,$$

where $\sum_{i=1}^N p_n(\Lambda) = 1$, $p_n(\Lambda) \geq 0$ for $1 \leq n \leq N$.

It is shown in the chapter that provided λ does not exceed the sum of the maximum throughputs at the nodes

Proposition. There is an integer $1 \leq K \leq N$ and a vector of routing probabilities $\mathbf{p} = (p_1, \dots, p_K, 0, \dots, 0)$ such that

$$R_i(\Lambda p_i) = R_{\min}(\Lambda) \text{ for } 1 \leq i \leq K$$

where $R_{\min}(\Lambda)$ is the minimum mean overall response time.

A simple algorithm to compute the allocation vector is given in the paper. Numerical results show that MMP attains fairness at a tolerable increase in mean response time.

56.4.4 Vacationing Server Model

We consider the *vacationing server model (VSM)* in the context of M/G/1 queues [111]. According to the VSM, the server goes on vacation after the busy period ends. In the case of the VSM with multiple vacations, the server repeats its vacation if the queue is empty after it returns from vacation. Otherwise it serves enqueued requests in FCFS order until the queue is emptied. Variations of the VSM within the context of M/G/1 queueing systems are analyzed in detail in [111].

The VSM with multiple vacations of variable durations is utilized in [130] for the analysis of rebuild processing in RAID5 disk arrays (see chapter on storage systems). The variability in service times is due to the fact that the first access for rebuild reading requires a seek, while succeeding rebuild reads do not. This complexity is taken into account in the analysis in [130], but not in the analysis that follows, where all rebuild reads are assumed to have a fixed service time. Given that the i th moment of vacation time is given as \bar{y}^i , then the mean residual delay observed by requests arriving while rebuild is in progress is $\bar{n}_1 = \bar{y}^2 / (2\bar{y})$ [78]. Based on PASTA, the mean waiting time in M/G/1 queues with vacations is

$$W = \bar{N}_q \bar{x} + \rho m_1 + (1 - \rho) n_1 \Rightarrow W = \frac{\lambda \bar{x}^2}{2(1 - \rho)} + \frac{\bar{y}^2}{2\bar{y}}. \quad (56.43)$$

That the mean waiting time W in this case is the sum of the mean waiting time in M/G/1 (see Equation 56.13) and the mean mean residual vacation time is attributable to the decomposition property of the VSM [67].

The busy period is elongated by the delay encountered by the first request arriving during the final vacation during which a request arrives. To simplify the discussion, we assume that vacation times have a fixed duration $y = T$, so that mean remaining vacation time after an arrival in a vacation period is given as

$$v_r = T - \frac{\int_0^T t e^{-\lambda t} dt}{\int_0^T e^{-\lambda t} dt} = \frac{T}{1 - e^{-\lambda T}} - \frac{1}{\lambda}.$$

The mean effective service time of the first request, which starts the next modified busy period, referred to as the delay cycle is given as $\bar{z} = v_r + \bar{x}$ is required to determine its duration [79]

$$\bar{d} = \frac{\bar{z}}{1 - \rho}. \quad (56.44)$$

Note similarity to the duration of busy period, which was given as $g_1 = \bar{x} / (1 - \rho)$ [78].

The probability that an arrival occurs according to a Poisson process with rate λ in an interval T is $p = 1 - e^{-\lambda T}$. The distribution of the number of vacations taken in the idle period is $P_k = p(1 - p)^{k-1}$ with a mean $\bar{k} = 1/p$. The time required per vacation is $(\bar{d} + 1/\lambda)/\bar{k}$.

The VSM can be used to determine the performance of rebuild processing in RAID5 to reconstruct the contents of a failed disk on a spare disk [138]. This requires the reading of consecutive tracks from surviving disks and *eXclusive-ORing (XOR)ing* them to rebuild missing tracks. The rebuild reading of the track in progress is completed before the service of user requests starts. The response time of user requests is increased by n_1 according to Equation 56.43, which equals $T/2$ in this case. The rebuild time can be estimated using the aforementioned analysis. The discussion can be extended to take into account the effect of read redirection and the update load as rebuild progresses [131,135].

56.4.5 VSM Analysis of Scheduling for Readers and Writers

Readers and writers is a classical paradigm in OS theory and practice. Readers can be processed concurrently, while writers are processed one at a time. The processing of readers and writers in FCFS order can be inefficient compared to a policy that processes read requests uninterrupted as long as possible.

The VSM was applied to the analysis of the *threshold fastest emptying (TFE)* policy for scheduling readers and writers in [124]. There is an infinite backlog of readers, which are processed with a degree of concurrency \bar{M} with rate ν . Writers arrive according to a Poisson process with rate λ and have service time moments \bar{x}^i for $i \geq 1$, so that the utilization of the system due to writers is $\rho = \lambda \bar{x} < 1$. Writers are processed until the writer queue is emptied, after which the processing of readers is resumed. No new readers are processed when the number of writers reaches the threshold $K \geq 1$. The analysis in [124] yields the throughput for readers and the mean number of writers in the queue

$$\gamma(K) = (1 - \rho_w) M \nu \frac{K + \lambda/\nu}{K + H_M \lambda/\nu},$$

$$\bar{N}_q = \frac{\lambda^2 \bar{x}^2}{2(1 - \rho_w)} + \frac{\alpha^{(2)}(1)}{2\alpha^{(1)}(1)}.$$

(note correction to Equation 3.8 in [124]). The z -transform $\alpha(z)$ is for the number of arrivals during a vacation, which is the sum $K + \tilde{J}$, where K is fixed and \tilde{J} is the number of arrivals while the system is being emptied from readers

$$\alpha(z) = M \nu \sum_{m=0}^{M-1} (-1)^m \binom{M-1}{m} \frac{z^K}{(m+1)\nu + \lambda(1-z)}.$$

It is shown in [124] that TFE with threshold $K = 1$ attains a higher throughput for writers than FCFS. The difference between the two policies is that writers arriving in a busy period are served in spite of intervening reader arrivals.

With exponential writer service times, a CTMC, which is infinite in one of its two dimensions, can be used to analyze this system. The more interesting case with both reader and writer arrivals with two thresholds to balance reader and writer response times and to attain a higher throughput was investigated via simulation in [133].

56.4.6 Priority Queueing Systems

The VSM is a special case of priority queues with an infinite backlog of low-priority requests. Consider an $M/G/1$ queue with P priority classes, where P is the highest priority. The arrival rate for class p requests is λ_p and the first two moments of its service time are \bar{x}_p and \bar{x}_p^2 , respectively. According to Kleinrock's conservation law [79],

$$\sum_{p=1}^P \rho_p W_p = \frac{\rho W_0}{1 - \rho}, \tag{56.45}$$

where $\rho_p = \lambda_p \bar{x}_p$, $\rho = \sum_{p=1}^P \rho_p$, and $W_0 = \frac{1}{2} \sum_{p=1}^P \lambda_p \bar{x}_p^2$. The intuition behind this law is that the reduced response time of some classes is at the cost of increased response time for others (borrow from Peter to pay Paul). In the case of two priority classes,

$$W_1 = \frac{W_0}{(1 - \rho_2)(1 - \rho)}, \quad W_2 = \frac{W_0}{1 - \rho_2}. \tag{56.46}$$

Note that both waiting times are affected by the residual service time of requests in progress (as reflected by W_0), but high-priority requests are only affected by ρ_2 .

In the case of preemptive priorities, as far as higher priority classes are concerned. It is as if lower priority classes do not exist. Hence, for class 2, we have an M/G/1 queueing system, the mean response time for class 1 requests according to Equation 3.65 in [82] is

$$E[r_1] = \frac{\bar{x}}{1-\rho_2} + \frac{\lambda_1 \bar{x}_1^2 + \lambda_2 \bar{x}_2^2}{2(1-\rho_2)(1-\rho)}, \quad E[r_2] = \bar{x}_2 + \frac{\lambda_2 \bar{x}_2^2}{2(1-\rho_2)}. \quad (56.47)$$

56.4.7 GI/M/m Queueing System

This queueing system has a general interarrival time and an exponential service times. The analysis is based on the embedded Markov chain at arrival instants [78] so that there is no residual interarrival time. The mean waiting time for the GI/M/1 queue can be specified similarly to M/M/1, but with a parameter σ instead of ρ , which in GI/M/1 queues is the probability that an arrival encounters a busy server. This parameter can be obtained by solving the following equation given in [78]

$$\sigma = \mathcal{A}^*(m\mu - m\mu\sigma), \quad m \geq 1, \quad (56.48)$$

where the probability σ that an arrival finds the server busy is obtained by solving the aforementioned equation and $\mathcal{A}^*(\cdot)$ is the LST of interarrival time. The value of σ is different from ρ , so that PASTA does not apply anymore, unless GI is M. Unlike M/G/m, there is an exact analysis for GI/M/m starting with the solution of Equation 56.48. The mean waiting time encountered by arriving requests at GI/M/1 queues is

$$W_{GI/M/1} = \frac{\sigma/\mu}{1-\sigma}. \quad (56.49)$$

It can be observed from Table 5.3.9 for GI/M/1 queues in [42] that for the four interarrival time distributions, H_2 , M, E_3 , and D, which have the same mean, the one with the smaller coefficient of variation has a lower σ and hence W , but this is not true in general.* That this is so we compute W with a uniform (U) and a Gamma (G) interarrival time distribution, whose mean, coefficient of variation, and LST are given by Equations 56.8 and 56.12 with the same mean and coefficient of variation. For the uniform distribution given $a = 0$ and $b = 2$, $\bar{x}_U = 1$ and $c_U^2 = 1/3$. For the Gamma distribution with $\alpha = \beta = 3$ $\bar{x}_G = 1$, $c_G^2 = 1/3$. We set $\bar{x} = 1/\mu = 0.5$, so that $\rho = 0.5$ and $W_{M/M/1} = \rho\bar{x}/(1-\rho) = 0.5$. The solution of Eq. (??) for the two distributions are $\sigma_U \approx 0.361$ and $\sigma_G = 0.334$. The Gamma distribution with $\alpha' = \beta' = 2.9$ with $c_{G'}^2 = 1/2.9 = 0.345 > c_U^2$ has a lower W than the uniform distribution since $\sigma_{G'} = 0.345$. We have $W_U = 0.361 \times 0.5 / (1 - 0.361) \approx 0.289$, $W_G = 0.334 \times 0.5 / (1 - 0.334) = 0.25075$ and $W_{G'} = 0.335 \times 0.5 / (1 - 0.335) = 0.252$.†

The probability that an arriving request encounters a queue of length k is given by $r_k = (1-\sigma)\sigma^k$. The PDF for the waiting time in GI/M/1 is $W(y) = 1 - \sigma e^{-\mu(1-\sigma)y}$, $y \geq 0$, so that $W(0) = 1 - \sigma$. The pdf and $w(y) = u_0(1-\sigma) + \sigma(1-\sigma)\mu e^{-\mu(1-\sigma)y}$, $y \geq 0$, where $u_0(1-\sigma)$ signifies a unit impulse at the origin.

56.4.8 Routing in Distributed Systems

In the context of mirrored disks classified as RAID level 1, there is the question of which one of the two forms of static routing to two disks is better: (1) uniformly with equal probabilities and (2) round-robin. The service time distribution at the disks is assumed to be exponential with mean service time $\bar{x} = 1/\mu$.

* Private communications from Prof. L. Takacs at Case Western Reserve University, 1978.

† This approach was proposed by Prof. I. Adan at Technical University at Eindhoven, 2012.

Given an arrival rate 2λ , the rate of arrivals to each disk is λ in both cases. In the first case, it follows from the decomposition property of Poisson processes that the arrival process at each disk is Poisson [42,78,80,143], so that the mean waiting time in this case is $W_{M/M/1} = \rho\bar{x}/(1 - \rho)$.

With round-robin routing, the interarrival time to each disk follows the Erlang-2 distribution with rate 2λ per stage, so that the interarrival time LST is $\mathcal{A}^*(s) = [2\lambda/(s + 2\lambda)]^2$ [78]. This is a GI/M/1 queue, so solving Equation 56.48 we obtain the smaller root $\sigma = (1 + 4\rho - \sqrt{1 + 8\rho})/2$. It is easy to show that $\sigma < \rho$, so that round-robin routing yields a lower W than uniform routing (at least for exponential service times).

Routing of requests may be dynamic, that is, based on the current state of the system. *Join the shortest queue (JSQ)* is an optimal policy for exponential service times [145]. This is not always true, as in the case where most service times are negligible with a high probability, but there is a small probability of encountering a high service time. For nonexponential service times, the expected service times need to be considered and counterintuitive behavior can be observed in this case.

The response time of txns processed in a locally distributed database can be improved by judicious data allocation and txn routing. An integer programming formulation is used in [149] as a first step to assign datasets and txn classes to computer systems (with directly attached disks) to balance processor loads. There are two alternatives dealing with remote accesses: (1) function shipping is a *remote procedure call (RPC)* to retrieve remote data. (2) I/O shipping returns referenced disk pages. The former can be implemented in SQL-based databases, which allow transparent distributed query processing, but this is not the case in navigational databases, such as IMS. Optimized static routing results in a further improvement in response time. Dynamic txn routing policies implemented at a frontend, which take into account routing histories and minimize the estimated response time of incoming txns is proposed and found to provide a substantial improvement over the optimal static strategy in [148].

56.4.9 Polling Systems

In the most common case, a single server serves a number of queues in a polling system in cyclic order [109,110]. Queues or buffers holding requests have been classified as single or infinite buffer systems. With infinite buffers the number of requests served per visit is exhaustive or gated. The latter means that requests arriving at a queue after service starts at the queue are not served in that service cycle. The default scheduling discipline from each queue is FCFS. Basic performance measures of interest are the mean cycle time $E[C]$ and the mean waiting time $E[W]$.

We consider a polling system with N queues. The switchover time from the i th node to the next node is r_i and its variance δ_i^2 , so that $R = \sum_{i=1}^N r_i$ and $\delta^2 = \sum_{i=1}^N \delta_i^2$. The arrival rate to node i is λ_i , its mean service time b_i , so that $\rho_i = \lambda_i b_i$ and $\rho = \sum_{i=1}^N \rho_i$.

In the case of the *symmetric* single buffer systems, the mean cycle time and mean waiting time are

$$E[C] = R + bE[Q], \quad E[W] = (N - 1)b - \frac{1}{\lambda} + \frac{NR}{E[Q]}, \tag{56.50}$$

where $E[Q]$ is the mean number of messages served in a polling cycle. Given the mean message interdeparture time $E[X] = E[W] + b + 1/\lambda$, the system throughput is $\gamma = 1/E[X]$.

A relatively simple expression for $E[Q]$ is available only for constant service and switchover times

$$E[Q] = \frac{N \sum_{n=0}^{N-1} \binom{N-1}{n} \prod_{j=0}^n [e^{\lambda(R+jb)} - 1]}{1 + \sum_{n=1}^N \binom{N}{n} \prod_{j=0}^{n-1} [e^{\lambda(R+jb)} - 1]}. \tag{56.51}$$

The mean waiting time $E[W]$ of a symmetric exhaustive service system is

$$E[W] = \frac{\delta^2}{2r} + \frac{N\lambda b^{(2)} + r(N - \rho)}{2(1 - \rho)}. \quad (56.52)$$

In the case of a symmetric gated service system,

$$E[W] = \frac{\delta}{2r} + \frac{N\lambda b^{(2)} + r(N - \rho)}{2(1 - \rho)}. \quad (56.53)$$

Polling analysis has been applied to evaluating the performance of communication network protocols and especially *local area networks (LANs)*, see for example, [46].

56.4.10 Load Sharing Policies in Distributed Systems

A system with multiple sources and servers is considered by Wang and Morris in [144], which classifies load sharing algorithms as source-initiated and server-initiated. The results of the study based on simulation and analysis show that (1) the choice of load sharing algorithm is a critical design decision. (2) For the same level of scheduling information exchange, server-initiative has the potential of outperforming source-initiative algorithms. (3) The Q-factor (quality of load sharing) performance metric summarizes overall efficiency and fairness of an algorithm and allows them to be ranked. (4) Some previously ignored algorithms may provide effective solutions.

A homogeneous distributed systems with N servers, which can be represented as $M/M/1$ queues, is considered in [84]. The arrival rate of requests at the N servers is λ . Given that the server service rate is μ , the server utilizations are $\rho = \lambda/\mu$. The probability that i servers are idle is $Q_i = (1 - \rho)^i$ and H_j denotes the probability that j servers are not idle and at least one request waits in the queue $H_j = \rho^j - \rho^j(1 - \rho)^j$. The probability P_w that at least one request waits, while at least one server is idle is

$$P_w = \sum_{i=1}^N \binom{N}{i} Q_i H_{N-i} = [1 - (1 - \rho)^N] [1 - (1 - \rho)^N - \rho^N].$$

Plotting P_w versus ρ shows that it reaches a peak at $\rho \approx 0.6$, which is close to one at $N \geq 20$, but is smaller for lower values of N . Provided the cost of transferring tasks is low, the system can be approximated by an $M/M/N$ system, so that $P_w = 0$. Tasks are transferred from node to node when (1) A task arrives at a busy server and there are less than N tasks in the system. (2) A server completes at a server whose queue is empty and there are more than N tasks in the system. A lower bound to task transfers to minimize W is given as

$$LT = \sum_{i=1}^{N-1} [i\lambda p_i + \mu(N - i)p_{N+i}],$$

where p_i are probabilities associated with an $M/M/N$ system. Plotting LT versus N for varying arrival rates, it is observed that LT increases linearly with N and has a higher slope for higher values of λ .

Adaptive load sharing policies in homogeneous distributed systems are discussed in two companion papers by Eager, Lazowska, and Zahorjan [61,62]. The goal of these studies is to improve the performance of systems with N processors (servers) by averting load imbalance as in [84]. Sender initiated policies are explored in [61], while receiver initiated policies are proposed in [62] and compared with sender initiated policies.

In the case of sender-initiated policies, the transfer policy determines whether a task should be processed locally or remotely. The transfer policy is based on a threshold whether the queue length at a node exceeds T . The *location policy* selects the node to which the task should be transferred. The following location policies are considered.

Random policy: Transferred tasks at a receiver node are considered to be as a new arrival, so that they may be transferred again if T is exceeded. This may lead to an instability similar to the Aloha communication system due to packet collisions and retransmissions as discussed in Section 5.11 and shown in Figure 5.39 in [79]. The thrashing phenomenon is alleviated simply by limiting the number of retransmissions. No exchange of information among nodes is required for this policy.

Threshold policy: Random nodes are probed for their queue length. A task is transferred only if the number of tasks at the node is less than L_p , so that useless task transfers are avoided. Probing is stopped when the probe limit L_p is exceeded and the task is processed at the receiving node.

Shortest queue: L_p randomly selected nodes are probed and the one with the shortest queue is selected.

Figure 2 in [62] compares the mean response times (RT) for different policies with $N = 20$ nodes, service time $S = 1$, $L_p = 1$, and $L_t = 3$. The overhead associated with task migration is taken into account as 10% of S . Queueing systems $M/M/1$ and $M/M/20$ are upper and lower bounds to RT. It turns out that threshold and shortest outperform the random policy significantly.

In the case of the *receiver initiated (RI)* policy, a receiver that has less than T tasks when a task completes probes L_p other nodes to initiate a task transfer [62]. No transfer occurs if the L_p nodes had T or more tasks in their queue (such a policy with $T = 1$ was considered in [84]). The reservation policy is similar to sender policy, but differs in that task transfers are considered upon task arrival. It follows from the graph for RT versus system load in the extended abstract version of [62] that the sender initiated policy for $T = 1$ outperforms others for up $\rho = 0.7$, but is outperformed by a sender initiated policy for $T = 2$ and a receiver initiated policy for $T = 1$. The reservation policy has the highest RT.

56.5 Fork-Join Queueing Systems

In *Fork-Join (F/J)* queueing systems arriving jobs spawn K tasks, which are served by K parallel servers. We first consider the case when jobs arriving at a rate λ are processed one at a time. Each job spawns K independent tasks to be processed at K servers, but this is done only when all the tasks associated with a previous job are completed. The completion time of all of the tasks of a job is simply the maximum of K service times denoted by R_k^{max} . The maximum throughput is then $\lambda_K^{max} = [R_k^{max}]^{-1}$. When the service times are exponentially distributed with rate μ , then $R_K = H_K/\mu$ and $\lambda_K^{max} = \mu/H_K$, where $H_K = \sum_{k=1}^K 1/k$ is the Harmonic sum. The server utilizations are given by $\rho = \min(\lambda, \lambda_K^{max})\bar{x}$, where $\bar{x} = 1/\mu$ is the mean service time.

F/J queueing systems allow overlapped execution of tasks belonging to successive jobs by sending the K tasks of an arriving job to the K queues for FCFS processing. When the arrival rate is λ and the service times are exponentially distributed with mean $\bar{x} = 1/\mu$, then the server utilizations are $\rho = \lambda/\mu$. In this case $\lambda_K^{max} = \mu$, which exceeds the previous throughput by a factor H_K . The distribution of response time at each server is exponential with mean $R(\rho) = \bar{x}/(1 - \rho)$, so that the expected value of the maximum of K response times is $R_K^{max} = H_K \times R(\rho)$. This is an upper bound to $R_K^{F/J}(\rho)$ for the exponential distribution according to [90]. Under Markovian assumptions, an exact analysis is available for two-way F/J queueing systems

$$R_2^{F/J}(\rho) = \left(1.5 - \frac{\rho}{8}\right) R(\rho) \leq R_2^{max}(\rho), \quad R_2^{max}(\rho) - R_2^{F/J}(\rho) = \frac{\rho}{8} R(\rho), \quad (56.54)$$

the introduced error increases with ρ . An approximate expression is obtained in [90] for $R_k^{F/J}(\rho)$ for $2 \leq K \leq 32$ with exponential service time distribution by curve-fitting against simulation results

$$R_k^{F/J}(\rho) \approx \left[\frac{H_K}{H_2} + \left(1 - \frac{H_K}{H_2}\right) \frac{4\rho}{11} \right] R_2^{F/J}(\rho). \quad (56.55)$$

Empirical expressions for $R_k^{F/J}(\rho)$ are derived in [128] for general service times by curve-fitting.

Fork-join requests may be utilized to estimate the mean response time of accesses to a failed disk in RAID5 disk arrays (see chapter on storage systems). We simplify the discussion by assuming that all disk accesses are due to read requests. The contents of a failed disks in this case are reconstructed by accessing and XORing the corresponding blocks on surviving disks. Note that disks in addition to fork-join requests process requests accessing them directly, so that the access rate and disk utilization on surviving disks are doubled. Simulation results in [128] have shown that for higher disk utilization due to interfering requests $R_K^{F/J}(\rho) \approx R_K^{max}(\rho)$, so that there is no need to use Equation 56.55 as was done in [87].

In order to compute R_K^{max} , the response time distributions at the disks are approximated by the Erlang, Hyperexponential, Coxian, or the extreme-value distribution. The latter is defined as [76] $F_Y(y) = P[Y < y] = \exp(-e^{-y-a/b})$, which has a mean $\bar{Y} = a + \gamma b$ and variance $\sigma_Y^2 = \pi^2 b^2 / 6$. The maximum of K r.v.'s with this distribution is [76]

$$Y_{max}^K = (a + \gamma b) + b \ln(K) = \bar{Y} + (\sqrt{6} \ln(K) / \pi) \sigma_Y.$$

Given that the extreme value distribution has two parameters, the mean and variance of response time in RAID5 arrays can be used to estimate them as was done in [136]. A detailed discussion of the queueing analysis of F/J and related systems is given in [140].

56.6 Queueing Network Models

Queueing network models (QNMs) comprise a set of nodes, where each node has single or multiple servers. Jobs completing their service at a node are routed to another node according to probabilities that are specified by a first-order or higher-order Markov chain [80] until they depart from the system. Jobs in a QNM may belong to a single class or multiple classes as defined by being open or closed chains, as in the case of OLTP txns and batch jobs, respectively, their routing matrices, and their service demands. Chapter 7 in [83] provides numerical examples for justifying multiple job classes.

Jobs belonging to an open chain arrive at one of its nodes and visit appropriate nodes according to a transition probability matrix $R = [r_{i,j}]$, where $r_{i,j}$ is the probability that a job leaving node i joins node j . Jobs leave the system with a departure rate equal to the arrival rate provided that no node is saturated. The response time of requests in an open chain is the sum of residence times at the nodes visited by the chain.

Closed QNMs with a fixed number of jobs are used to represent batch systems with an infinite backlog of jobs, so that as one job is completed there is another job available for activation. Closed chains have special transitions, signifying the completion of a job. This may be a transition to a delay server, which stands for user think times, or an immediate transition of a job to the same node, indicating its completion and replacement by a new job, so that the number of jobs in the closed QNM remains fixed. Hybrid QNMs allow both open and closed chains.

In what follows, we start our discussion with open QNMs in Section 56.6.1 and then proceed to closed QNMs in Section 56.6.2. Buzen's algorithm for the analysis of closed QNMs is given in Section 56.6.3 and *mean value analysis (MVA)* in Section 56.6.4. Bounds applicable to closed QNMs are specified in Section 56.6.5. The analysis of hybrid QNMs with open and closed chains is outlined in Section 56.6.6. Hierarchical decomposition and aggregation in the context of QNMs is discussed in Section 56.6.7. This approach is used to analyze parallel processing based on [122] and serialization delays based on [119].

56.6.1 Open QNMs

In open QNMs, external arrivals to the N nodes of the network are γ_i for $1 \leq i \leq N$. The transition probability from node i to j is given by $r_{i,j}$. The probability that a request leaves the network at node i

is $r_{i,out} = 1 - \sum_{j=1}^N r_{i,j}$. The arrival rates to the nodes (λ_i for $1 \leq i \leq N$) can be obtained by solving a set of linear equations given as

$$\lambda_i = \gamma_i + \sum_{j=1}^N \lambda_j r_{j,i} \quad \text{for } 1 \leq i \leq N \text{ or } \underline{\lambda} = \underline{\gamma} + \underline{\lambda}R, \tag{56.56}$$

where $\underline{\lambda}$ and $\underline{\gamma}$ are row vectors and R is a probabilistic routing matrix. The mean delay encountered by messages arriving at node j and departing at node k is denoted by $Z_{j,k}$ and $\gamma_{j,k}$ is the rate of messages from node j to node k . The mean delay overall messages are then [79]

$$T = \sum_{j=1}^N \sum_{k=1}^N \frac{\gamma_{j,k}}{\gamma} Z_{j,k}, \quad \gamma = \sum_{j=1}^N \sum_{k=1}^N \gamma_{j,k}. \tag{56.57}$$

Consider two queues in tandem, with the output from the first queue being fed to the second queue. The arrivals to the first queue are Poisson with rate λ . The service times at the two queues are exponential with rates μ_1 and μ_2 . Provided the first queue is not saturated ($\lambda < \mu_1$), due to conservation of flow the arrival rate to the second queue is also λ . The utilizations of the two servers are $\rho_1 = \lambda/\mu_1$ and $\rho_2 = \lambda/\mu_2$, respectively. The system is not saturated if $\min(\mu_1, \mu_2) > \lambda$. Burke's theorem states that the arrival rate to the second queue is also Poisson with the same rate. A proof of Burke's theorem based on [78] is given by Equation 56.58. The LST for interdeparture time ($\mathcal{D}^*(s)$) depends on whether the queue is busy or not. When the first queue is idle, the interdeparture time is the sum of interarrival and service times (product of the two LSTs), while it is simply the LST of service time when the server is busy

$$\mathcal{D}^*(s) = (1 - \rho_1) \frac{\lambda}{s + \lambda} \frac{\mu_1}{s + \mu_1} + \rho_1 \frac{\mu_1}{s + \mu_1} = \frac{\lambda}{s + \lambda} \Leftrightarrow d(t) = \lambda e^{-\lambda t}. \tag{56.58}$$

Both queues can be analyzed simply since they have Poisson arrivals. In case a fraction q of departures from the first queue are fed back, then it can be shown that the arrival process to that queue is not Poisson, but the departure process from the queue remains Poisson [143].

The analysis of tandem queues undertaken in Chapter 3 in [77] demonstrates the difficulty of the problem at hand. This led to the proposal of the *independence assumption* that message lengths are resampled from an exponential distribution in the network. As verified by simulation results this assumption is more accurate for higher fan-ins and fan-outs.

In the case of two queues in tandem with a Poisson arrival rate λ to the first queue and service rates μ_1 and μ_2 at the two servers with $\min(\mu_1, \mu_2) > \lambda$, the state equilibrium equations for the two-dimensional CTMC with states (k_1, k_2) are satisfied by

$$P[k_1, k_2] = (1 - \rho_1)\rho_1^{k_1} (1 - \rho_2)\rho_2^{k_2} \quad \text{for } k_1 \geq 0, k_2 \geq 0.$$

Even when the transitions are not feedforward and hence the arrival rates to the nodes are not Poisson [143], Jackson's theorem guarantees a product form solution in open QNMs where the external arrivals are Poisson with arbitrary transition probabilities, as if the arrival rates to all nodes are Poisson. Given m_n servers with service rates μ_n at node $1 \leq n \leq N$, the server utilizations at that node are $\rho_n = \lambda_n/(m_n \mu_n)$. Given that $P_n[k_n]$ is the distribution of the number requests at node n , the probability that the system is at state $\underline{k} = (k_1, k_2, \dots, k_N)$ is given as [45,78,143]

$$P[\underline{k}] = \prod_{n=1}^N P_n[k_n]. \tag{56.59}$$

Analysis of open QNMs with multiple chains is given by Algorithm 7.1 in [83]. The analysis with single servers, which can be easily extended to multiple servers, proceeds as follows: (1) ascertain that the server utilizations at no node exceeds one. (2) Obtain the residence times at various nodes. (3) Obtain queue lengths at various nodes. (4) Obtain residence time in QNM by summing residence times over all nodes constituting a chain (from the arrival node to the departure node). (5) Obtain the mean number of jobs in a chain by using Little's result.

56.6.2 Closed QNMs

We next consider the closed QNM of the *central server model (CSM)*, which consists of a single CPU (node 1) and $N - 1$ disks (nodes 2 : N). The number of jobs at the computer system or its MPL is M . Jobs alternate between processing at the CPU and the disks, returning to the CPU after completing their service at the disks. A job finishing its execution at the CPU completes its processing with probability p_1 or accesses the n th disk with probability p_n for $2 \leq n \leq N$, so that $\sum_{n=1}^N p_n = 1$. A completed job is immediately replaced by a new job, so that the MPL remains fixed at M . The number of visits to the CPU is given by the modified geometric distribution $P_k = p_1(1 - p_1)^{k-1}$, so that the mean number of visits to the CPU is $v_0 = 1/p_1$ and the disks $v_n = (1/p_1 - 1)(p_n/(1 - p_1)) = p_n/p_1$ for $2 \leq n \leq N$.^{*} Given that \bar{x}_n is the mean service time per visit at node n , the service demands $D_n = v_n \bar{x}_n$ for $1 \leq n \leq N$. These are the mean times the jobs spend being served at the nodes of the QNM.

The state probabilities of closed QNMs with four types of nodes satisfying the conditions of the BCMP theorem can be expressed in product form [43,45,79,83]:

1. *FCFS*: exponential service time, single or multiple servers
2. *Processor sharing (PS)*: general service time, single server
3. *Infinite servers (IS)*: general service time, also a delay server
4. *Last-come, first served (LCFS)*: preemptive resume, general service time, single server

The service rate at type 1 nodes with m servers equals $k\mu$ for $k \leq m$ and $m\mu$ for $k \geq m$ requests at the node. Multiservers and delay servers are examples of state-dependent servers. At type 3 nodes there is no queueing, since there are as many servers as there are requests, so that the mean response time equals the mean service time. The increase in the total service rate in multiprocessors is sublinear in the number of processors, which may be due to cache interference or synchronization delays [70]. For example, in a hypothetical four-way multiprocessor, the processing rate may increase as (1, 1.75, 2.5, 3.25).

Consider a closed QNM with N nodes and M jobs. The state of the QNM can be represented as $\underline{m} = (m_1, m_2, \dots, m_N)$, so that $\sum_{n=1}^N m_n = M$. The probability distribution of the number of jobs at the N nodes is given as[†]

$$P[\underline{m}] = \frac{1}{G(M)} \prod_{n=1}^N F_n(m_n), \quad F_n(m_n) = D_n^{m_n} \quad \text{or} \quad F_n(m_n) = \frac{D_n^{m_n}}{\prod_{i=1}^{m_n} \alpha_n(i)}. \tag{56.60}$$

The first expression for $F_n(m_n)$ is applicable to type 1, 2, and 4 state-independent queueing stations, while the second expression applies to multiservers and delay servers. Given $F_n(0) = 1$, $F_n(i) = (D_n/\alpha_n(i))F_n(i - 1)$ for $i \geq 1$. For the aforementioned multiprocessor, $\underline{\alpha} = \{1, 1.75, 2, 5, 3.25, 3.25, \dots\}$.

^{*} The analysis of the fundamental matrix in Section 7.2 in [143] to obtain the mean number of visits to the states of a finite state Markov chain is applicable to this discussion.

[†] In the case of single servers, the probabilities can be expressed as server utilizations by multiplying them by the system throughput $(T(M))$.

Given the number of jobs M and the service demands $\underline{D} = (D_1, D_2, \dots, D_N)$, a closed QNM can be solved to determine the throughput for jobs and their mean residence time in the QNM, device queue lengths, and utilizations. The job transition probability matrix should be specified to determine the job response time distribution.

There are several efficient algorithms for analyzing closed QNMs satisfying the BCMP theorem. Buzen's algorithm [28,47] for single job classes was later extended to multiple job classes by Buzen, Reiser and Kobayashi at IBM's T. J. Watson Research Center, and Williams and Bhandiwad using generating functions [45,146]. The analysis in the latter paper was extended by Thomasian and Nadjji in [117]. *Mean value analysis (MVA)* [29,83,98] and *REcursion by Chain ALgorithm (RECAL)* [54,55] are two other algorithms for closed QNMs.

56.6.3 Buzen's Algorithm

It can be shown that in a QNM with N nodes and M jobs there are $S = \binom{M+N-1}{N-1}$ states for the number of jobs at the nodes. To show this is so consider $(N-1)$ bars to delineate the boundaries among the N nodes and M asterisks specifying as many jobs, so that the state of the system can be represented as $***|**|..|*$, three jobs at node 1, two jobs at node 2, and one job at node N . There are $(M+N-1)!$ permutations, which are divided by $M!$ for the M indistinguishable jobs and $(N-1)!$ for the $(N-1)$ indistinguishable bars [59]. Multiple job classes are not considered in this study for the sake of brevity, but it suffices to say that the number of states increases rapidly with K job classes, that is, $S_K = \prod_{k=1}^K \binom{M_k+N-1}{N-1}$. The normalization constant in Equation 56.60 is given as

$$G(M) = \sum_{\sum_{n=1}^N m_n = M} \prod_{n=1}^N F_n(k_n). \tag{56.61}$$

For state-independent nodes with the normalization constant, $G(M)$ is the sum of the S terms of the form $F_n(m_n) = D_n^{m_n}$. A straightforward computation of $G(M)$ requires at most $M-1$ multiplications for each one of the S terms and $S-1$ summations.

Arguments based on generating functions [78,143] have been used in [117,146] to derive the recursion for $G(M)$ and other performance metrics. Provided that the dummy variable t is selected to be small enough ($tD_n < 1$), the sum given next converges for state-independent servers

$$x_n(t) = \sum_{m \geq 0} F_n(m)t^m = \sum_{m \geq 0} (tD_n)^m = (1-tD_n)^{-1}. \tag{56.62}$$

The generating function for the QNM is

$$g(t) = \prod_{n=1}^N x_n(t) = \sum_{m \geq 0} G(m)t^m. \tag{56.63}$$

Using Equation 56.62, the following recursion is obtained for the n th node

$$g_n(t) = \prod_{i=1}^n x_i(t) = g_{n-1}(t)x_n(t) \Rightarrow g_n(t) = g_{n-1}(t) + tD_n g_n(t). \tag{56.64}$$

Setting the coefficients of the same powers of t on both sides equal to each other

$$G_n(m) = G_{n-1}(m) + D_n G_n(m-1) \quad \text{for } 1 \leq m \leq M, 1 \leq n \leq N. \quad (56.65)$$

Instead of a two-dimensional array, memory space can be saved by using a one-dimensional array or a vector initialized as $G(0) = 1$ and $G(m) = 0$ for $1 \leq m \leq M$. The iterative solution proceeds one node at a time, while varying the number of jobs at the node

$$G(m) = G(m) + D_n G(m-1) \quad \text{for } 1 \leq m \leq M, 1 \leq n \leq N. \quad (56.66)$$

Generating functions can be used to show that $T(M) = G(M-1)/G(M)$, from which it follows that the mean residence time is $R(M) = M/T(M)$. The utilizations and mean queue lengths at the nodes are $U_n(M) = D_n T(M)$ and $Q_n(M) = \sum_{m=1}^M D_n^N G(M-m)/G(M)$ for $1 \leq n \leq N$, respectively.

Convolution is only applied to state-dependent servers, so that starting with $g_n(t) = g_{n-1}(t)x_n(t)$ for $1 \leq n \leq N$ and equating the coefficients of m on both sides we have

$$G_n(m) = \sum_{j=0}^m G_{n-1}(m-j)F_n(j) \quad \text{for } 1 \leq m \leq M, 1 \leq n \leq N. \quad (56.67)$$

If there is only one state-dependent server, the need for convolution is obviated by designating the state-dependent node as node 1 $G(m) = F_1(m)$ for $1 \leq m \leq M$.

56.6.4 Mean Value Analysis

The MVA method was developed at the IBM Research at Yorktown in late 1970s through a collaboration between Reiser and Schweitzer according to [99], which also states that Lavenberg was instrumental in formalizing the proofs in [98]. The MVA method has the advantage over Buzen's algorithm that it is easy to explain and intuitively appealing. Buzen's algorithm for state-independent station is specified by two nested iterations in Equation 56.66, while the order of iterations is reversed in MVA, as specified next:

MVA algorithm for N single server nodes and M jobs.

Initialize queue lengths at all nodes $Q_n(0) = 0, \forall n$.

For $1 \leq m \leq M$ requests repeat steps inside brackets:

{

Compute residence time at all single server nodes: $R_n(m) = D_n[1 + Q_n(m-1)]$.

Compute residence time at all IS nodes: $R_n(m) = D_n$.

Compute system throughput: $T(m) = m / \sum_{n=1}^N R_n(m)$.

Compute queue lengths at all nodes: $Q_n(m) = T(m)R_n(m), \forall n$.

}

Compute device utilizations at all nodes: $U_n(m) = D_n T(m), \forall n$.

The formula for residence times is based on the Arrival Theorem [98], which states that arrivals to a node encounter a queue length, as if there is one less job in the closed QNM [98].

MVA can be easily extended to multiple job classes [45,82,83]. There are numerical stability problems associated with state-dependent servers, since instead of just the mean queue length, MVA computes

the distribution of the number of jobs at a node. The probability of zero jobs at a node may turn out to be negative for higher utilizations, since it is computed as one minus the sum of other probabilities (see Chapter 20 in [83]). This does not pose a problem in the case of Buzen's Algorithm developed a decade before MVA. There is also the N -fold increase in memory size requirements for MVA with respect to Buzen's algorithm (see Table 8.5 in [45]). Note that both time and space requirements grow as the product of the number of jobs in different chains.

There are several approximate iterative methods based on MVA that lead to a direct solution for large number of jobs. The Bard-Schweitzer approximate iterative solution method is based on MVA [45,82,83]. It uses the initialization assuming that service demands at the nodes are equal $Q_n(M) = M/N$ and then sets $Q_n(M-1) = [(M-1)/M]Q_n(M)$ for $1 \leq n \leq N$. The iteration continues until $Q_n(M)$ obtained in successive iterations are approximately equal [45,83]. The *self-correcting approximation technique* (SCAT) and the linearizer [45,85] developed by Chandy and Neuse provide more accurate results than the Bard-Schweitzer approximation and allows state-dependent servers, while reducing the computational cost with respect to MVA. A comparison of approximate algorithms for QNMs is given in Table 9.13 in [45]. This is a more important issue in QNMs with multiple job classes. See Table 8.5 in [45], which is extracted from [54].

Priority queueing at the CPU can be incorporated approximately in MVA by inflating the $D_{CPU}^{low} = D_{CPU}^{low-original} / (1 - U_{CPU}^{high})$ and since U_{CPU}^{high} is not known a priori, iteration is required (see Algorithm 11.1 in [83]). The so-called shadow CPU technique was proposed by Sevcik to obtain optimistic and pessimistic bounds on the performance of nodes with priorities. Additional approximations to deal with violations of the BCMP theorem, such as different exponential service times across job classes and nonexponential service times, both in the case of FCFS scheduling (see Chapter 11 in [83]).

56.6.5 Bounds to QNM Performance

The *Balanced Job Bounds (BJB)* [83] by Zahorjan, Sevcik, Eager, and Galler provides an upper bound to the throughput $T(M)$ of closed QNMs ($T(M)$) with nodes with single servers using the average service demand $D_a = \sum_{n=1}^N D_n/N$. In a balanced QNM due to symmetry, the queue lengths encountered at the nodes due to the Arrival Theorem are $Q_n(M-1) = (M-1)/N, \forall n$. The residence time at node n is $R_n(M) = D_a(1 + M - 1)/N, \forall n$, so that

$$R(M) = (N + M - 1)D_a \Rightarrow T(M) = \frac{M}{(M + N - 1)D_a}. \quad (56.68)$$

It can be observed from Equation 56.68 that in balanced QNMs $T(M)$ increases with M . Generally, according to Theorem 2 in [60] the throughput characteristic of QNMs with state-independent and delay nodes is a concave nondecreasing function. This is shown in Figure 9.1 in [83], that is, $T(M) > [T(M-1) + T(M+1)]/2$.

An alternate analysis using generating functions and the binomial theorem [30] was developed by Thomasian and Nadji to derive Equation 56.68 [118]. The generating function for N single server stations is

$$g(t) = \prod_{n=1}^N x_n(t) = (1 - Dt)^{-N} = \sum_{m=0}^{\infty} \binom{N+m-1}{m} (Dt)^m, \quad (56.69)$$

hence $G(M) = \binom{N+M-1}{M} D^M$ and $G(M-1) = \binom{N+M-2}{M-1} D^{M-1}$, so that $T(M) = G(M-1)/G(M)$, which is the throughput in Equation 56.68.

The same work develops an approximation based on Taylor series expansion with respect to the mean service demand $D_0 = \sum_{n=1}^N D_n/N$. Let $E_j = \sum_{n=1}^N D_n^j (D_n/D_0 - 1)^j$

$$R_0(m) = \sum_{j \geq 2} \frac{E_j}{j} \left[\prod_{i=0}^{j-1} \frac{M-i}{N+i} \right].$$

Successively more accurate approximations to $T(M)$ as given by Equation 56.58, which may be considered a 0th order approximation, are given as follows

$$T_i(M) = T(M) \frac{1 + R_0(M-1)}{1 + R_0(M)}.$$

Maintaining only one term in the summation for $R_0(M)$ we have

$$T_1(M) = T(M) \left[1 - \frac{\frac{M-1}{M(M+1)} E_2}{1 + \frac{M(M-1)}{2M(M+1)} E_2} \right].$$

The analysis has been extended to two job classes in [89].

Nodes with single servers and delay servers are considered in [83]. The service demands at the delay servers can be easily added to the mean residence time in the system $R(M)$ in Equation 56.58.

Asymptotic bounds analysis (ABA) developed by Muntz and Wong in 1975 [79] is similar to BJB where the system is obtained using the maximum service demand [83], but in fact the former is more useful since it is applicable to all types of nodes, while the latter applies only to state-independent nodes. Given that the n th node has m_n servers with service demand D_n for $1 \leq n \leq N$.

$$T_{max} = \min \left\{ \frac{m_1}{D_1}, \frac{m_2}{D_2}, \dots, \frac{m_N}{D_N} \right\}. \quad (56.70)$$

In the case of state-dependent servers with the implicit assumption that the service rate is an increasing function of the number of requests, the maximum throughput at each node can be used in this calculation. T_{max} is approached as $M \rightarrow \infty$. At lower values of M , $T(M)$ is upper bounded by the line passing through $(0, 0)$ and $(1, T(1))$, where $T(1) = 1 / \left[\sum_{n=1}^N D_n \right]$. Chapter 5 in [83] has several examples on utilization bounds in performance analysis.

56.6.6 Hybrid QNMs with Open and Closed Chains

We conclude the discussion of QNMs, which combine open and closed chains. We summarize Algorithm 7.4 in [83] with multiple open chains and a single closed chain. Only single server state-independent nodes are considered at this point for the sake of brevity.

1. Solve QNM considering open chains alone and determine server utilizations due to them.
2. Expand service demands of closed chains by dividing them by one minus the server utilizations due to open chains.
3. Solve QNM for closed chains to determine queue lengths at the nodes.
4. Determine residence time for open chains and multiply them by one plus the sum of queue lengths for closed chains.

56.6.7 Hierarchical Decomposition and Aggregation for QNMs

Hierarchical decomposition and aggregation can be explained by considering a multiprogrammed computer system represented by a closed QNM with a maximum MPL M_{max} . It is substituted with a single *Flow-Equivalent Service Center (FESC)*, with service rate $T(m)$ for $1 \leq m \leq M_{max}$ and $T(m) = T(M)$ for $m \geq M_{max}$, which is a flattened throughput characteristic [83].

Given N users with think time $Z = 1/\lambda$ and m jobs at the computer system, the arrival rate to the FESC representing the computer system is $\Lambda(m) = (N - m)\lambda$. The system can be analyzed by solving the BD process for the machine repairman model (MRM) in Section 56.3.5 with variable service rates. Alternatively a graphical method that plots the arrival rate and the completion rate versus the number of the jobs at the computer system can be adopted (see Figure 3.37 in [80] or Figure 20 in [59]). The intersection of the two graphs is the operational point of the system M^* . The distribution of the number of jobs surrounding M^* roughly follows a normal distribution [42,143]. *Equilibrium point analysis (EPA)*, which is based on an iterative *fixed point approximation (FPA)*, can be used to analyze the system directly without resorting to a detailed solution based on BDs [113].

The problem is more complex in the case of QNMs with external arrivals from multiple job classes and population size constrains. This problem has been studied in the context of multiprogrammed computers processing multiple job streams with Poisson arrivals. The MPL constraint may be per class or over all classes. Solution methods to deal with this problem are given in Chapter 9 in [83], while [121] compares the accuracy of several approximations proposed for this problem.

In a virtual memory environment as the number of activated jobs is increased, the main memory may be overloaded leading to excessive page faults. System resources will be used in handling page faults rather than in processing jobs, so that there is a drop in system throughput, which is known as thrashing [31]. Another reason for the drop in system throughput (in theory) is database lock contention, which is discussed in Section 56.8.1. According to Figure 8 in [127], there is a drop in $T(m)$ for $m \geq 1$ yields three intersection points with $\Lambda(m) = (N - m)\lambda$. The stable intersection points are A and C, where A is desirable and C is in the thrashing region, and B is unstable and the system can drift from it to the other two stable points.

Aggregation and decomposition has been applied in analyzing QNMs that do not lend themselves to a product-form solution. Two such examples are given next.

Serialization delays occur when the processing of certain phases of jobs in a computer system is single-threaded, so that only one of multiple jobs executing concurrently can proceed in the serialized phase, while the other jobs are blocked from entering the serialized phase. The analysis of a single job class with $M = 4$ jobs and $S = 2$ *serialization phases (SPs)* is considered in [119]. The underlying CSM consists of a CPU and disks as in CSM. Jobs completing their service at the CPU access the disks or attempt access to one of two SPs. The job is blocked if there is another job already active at the SP.

A CTMC is required to specify the state of the system, which is represented by the numbers of jobs in the nonserialized phase and two serialized phases $\underline{m} = (m_0, m_1, m_2)$, so that $m_0 + m_1 + m_2 = M$. The analysis of the QNM yields $T_i(\underline{m})$, $0 \leq i \leq 2$. The explosion in the number of CTMC states can be handled by coalescing states to attain a more compact *state representation (SR)*. The number of states of the CTMC can be reduced from 15 to 12 by combining states (1,2,1) and (1,1,2) into (1,1,1) and also states (0,3,1), (0,2,2), and (0, 1, 3) into (0,1,1). The reduction in the number of states due to lumping of states is more dramatic when there are multiple job classes. Five different SRs with a large variation in the number of states are considered in [126].

QNMs whose jobs exhibit parallelism are not product-form, but can be analyzed using hierarchical decomposition. An efficient method to analyze such QNMs whose jobs can be specified as task structures was developed by Thomasian and Bay in [122]. We illustrate the analysis via a small example to determine the completion time of two parallel tasks \mathcal{T}_1 and \mathcal{T}_2 , which belong to different job classes. The initial system state is (1, 1), with one job in each class. The throughputs in the two classes are $T_i(1, 1)$ for $i = 1, 2$. Given that the completion rates of the two tasks are exponential, the probability that \mathcal{T}_1 completes

first is $p_i = T_i(1, 1)/T(1, 1)$, with $T(1, 1) = T_1(1, 1) + T_2(1, 1)$. The holding time in that state is $R(1, 1) = 1/T(1, 1)$. The completion of T_1 and T_2 leads to a transition to states $(-, 1)$ and $(1, -)$ with holding times $R(2)$ and $R(1)$, respectively. It follows that the completion time of the two tasks is given as $C = R(1, 1) + p_1R(2) + p_2R(1)$. The solution method for complex task structures in [122] generates the states of the CTMC and computes their unnormalized probabilities one level at a time, after solving the underlying QNM. The number of states in the CTMC can be trimmed by ignoring states whose occurrence is highly unlikely.

The use of hierarchical decomposition in evaluating the performance of a CSM with higher priorities assigned to one of two classes was proposed in [117]. A similar example is given in Section 8.5.1 in [83].

The effect of lock contention on overall system performance is analyzed using the hierarchical decomposition method in two companion papers. The effect of lock preclaiming on the delay of activating jobs due to lock conflicts with already active jobs is considered in [120], while [102] deals with dynamic locking systems, but uses a more detailed analysis than the one given in [127] (see Section 56.8.1 for details).

Hybrid models combine simulation for higher level activities, such as txn arrivals and job activation, and analysis of QNMs for lower level activities, such as the processing of txns by the CSM. The hybrid modeling of IBM's *System Resource Manager (SRM)* for the MVS OS given in [52] is described in Section 15.6 in [83].

Hybrid simulation proposed by Schwetman in [105] counts cycles to determine job progress in a variation of CSM, referred to as the cyclic server model, where jobs leave the system after processing at the disks. This method was adopted in [123] in a simulation study to minimize the mean response time in distributed systems. Job processing demands are given as the service demands per cycle and the number of cycles required by jobs in a cyclic server model, where job completions occur at the disks rather than the CPU. Jobs may be characterized as CPU or I/O bound, so that it is the composition of jobs at the computer system rather than just their MPL that needs to be considered when routing incoming jobs. Jobs are routed to the node that minimizes their mean response time, but this mean response time will only hold if there are no further arrivals to the queue until the job completes. This method works better with high variability in interarrival times and in the extreme case of batch arrivals.

A first-order Markov chain model for routing of jobs implies a geometric distribution for the number of cycles $p_n = (1 - p)p^{n-1}$. Approximating the processing time of jobs per cycle with an exponential distribution (with parameter λ) implies an exponential residence time distribution with mean $[(1 - p)\lambda]^{-1}$

$$\mathcal{Y}^*(s) = \sum_{k \geq 1} (1-p)p^{k-1} \left(\frac{\lambda}{s + \lambda} \right)^k = \frac{(1-p)\lambda}{s + (1-p)\lambda} \Leftrightarrow r(t) = (1-p)\lambda e^{-(1-p)\lambda t}.$$

Generally for arbitrary distributions for \tilde{k} with pmf p_k and z -transform $K(z)$ and \tilde{x} with LST $\mathcal{X}(s)$, the LST of $\tilde{y} = \sum_{j=1}^{\tilde{k}} x_j$ is

$$\mathcal{Y}^*(s) = \sum_{k \geq 0} [\mathcal{X}^*(s)]^k p_k = K(\mathcal{X}^*(s)), \tag{56.71}$$

where $K(\cdot)$ is the z -transform of the number of cycles.

The mean and variance of this distribution are obtained by integration by parts (in what follows $z = \mathcal{X}^*(s)$)

$$\bar{Y} = -\frac{d\mathcal{Y}^*(s)}{ds} = -\frac{dK(z)}{dz} \Big|_{z=1} \left[-\frac{dz}{ds} \Big|_{s=0} \right] = \bar{K} \times \bar{X}, \quad \sigma_Y^2 = \bar{K} \sigma_X^2 + \sigma_{\bar{K}}^2 (\bar{X})^2. \tag{56.72}$$

The number of jobs completed in a time interval approaches a Poisson process when the cycling probability $p \rightarrow 1$, signifying a large number of cycles, since transitions leading to a job completion are rare. Poisson inter-departure times imply exponentially distributed residence times [103].

Several approximate analyses have been developed to estimate the distribution of response time distribution in QNMs. At a first glance its LST is given as the product of the LSTs at the nodes visited by the chain. Complications such as “overtaking” are discussed in Chapter 9 in [72].

56.7 Page Replacement and Buffer Management

Early studies in this area dealt with the page reference pattern of computer programs residing in a virtual memory environment. The problem becomes more complex when multiple programs share memory space, which is referred to as multiprogrammed memory management. Early discussions of these two topics appear in Chapters 6 and 7 in [53].

Cache memories differ from virtual memories in that they utilize a smaller block size and are more restrictive from the mapping viewpoint, since they rely on a hardware implementation, such as direct or a low-degree set associative mapping for speed, while the more flexible fully associative mapping (with some limitations) is applicable to virtual memories [73]. Main memory access is only required when a CPU cache miss occurs and this requires the translation of virtual addresses generated by processors to physical main memory addresses. This translation is assisted by associative memories known as *translation lookaside buffers (TLBs)* [73]. Very low miss rates at the caches and TLBs are required to ensure high performance. System performance at this level can only be determined a priori by trace-driven simulation.

When the miss rates at the two levels are negligibly small, the effective mean access time can be approximated by the access time to the highest level. The following equation for two levels of caching can be generalized to multiple levels [73]

$$\text{Hit_time}_{L1} + \text{Miss_rate}_{L1} \times (\text{Hit_time}_{L2} + \text{Miss_rate}_{L2} \times \text{Miss_penalty}_{\text{Main-memory}})$$

The execution of a program is interrupted and context switching occurs when it encounters a page fault in a virtual memory environment. With multiprogramming the processor is reassigned to another program, which is eligible for execution, for example, because its page fault was satisfied. The miss rate, which is the fraction of main memory accesses that result in a page fault, is an appropriate performance metric in this context. When page faults occur, the system throughput is not affected significantly since the CPU is kept busy in multiprogrammed computer systems. With the advent of large main memories, most programs are fully loaded so that the memory miss rate is not an important issue.

A block (or page) replacement policy determines the block is to be overwritten. Better replacement policies minimize the number of misses by not overwriting blocks, which are referenced soon thereafter so that replacing them would result in increasing the execution time of a program. Stack algorithms which include the *least recently used (LRU)* policy have the desirable property of reducing the miss rate as the memory space allocated to a program is increased [100]. Policy MIN that minimizes the miss rate by replacing the page referenced furthest in the future, or not at all, is not a feasible policy, but useful in comparing the relative performance improvement. Several other page replacement policies are *first-in, first-out (FIFO)*, *Last-in, first-out (LIFO)*, *CLOCK*, *Second-Chance*, *Generalized CLOCK*, *working set (WS)*, *page fault frequency (PFF)*, etc. [32]. It is the size of allocated memory that has a first-order effect on the miss rate.

Overextending the main memory underlying the virtual memory may lead to the thrashing phenomenon [58], which may be dealt with by swapping out programs to make more memory space available for active jobs [50]. Programs exhibit a low miss rate when their working set is allocated in main memory so that the number of allocated pages should be increased when the miss rate is high [58]. The WS [58] and the PFF [94] algorithms vary the number of allocated pages in a multiprogrammed computer system to optimize performance. PFF allocates more memory pages when the the miss rate exceeds a certain threshold and otherwise reduces the number of allocated pages.

Buffer management studies estimate the parameters of reference strings for a given reference model and propose and evaluate replacement policies. Two early page reference models are the *independent reference model (IRM)* (blocks are accessed with fixed probabilities) and the LRU stack-depth model (stack distances are given by fixed probabilities). McNutt's hierarchical reuse (fractal) model reveals the following relationship between miss rates ($s < s'$) and memory sizes ($m > m'$) $s/s' = (m/m')^{-1/3}$, that is, to halve the miss ratio an eightfold increase in the buffers size is required [86].

The miss rate can be evaluated using random-number-driven or trace-driven simulations. Trace driven simulations are the more credible, but multiple traces should be used for a higher confidence level (86 traces were used in evaluating the cache for the IBM's 360/85, the first commercial computer with a cache in late 1960s). There have been a limited number of analytic models of paging algorithms, for example, the analysis via a Markov chain model of the generalized CLOCK algorithm in [93].

An empirical formula for the number of page faults (n) versus memory size (M) is derived in [114]. Memory sizes M_0 and M^* are the min and max M that are sufficient and necessary. The number of cold memory misses starting with an empty buffer is n_0 . The parameters vary with program behavior and replacement policy:

$$n = \frac{1}{2} \left[H + \sqrt{H^2 - 4} \right] (n^* + n_0) - n_0, \quad H = 1 + \frac{M^* - M_0}{M - M_0}, \quad M \leq M^*.$$

One observation of this study is that policies have different n for smaller memory sizes and otherwise all policies yield about the same n .

The *buffer miss rate (BMR)* is applicable to various levels of the memory hierarchy. Misses in the main memory buffer result in accesses to the cache at the *disk array controller (DAC)* are accessed following a miss at both levels. BMR is affected by the buffer size, the replacement policy, and the workload. Of interest is improving the performance of shared DAC caches in processing sequential and random streams for large disk arrays. The *sequential prefetching adaptive replacement cache (SARC)* improves performance by a judicious combination of caching and prefetching policies [69]. SARC dynamically and adaptively partitions the cache space between sequential and random streams so as to reduce read misses. It outperforms two variants of the LRU policy at peak system throughput in processing a TPC-1 like workload in a RAID5 disk array with an 8 GB cache.

Early articles on page replacement and buffer management policies are summarized in a web page dealing with database implementation [33].

56.8 Analyses of Concurrency Control Methods

Four requirements for txn processing systems are *atomicity, consistency, integrity, and durability (ACID)* [97]. *Concurrency control (CC)* methods are required to ensure database consistency and integrity and also correctness in txn execution, which is tantamount to serializability, that the execution of a sequence of txns is equivalent to their execution in some serial order [97]. Txn recovery methods, such as write-ahead logging, are used to ensure txn atomicity and durability [97]. Almost all operational database systems utilize the standard locking method and the performance degradation due to this method is analyzed in Section 56.8.1. Two alternative CC methods have been proposed for high data contention environments [64]. Restart-oriented locking methods are discussed and their performance analyzed in Section 56.8.2. The results in the first two sections are due to Thomasian [127,132]. The analysis of the *optimistic CC (OCC)* in Section 56.8.3 is based on Morris and Wong in [88]. The extensions of this work by Ryu and Thomasian in [101] are briefly discussed.

56.8.1 Standard Locking and Its Threshing Behavior

Standard locking follows the strict *two-phase locking* (2PL) paradigm, where locks are requested on demand and strictness requires that no locks are released until the completion of txn execution known as txn commit. This allows the undoing of txn updates when the txn is aborted [97,131]. Locks are released upon txn abort to resolve deadlocks or to relieve lock congestion in conjunction with restart-oriented policies in Section 56.8.2.

An abstract model of standard locking to analyze the effect of lock contention on the performance of txn processing systems is postulated in [127]. There are M txns in a closed system, so that a completed txn is immediately replaced by a new txn. Txns of size k have $k+1$ steps with mean duration (s), so that the mean txn residence time with no lock contention is $r_k = (k+1)s$. Locks are requested at the end of the first k txn steps and all locks are released at the end of the $k+1$ st step. The mean duration of each step taking into account txn blocking due to lock conflicts, but not txn restarts due to rare deadlocks is $(s+u)$. We have $u = P_c W$, where P_c is the probability of a lock conflict per lock request and W the mean waiting time per lock conflict [127]. The mean number of locks held by a txn is $\bar{L} \approx k/2$. It is assumed that all locks are exclusive and are distributed uniformly over the D pages in the database, so that the probability of lock conflict $P_c \approx (M-1)\bar{L}/D$ tends to be small. Shared locks whose fraction is f_s can be taken into account by adjusting the database size to $D_{eff} = D/(1-f_s^2)$ [131]. The probability that a txn encounters a lock conflict is $P_w = 1 - (1-P_c)^k \approx kP_c = (M-1)k^2/D$. A two-way deadlock can *only* occur if txn T_A requests a lock held by txn T_B , which is blocked because of its conflict with txn T_A :

$$P_{D(2)}(k) \approx \frac{P[T_A \rightarrow T_B]P[T_B \rightarrow T_A]}{M-1} = \frac{P_w^2}{M-1} \approx \frac{(M-1)k^4}{4D^2}.$$

Multiway deadlocks are not considered since they are rare. The aforementioned analysis was refined to take into account the fact that a deadlock only occurs if T_B was already blocked [125]. We obtain the mean blocking delay of a txn with respect to an active txn holding the requested lock (W_1) by noting that the probability of lock conflict increases with the number of locks held by the txn (j) and that there are $(k-j)$ remaining steps [127]

$$W_1 \approx \sum_{j=1}^k \frac{2j}{k(k+1)} [(k-j)(s+u)] + s' = \frac{k-1}{3} [r+u] + s'.$$

where s' is the remaining processing time of a step at which the lock conflict occurred.

Since deadlocks are rare, the mean txn response time only takes into account txn blocking time due to lock conflicts, but not restarts due to deadlocks since they are rare $R_k \approx (k+1)s + kP_c W_1$. The fraction of txn blocking time per lock conflict with an active txn is $A = W_1/R_k \approx 1/3$. A more accurate expression for two-way deadlocks, as verified by simulation, is given by Equation 56.73 in [126] as $P'_{D(2)}(k) \approx AP_{D(2)}(k) = P_{D(2)}(k)/3$. In the case of variable size txns (with a closed model), a completed txn is replaced by another txn of size ℓ with frequency f_ℓ . Given that the i th moment of the number of requested locks is K_i , then $\bar{L} \approx K_2/K_1$ and $A = (K_3 - K_1)(3K_1(K_2 + K_1))$ [128].

Ignoring the difference in the number of locks held by active and blocked txns, the probability that a txn has a lock conflict with an active txn at level $i = 0$ (resp. a blocked txn at level $i = 1$) in the forest of waits-for graph for active and blocks txns is $1 - \beta$ (resp. β) and the mean blocking time is W_1 (resp. $W_2 = 1.5W_1$). The expression for W_2 relies on the fact that at the random instant when the lock conflict occurs, the active txn is halfway to its completion. The probability that a txn is blocked at level i is approximated as

$$P_b(i) \approx \beta^{i-1} \quad \text{for } i > 1 \text{ and } P_b(1) = 1 - \beta - \beta^2 - \beta^3 \dots$$

The mean delay at level $i > 1$ is approximated by $W_i \approx (i - 0.5)W_1$. The mean blocking time is a weighted sum of delays incurred by txns blocked at different levels

$$W = \sum_{i \geq 1} P_b(i)W_i = W_1 \left[1 - \sum_{i \geq 1} \beta^i + \sum_{i > 1} (i - 0.5)\beta^{i-1} \right].$$

Let \bar{M}_A and $\bar{M}_B = M - \bar{M}_A$ denote the mean number of active and blocked txns in a closed QNM with M txns. We multiply both sides of the equation by $K_1 P_c / R$ and note that $\beta = K_1 P_c W / R$ is the fraction of blocked txns. We define the fraction of time txns are blocked by active txns as $\alpha = K_1 P_c W_1 / R$. It follows $\beta = \alpha(1 + 0.5\beta + 1.5\beta^2 + 2.5\beta^3 + \dots)$. A closed-form expression for β can be obtained by noting that $\beta < 1$ and assuming that M is infinite yields

$$f(\beta) = \beta^3 - (1.5\alpha + 2)\beta^2 + (1.5\alpha + 1)\beta - \alpha = 0.$$

The function $f(\beta)$ versus β is plotted in Figure 1 in [127]. The cubic equation has three roots $0 \leq \beta_1 < \beta_2 \leq 1$ and $\beta_3 \geq 1$ for $\alpha \leq \alpha^* = 0.226$ and a single root $\beta_3 > 1$ for $\alpha > \alpha^*$, where α^* is the only root of the discriminant function of the cubic [34] (see Appendix B in [127]). The single parameter α determines the level of lock contention for standard locking and its critical value α^* determines the onset of thrashing. The smallest root β_1 for $\alpha \leq \alpha^*$, which determines the mean number of active txns $\bar{M}_A = M(1 - \beta_1)$. \bar{M}_A increases with the MPL M reaching a maximum point before dropping. This is because of a snowball effect that blocked txns cause further txn blocking. The associated thrashing behavior is shown in Figure 2 in [127]. It is also shown in this study that txn size variability has a major effect on lock contention.

56.8.2 Restart-Oriented Locking Methods

Performance degradation in standard locking is mainly caused by txn blocking, since deadlocks are rare and txn aborts to resolve deadlocks have little effect on performance. Restart-oriented locking methods follow the strict 2PL paradigm, but instead of blocking all txns when lock conflicts occur, txns are selectively restarted to increase the degree of txn concurrency. This would allow higher txn throughputs in high data contention systems, such as an early release of DB2 with page level, rather than record level locking [97].

The *running priority* (RP) method aborts txn T_B in the waits-for-graph $T_A \rightarrow T_B \rightarrow T_C$, when T_A encounters a lock conflict with T_B [64]. Similarly according to symmetric RP, T_B , which is already blocking T_A , is aborted when it is blocked requesting a lock held by T_C . In effect RP increases the degree of txn concurrency. The restart of an aborted txn is delayed until the conflicted txn has left the system. The no-waiting and cautious waiting methods abort and restart a txn encountering a lock conflict with an active and blocked txn, respectively. There is no increase in the number of active txns.

The *wait depth limited* (WDL) method measures txn progress by its length, which in [64] is approximated by the number of locks it holds. WDL differs from RP in that it attempts to minimize wasted lock holding time by not restarting txns holding many locks. For example, if T_A , which is blocking another txn, has a lock conflict with T_B , then if $L(T_A) < L(T_B)$ then abort T_A , else abort T_B [64]. The superior performance of WDL over RP and especially standard locking has been shown via random-number-driven simulation in [64], but also trace-driven simulation as discussed in [131]. RP and WDL attempt to attain *essential blocking*, that is, allowing a txn to be blocked only by active txns (bound to complete successfully) and not requesting a lock until required.

Immediately restarting an aborted txn may result in *cyclic restarts* or *livelocks*, which should be prevented to reduce wasted processing and to ensure timely txn completion. *Restart waiting* delays the restart of an aborted txn until *all* conflicting txns are completed [64]. Conflict avoidance delays with random duration are a less reliable method to prevent cyclic restarts.

Restart-oriented locking methods can be analyzed using Markov chain models [131,132]. Active (resp. blocked) txns with j locks are represented by states S_{2j} for $0 \leq j \leq k$ (resp. S_{2j+1} for $0 \leq j \leq k-1$). In the case of the no-waiting or immediate restart method, there is a transition forward when there is no lock conflict: $S_{2j} \rightarrow S_{2j+2}$ for $0 \leq j \leq k-1$, otherwise the txn is aborted $S_{2j} \rightarrow S_0$. The state equilibrium equations for the Markov chain yield the steady-state probabilities π_i for $0 \leq i \leq 2k$. The mean number of visits v_i to S_i can be obtained similarly by noting that $v_{2k} = 1$, which is the state at which the txn commits. Given that h_i is the mean holding time (the inverse of the transition rate) at S_i , then $\pi_i = v_i h_i / \sum_{j=0}^{2k} v_j h_j$ for $0 \leq i \leq 2k$. The mean number of txn restarts is given by $v_0 - 1$. A shortcoming of this analysis is that locks requested by restarted txns are resampled. Transition rates for the RP and WDL methods are given in [132].

56.8.3 Optimistic Concurrency Control Methods

A txn executing according to OCC copies pages (database blocks) it needs to modify to its private workspace, by noting its timestamp, that is, the last time the page was modified. The validation phase ascertains serializability, which is the universally accepted criterion for correct txn execution, that none of its accessed objects was modified by another txn after it was read. If the validation is successful, the txn commits and otherwise it is immediately restarted. Given that the k objects updated by txns are uniformly distributed over a database of size D , the probability of data conflict between two txns of size k is $\psi = 1 - (1 - k/D)^k \approx k^2/D$. This is referred to as the *quadratic effect* in [64]. The completion rate of successfully validated txns is $p\mu s(M)$, where p is the probability of successful validation and μ is the completion rate of txns. If there is no hardware resource contention $s(M) \propto M$, but since hardware resource contention is inevitable $s(M)$ is sublinear. A txn with processing time x will require $xM/s(M)$ time units to complete, where $s(M)$ is a nondecreasing function of M . A txn observes the commits of other txns at random times approximated by a Poisson process with rate $\lambda = (1 - 1/M)p\mu s(M)$. Txns encountering data conflict with rate $\gamma = \lambda\psi$ fail their validation with probability $q = 1 - e^{-\gamma x M/s(M)}$. The number of txns executing successfully at the system follows a geometric distribution $P_j = (1 - q)q^{j-1}$ for $j \geq 1$ with a mean $\bar{J} = 1/(1 - q) = e^{\gamma x M/s(M)}$. The system efficiency p can be expressed as the ratio of the mean execution time of a txn without and with data contention, that is, with the possibility of restarts due to failed validation

$$p = \frac{E[xM/s(M)]}{E[(xM/s(M))e^{\gamma x M/s(M)}]} = \frac{\int_0^{\infty} x e^{-\mu x} dx}{\int_0^{\infty} x e^{(\gamma M/s(M) - \mu)x} dx} = [1 - (M - 1)\psi p]^2.$$

The equation yields one acceptable root $p < 1$, provided $\gamma M/s(M) < \mu$ and the integral in the denominator converges:

$$p = \left[1 + 2(M - 1)\psi - \sqrt{1 + 4(M - 1)\psi} \right] / \left[2(M - 1)^2 \psi^2 \right] < 1.$$

Txn execution time is not resampled in this analysis because resampling processing times results in a mix of completed txns, which is shorter than the original processing time. Shorter txns have a higher probability of successful validation so that resampling would result in overestimating performance.

The aforementioned discussion follows *static* data access considered in [144], which postulates that all objects are accessed at the beginning of txn execution. This work was extended in [101] to allow the more realistic dynamic or on-demand data accesses preceded by lock requests [101]. The analysis is also that of OCC with the *die* method [64], which is inefficient in that a conflicted txn is allowed to execute to the end, at which point it is restarted. The OCC *broadcast* or *kill* method instead aborts a txn as soon as a data conflict is detected, alleviating further wasted processing [64,101].

Although the optimistic die method seems to be less efficient than the kill method, this is not the case when due to database buffer misses txns make disk accesses. It is advantageous then to allow a conflicted txn to run to its completion to prime the database buffer with all the required objects for its re-execution in a second phase, which is expected to have a much shorter processing time, since disk accesses are not required. This is so provided *access invariance* or *buffer retention* prevails, that is, a restarted txn accesses the same set of objects as it did in its first execution phase [64]. The second execution phase may use the optimistic kill method. Standard locking with on demand lock requests, or lock preclaiming. The latter is possible since given access invariance prevails, the identity of pages to be locked by the txn has been determined in the first execution phase. Lock preclaiming ensures that the txn will not be restarted. In general, we have multiphase processing methods with CC methods with increasing strengths, for example, OCC followed by locking, so that a lock request on an object accessed in optimistic mode will result in the abort of the respective txn.

The WDL and RP restart-oriented locking methods outperform two-phase methods and are easier to implement since they only require modifications to the lock manager shared by DBMSs associated with IBM's MVS OS and its descendants so that no modifications are required to the DBMSs.

56.9 Simulation Modeling and Measurement

The performance of computer systems is determined by hardware and software measurement tools. Most systems are also equipped with software to determine the causes of system crashes in operational systems. A description of measurement tools for IBM's MVS operating system (OS) [35], which is a forerunner to the z/390 OS appears in [50] and Chapter 17 in [83]. These measurements are carried out at the level of workloads, for example, response time and throughput, and device level, for example, processors and disk utilizations and mean queue lengths. In the case of BGS's BEST/1 capacity planning tool, complementary software was developed to summarize these results into service demands, which were direct inputs to BEST/1 [50]. For example, when the number of timesharing users is increased, BEST/1 can determine the effect of modifications to the current computer configuration to provide an acceptable response time. It is easier to deal with active rather than passive resources. Before proceeding with capacity planning, there is the important validation phase to ensure that the model accurately predicts performance. Otherwise the model has to be modified (see [59] and Section 2.2 in [83]).

Robust performance models proposed in [115] take into account that the underlying system may be misconfigured or buggy. The IronModel is made part of the system and is aware of all system requests and their performance. It uses localization to determine the sources of mismatches and then uses refinement techniques to make educated guesses. There is reliance on statistical methods and *machine learning* (ML) techniques such as *classification and regression tree* (CART) to modify the model [115]. A preliminary effort to build applications exporting their state and associated performance metrics is described in [116].

Simulation and analytical modeling can be carried out at multiple levels, such as estimating CPU performance as affected by its caches. While there have been analytic studies of caches and memory hierarchies [81], trace-driven simulation is more appropriate in this case. There are also simulation tools for disk subsystems, such as DiskSim from CMU's *Parallel Data Laboratory* (PDL) [36]. Dixtrac extracts disk parameters, which are then used by the DiskSim simulation tool. The ns2 network simulator provides support for simulating *transport control protocol* (TCP), routing, and multicast over wired and wireless networks [37].

Random number simulations, as opposed to, trace-driven simulations, utilizes the pattern extracted from traces of workload activity, but are less credible than trace-driven simulations since workload characterization may not capture all subtleties of the workload. Trace analysis may show that accesses to a disk are concentrated in two small regions, but given that the accesses occurred in disjoint periods of time implies little seek activity.

While simulations deal with multiple concurrent events, most simulation programs are sequential and use the next event approach processing one event at a time. Several languages developed for simulation programming, but many sophisticated simulators, such as DiskSim and ns2 are mainly based on general purpose programming languages (such as C or C++). Simulator design and programming is described by Markowitz in Chapter 7 in [82].*

As events are generated they are held in an event queue based on their occurrence time in the future. With a large number events (n), efficient data structures such as heaps with an $O(\log_2(n))$ insertion and deletion cost may result in a significant reduction in simulation cost in comparison with $O(n)$ for linear lists.

Random number generators (RNGs) are based on a pseudo-random sequence of a *linear congruential generator (LCG)* of the form $X_n = aX_{n-1} + c(\text{mod } m)$, where the modulus m is of the form $m = 2^{32}$ [38]. A “built-in radioactive RNG” in addition to a software RNG was used in [77]. X_0 is the seed and determines the sequence of the numbers generated, hence the sequence is pseudo-random. Using the current computer time as the seed has the advantage of generating an independent stream of pseudo-random numbers, which may be used by the batch means method (see below). It is best to use the same seed to reproduce the same events during the debugging phase. Uniform numbers $0 \leq u \leq 1$ are generated using appropriate transformations, such as $t = -(1/\lambda)\ln(1 - u)$ or equivalently $t = (-1/\lambda)\ln(u)$ for an exponential distribution with parameter λ . RNG for discrete event simulation is described by Shedler in Chapter 5 in [82].

The simulation of a queueing system, such as a CSM with external arrivals, maintains statistics on response times and mean queue lengths at various devices. Simulations starting with an empty system require statistics accumulated in the warmup period to be discarded. There is the issue of the length of the simulation run. This is usually expressed by the number of completed jobs. The statistical analysis of simulation results is an important aspect of simulation. In the case of an M/M/1 queue with $\lambda = 0.5$ and $\mu = 1$, the mean response times is $R = (\mu - \lambda)^{-1} = 2$, but even very lengthy simulations will only yield approximations to this value.

Three methods—batch means, regenerative simulation, and spectral—are described in Chapter 6 by Welch in [82]. The batch means method is based on running the simulation n times (with different seeds) to obtain R_i for $1 \leq i \leq n$. These are then used to obtain the mean and standard deviation: $\bar{R} = \sum_{i=1}^n R_i/n$ and $\sigma = \sqrt{\sum_{i=1}^n (R_i - \bar{R})^2 / (n - 1)}$. The confidence interval at a confidence level $1 - \alpha = 90\%, 95\%, 99\%$ is $\bar{R} \pm z_{\alpha/2} \sigma/n$, where $z_{\alpha/2}$ is 1.645, 1.96, and 2.576, respectively.

With the advent of fast inexpensive computers and the possibility of using idle workstation cycles in distributed systems [39], large-scale simulations at a low cost remain a possibility. Understanding the operation of complex systems and developing the simulator and interpreting simulation results remain the chief obstacles to such studies. Simulation tools for Extended QNMs described by Sauer and MacNair in [82] equipped with graphical interfaces are intended to reduce the difficulty of developing simulations.

56.10 Conclusions

A combination of analytic models, simulation, measurement, and statistical methods have been used for designing and operating computer complexes for web servers, e-commerce, etc. With the advent of cloud computing, existing tools may need to be extended for their performance analysis and capacity planning. As noted in [115] there is the issue of understanding system behavior. In a few cases, this has led to fixing implementation bugs, when the predicted performance does not agree with measured performance.

Real systems are rarely amenable to exact and even approximate analytic solutions, although the surprising robustness of QNMs based on *operational analysis (OA)* has been noted in [59]. OA proposed

* Markowitz was the winner of a Nobel Prize in economics for his early work on portfolio selection and later got involved in developing the Simscript simulation language.

by Buzen allows “queueing analysis” without resorting to stochastic processes. OA is therefore of great pedagogic value in explaining the behavior of queueing systems and their simulation and has been adopted in several textbooks, for example, [83].

Statistical methods have been used since the early days of computing in computer performance evaluation. An early collection of papers in this area is [66]. Part 3 of [42,80,143] covers the application of statistical methods to computer system modeling. There is a recent interest in applying ML (machine learning) methods to performance analysis.

The use of *Generalized Stochastic Petri Nets (GSPNs)* in the performance analysis of computer systems has been advocated since mid-1980s by researchers at University of Torino in Italy [41]. These models are highly descriptive and can be used to evaluate aspects other than system performance, such as deadlock-freedom. A GSPN has to be translated to a CTMC or a semi-Markov chain for analysis. Related tools have been developed by Trivedi at Duke University [40]. Direct and iterative methods for the analysis of linear equations arising in solving large CTMCs are described in Chapter 3 in [45].

Abbreviations

BD: birth-death process
CC: concurrency control
CPU: central processing unit
CSM: central server model
CTMC: continuous time Markov chain
DBMS: data base management system
FCFS: first-come, first-served
JSQ: join shortest queue
LCFS: last-come, first-served
LST: Laplace–Stieltjes transform
ML: machine learning
MPL: multiprogramming level
MRM: machine repairman model
MVA: mean value analysis
OA: operational analysis
OCC: optimistic concurrency control
OLTP: online transaction processing
pdf: probability density function
PDF: probability distribution function
QNM: queueing network model
RAID: redundant array of independent disks
r.v.: random variable
SATF: shortest access time first
SPT: shortest processing time
txn: transaction
VSM: vacationing server model
XOR: eXclusive-OR

Glossary

Arrival Theorem: The mean number of requests encountered by arrivals at the nodes of a closed QNM with M requests is the queue length of a QNM with $M - 1$ requests.

Asymptotic Bounds Analysis (ABA): The maximum throughput in a closed QNM with N nodes with service demand D_n and m_n servers at node n is $\min_{v_n}(m_n/D_n)$.

Balanced Job Bounds (BJB): Given that the service demands at the N nodes of a QNM with single servers are $\{D_1, D_2, \dots, D_N\}$, then an upper bound to system throughput at MPL M is $T_{max}(M) = M / [(N + M - 1)D_a]$ with $D_a = \sum_{n=1}^N D_n / N$.

BCMP Theorem: Named after the initials of the four authors of [43], who identified the four queueing systems, which lend themselves to a product-form solution. These are (1) FCFS with exponential service times, (2) processor sharing (PS), (3) infinite servers (IS), and (4) last-come, first-served (LCFS) preemptive. The last three allow general service times. FCFS with multiple servers and IS are examples of state-dependent servers.

Buzen's Algorithm: The state probabilities and performance metrics in closed QNMs with N nodes and M jobs are costly to calculate using a brute-force method because of the large number of system states. Buzen's algorithm requires a multiplication and an addition per step for state-independent nodes. Calculating convolutions is required for state-dependent nodes unless they are designated as the first node.

Central Server Model (CSM): A closed QNM with N nodes, where the central server is the CPU and the peripheral servers are the disks. Job completions are indicated by a self-transition to the CPU, while in the *cyclic server model* jobs leave the system after completing their service at the disks.

Concurrency Control (CC): CC ensures transaction serializability and database integrity. Standard locking utilizes on demand locking and txns encountering a lock conflict are blocked. Restart-oriented locking methods utilize txn restarts to relieve the level of lock contention. Optimistic CC checks whether any data conflicts were encountered during txn execution and if so aborts and restarts it.

Flow Equivalent Service Center (FESC): An FESC replaces multiple nodes in a QNM with a single state-dependent server specified by the throughput characteristic $T(m)$, $1 \leq m \leq M_{max}$. The CTMC for two job classes is specified by its throughputs in processing mixtures of the two job classes $T_i(m_1, m_2)$, $i = 1, 2$.

Fork-Join: Jobs spawn K tasks to K independent servers. A job is considered completed when all K tasks complete, joining at a synchronization point.

Kendall's Notation: A queueing system is specified as $A/B/C/D/E$. The arrival process is $A \in \{M, GI, \dots\}$, where M stands for Markovian or Poisson, GI for general independent, etc. The service time distribution is $B \in \{M, G, \dots\}$, where M is the exponential distribution, G a general distribution, etc. C is the number servers; D is the capacity of the system, which is equal to C if there is no queueing. E is the number of sources. D and E are infinite by default.

Little's Result: The mean number of requests at the queue, the servers, a queueing subnetwork, and the QNM is the product of the arrival rate, which equals the completion rate, and the mean residence time of requests at that entity.

Mean Value Analysis (MVA): A method to solve a closed QNM using the Arrival Theorem. It has higher computational cost and storage requirements than Buzen's algorithm and is less robust numerically.

Page Replacement Algorithms: FIFO, LRU, Clock, generalized Clock, random, LIFO, OPT, working set (WS), page fault frequency (PFF), etc.

Poisson Arrivals See Time Averages (PASTA): This property is used in obtaining the mean waiting time incurred by incoming requests in the $M/G/1$ queue.

Queueing Network Model (QNM): In open and closed QNMs, jobs are routed from node to node. In open QNMs, there are external job arrivals and job departures. In closed QNMs, special job transitions signify the completion of the job and its replacement by a new job, so that the number of jobs in the QNM remains fixed.

Readers and Writers Scheduling: Readers can be processed concurrently with other readers, while writers can only be processed singly. A significant improvement in performance can be attained by not interrupting the processing of readers every time a writer arrives, for example, by adopting the *threshold fastest emptying (TFE)* policy.

Scheduling Discipline: There are specialized scheduling disciplines at the computer system level for activating jobs, for CPU scheduling, and disk scheduling. Scheduling policies can be nonpreemptive or preemptive and the latter can be preemptive resume or repeat.

Serialization Delays: The processing of certain phases of a job in computer systems is single-threaded so that only one of multiple job executing concurrently can proceed in the serialized phase, while other jobs are blocked.

Thrashing: A severe degradation in system performance, which may be due to unproductive processing, such as excessive paging in a virtual memory environment. In the case of standard locking, thrashing occurs when a large fraction of txns are blocked so that there is a significant drop in system throughput.

References to web pages occur in the order of their occurrence in the text, while other references are listed alphabetically according to the last name the first author and the year. Readers should attempt searches of their own with appropriate keywords since web pages may become unavailable over time. It is assumed that the reader has access to digital libraries to check referenced papers.

Further Information

Readers are expected to have access to digital libraries for the journals and conferences referenced in this paper. Given a background in elementary calculus, the interested reader should first study appropriate chapters in one of the following texts [42,143] to gain the necessary background in probability and stochastic processes. The reader can then proceed to read queueing theory texts such as [78,79]. We recommend a comprehensive textbook on performance modeling and analysis by Kobayashi and Mark [80a], which does not however cover some material in Kobayashi's early textbook [80], so that text is given as a reference.

Journals and conferences on systems and performance evaluation and analysis are reviewed in [137]. Conferences and journals sponsored by ACM: <http://www.acm.org>. IEEE: <http://www.ieee.org>. and its Computer Society: <http://www.computer.org>. and USENIX: <http://www.usenix.org>. There are large number of high quality publications on queueing theory: *Operations Research*, *Queueing Systems*, *Management Science*, *Naval Research Logistics*, etc.

Performance evaluation is covered by numerous conferences. ACM's *SIGMETRICS Conf. on Measurement and Modeling of Computer Systems* is held annually and together with the IFIP Working Group 7.3 Performance Conference every other year. ACM publishes the quarterly *Performance Evaluation Review (PER)*, which includes the proceedings of the SIGMETRICS Conf. and various workshops, such as *MAThematical performance Modeling and Analysis (MAMA)*. *Performance Evaluation* is a reviewed journal published since 1981 by Elsevier, which also publishes papers from the *Performance Conference*. The *Computer Performance* journal was published for several years by IPC Science and Technology Press until 1984. *Computer Systems: Science and Engineering* partially replaces *Computer Performance*, since 1986. <http://www.crlpublishing.co.uk/>.

IEEE's *Trans. on Computers*, *Trans. on Software Engineering*, and *Trans. on Parallel and Distributed Systems (TPDS)* publish papers dealing with computer performance analysis. ACM's *Trans. on Computer Systems (TOCS)* *Trans. on Storage Systems (TOS)*, *Trans. on Database Systems (TODS)*, *Trans. on Modeling and Computer Simulations (TOMACS)* are also relevant.

The *IEEE/ACM Int'l Symp. on Modeling, analysis and Simulation of Computer and Telecommunication Systems (MASCOTS)* is in its 20th year in 2012. The *Int'l Conf. on Quantitative Evaluation of Systems (QEST)* has been held in Europe since 2004 and is sponsored by the IEEE Computer Society. The Winter Simulation Conference <http://www.wintersim.org>. is held annually with multiple sponsors, such as: *American Statistical Association (ASA)*, <http://www.amstat.org>. ACM, IEEE's Man and Cybernetics Society (IEEE/SMC): <http://www.ieeesmc.org>. Institute for Operations Research and the Management Sciences: Simulation Society (INFORMS-SIM): <http://www.informs.org>. *National Institute of Standards (NIST)*: <http://www.nist.gov>. and the Society for Modeling and Simulation (SCS),

which also sponsors the *Int'l Symp. on Performance Evaluation of Computer and Telecommunication Systems (SPECTS)*. <http://www.scs.org>. The *Computer Measurement Group (CMG)*: <http://www.cmg.org>. holds an annual conference of interest to Information Technology professionals.

ACM's *Int'l Symp. on Computer Architecture (ISCA)* and USENIX's *File and Storage Technologies (FAST)* are two conferences with papers dealing with the performance of computer systems and storage systems, respectively. Database conferences such as SIGMOD, <http://www.sigmod.org>. *Very Large Data Bases (VLDB)*: <http://www.vldb.org>. and the *IEEE Int'l Conf. on Data Engineering (ICDE)* publish papers dealing with database performance. There is also the *VLDB Journal*.

The material in Section 56.8 is complementary to the Chapter on Concurrency Control and Recovery. The material in Section 56.7 on page replacement and buffer management is complementary to the Chapter on Operating Systems. This also applies the analysis of QNMs and measurement and simulation in Section 56.9.

57.1 Introduction

Scientists and practitioners are increasingly reliant on large amounts of computational resources to solve complicated problems and obtain results in a timely manner. To satisfy the demand for large computational resources, organizations build or utilize distributed computing systems.

A distributed computing system is essentially a set of computers that share their resources via a computer network and interact with each other toward achieving a common goal [31]. The shared resources in a distributed system include data, computational power, and storage capacity. The common goal can also range from running resource-intensive applications, tolerating faults in a server, and serving scalable Internet applications.

Distributed computing systems such as Clusters, Grids, and recently Clouds have become ubiquitous platforms for supporting resource-intensive and scalable applications. However, surge in demand is still a common problem in distributed systems [26] in a way that no single system (specially Clusters and Grids) can meet the needs of all users. Therefore, the notion of interconnected distributed computing systems has emerged.

In an interconnected distributed computing system, as depicted in Figure 57.1, organizations share their resources over the Internet and consequently are able to access larger resources. In fact,

FIGURE 57.1 Interconnected distributed computing systems.

interconnected distributed systems construct an overlay network on top of the Internet to facilitate resource sharing between the constituents.

However, there are concerns in interconnected distributed systems regarding contention between requests to access resources, low access level, security, and reliability. These concerns necessitate a resource management platform that encompasses these aspects. The way current platforms consider these concerns depends on the structure of the interconnected distributed system. In practice, interconnection of distributed systems can be achieved in different levels. These approaches are categorized in Figure 57.2 and explained over the following paragraphs.

- User level (Broker-based): Is useful for creating loosely coupled interconnected distributed systems. In this approach, users/organizations are interconnected through accessing multiple distributed systems. This approach involves repetitive efforts to develop interfaces for different distributed systems and, thus, scaling to many distributed systems is difficult. Gridway [103] and GridBus broker [104] are examples of broker-based interconnection approach. The former, achieves interconnection in organization level, whereas the latter, works in the enduser level.
- Resource level: In this approach, different interfaces are developed on the resource side and consequently the resource can be available to multiple distributed systems. This approach involves administration overhead, since the resource administrator has to be aware of well-known services. This approach is difficult to scale to many distributed systems, hence, it is suggested mostly for large distributed systems. Interconnection of EGEE, NorduGrid, and D-Grid is done based on

FIGURE 57.2 Interconnection mechanisms in distributed computing systems.

this approach [31]. Particularly, D-Grid [35] leverages interconnectivity via implementing interfaces of UNICORE, gLite, and Globus on each resource provider in a way that resources can be accessed by any of the middlewares.

- Platform level (Gateways): A third platform (usually called a gateway) handles the arrangements between distributed systems. Ideally, the gateway is transparent both from users and resources and makes the illusion of single system for the user. However, in this approach gateways are single point of failure and also a scalability bottleneck. InterGrid [26] and the interconnection of Naregi and EGEE [65] are instances of this approach.
- Standardization: Common and standard interfaces have been accepted as a comprehensive and sustainable solution for interconnecting distributed systems. However, current distributed systems (e.g., current Grid platforms) have already been developed based on different standards and it is a hard and long process to change them to a common standard interface. Issues regarding creating standards for interconnecting distributed systems are also known as interoperability of distributed systems.

UniGrid [88] is a large-scale interconnected distributed system implemented based on a standard and connects more than 30 sites in Taiwan. It offers a web interface that bridges the user and the lower-level middleware. The core of UniGrid orchestrates different middlewares, including Globus Toolkit [33], Condor [96], and Ganglia [80] transparently from the user. Another project that sought to achieve the idea of World Wide Grid through developing standards and service-oriented architecture is GRIP [25].

Grid computing is a prominent example of interconnected distributed systems. Grids are usually comprised of various organizations that share their resources (e.g., Clusters or SMPs) and form Virtual Organizations (VOs). The concept of Grid has specifically been fascinating for users/organizations that did not have huge resources available or did not have the budget to manage such resources. Nowadays, Grids are utilized predominantly in scientific communities to run high performance computing (HPC) applications. Over the last decade, variety of Grids have emerged based on different interconnection mechanisms. TeraGrid in the United States [102], DAS in the Netherlands [61], and Grid5000 in France [17] are such examples.

Generally, in an interconnected environment, requests from different sources co-exist and, therefore, these systems are prone to contention between different requests competing to access resources. There are various types of contentions that can occur in an interconnected distributed system and, accordingly, there are different ways to cope with these contentions.

The survey will help people in the research community and industry to understand the potential benefits of contention-aware resource management systems in distributed systems. For people unfamiliar with the field, it provides a general overview, as well as detailed case studies.

The rest of this chapter is organized as follows: In Section 57.2, an overview on resource management systems of interconnected distributed systems is presented. Next, in Section 57.3 contention in interconnected distributed systems is discussed which is followed by investigating the architectural models of the contention-aware resource management systems in Section 57.4. In Section 57.5, we discuss about different approaches for contention management in well-known interconnected distributed systems. Finally, conclusion and avenues of future works for researchers are provided in Section 57.6.

57.2 Request Management Systems

Interconnected distributed systems, normally, encounter various users and usage scenarios from users. For instance, the following usage scenarios are expectable:

- Scientists in a research organization run scientific simulations, which are in the form of long running batch jobs without specific deadlines.
- A corporate web site needs to be hosted for a long period of time with a guaranteed availability and low latency.
- A college instructor requires few resources at certain times every week for demonstration purposes.

In response to such diverse demands, interconnected distributed systems offer different service levels (also called multiple quality of service (QoS) levels).

For example, Amazon EC2* supports reserved (availability guaranteed), on-demand, and spot (best-effort) virtual machine (VM) instances. Offering a combination of advance-reservation and best-effort schemes [93], interactive and batch jobs [109], tight-deadline and loose-deadline jobs [37] are common practices in interconnected distributed systems.

These diverse service levels usually imply different prices and priorities for the services that have to be managed by the resource management system. Additionally, interconnected distributed systems can be aware of the origin of the requests and they may discriminate requests based on that. Another challenge in job management of interconnected distributed systems is managing accounting issues of sending/receiving requests to/from peer distributed systems.

There are many approaches for tackling these challenges in resource management systems of interconnected distributed systems. One common approach is prioritizing requests based on criteria, such as service (QoS) or origin. For example, in an interconnected distributed system usually local requests (i.e., local organizations' users) have priority over the requests from external users [5]. Another example is in urgent computing [15] (urgent applications), such as earthquake and bush-fire prediction applications where the applications intend to acquire many resources in an urgent manner. In circumstances that there is surge in demand, requests with different priorities compete to gain access to resources. This condition is generally known as resource contention between requests.

Resource contention is the main challenge in request management of interconnected distributed systems and occurs when a user request cannot be admitted or cannot receive adequate resources, because the resources are occupied by other (higher priority) requests.

In the remainder of this survey, we explore different aspects of resource contention in interconnected distributed systems and also we investigate the possible solutions for them.

57.3 Origins of Resource Contentions

There are various causes for resource contention in interconnected distributed systems. They broadly can be categorized as request-initiated, interdomain-initiated, origin-initiated and hybrid. A taxonomy of different contention types along with their solutions is shown in Figure 57.3.

57.3.1 Request-Initiated Resource Contention

Request-initiated resource contention occurs if any of the requests monopolizes resources to such an extent that deprives other requests from gaining access to them. It is prevalent in all forms of distributed systems, even where there is no interconnection. There are several scenarios that can potentially lead to request-initiated resource contention. One important situation is when there is an imbalance in request sizes, mainly, in terms of required number of nodes or execution time (duration). In this circumstance, small requests may have to wait for a long time behind a long job to access resources.

Another cause for request-initiated resource contention is situation that requests have QoS constraints and they selfishly try to satisfy them. Generally, resource management systems can support three types of QoS requirements for users' requests:

1. Hard QoS: Where the QoS constraints cannot be negotiated. These systems are prone to QoS violation and, hence, managing resource contention is critical [73].
2. Soft QoS: Where the QoS constraints are flexible and can be negotiated based upon the resource availabilities or when there is a surge in demand. The flexibility enables resource management systems to apply diverse resource contention solutions [73].

* <http://aws.amazon.com/ec2/>

FIGURE 57.3 Taxonomy of different types of resource contentions and possible solutions in interconnected distributed computing systems.

3. Hybrid QoS: Where the resource management system supports a combination of Hard QoS and Soft QoS requirements for the user requests. This fashion is common in commercial resource providers such as Cloud providers. For instance, Amazon EC2 supports services with distinct QoS requirements including reserved (hard QoS), and spot (soft QoS) VM instances. Another example, are the resource management systems that support combination of interactive (hard QoS) and batch requests (usually soft QoS) [109].

Solutions for managing request-initiated contentions are mostly achieved in the context of scheduling and/or admission control units of resource management systems. Over the next paragraphs, we categorize and describe different solutions for resource contention.

Differentiated services (DiffServ) technique that initially was used in Computer Networks and developed to guarantee different QoS levels (with different priorities) for various Internet services, such as VOIP and web. In Computer Networks, DiffServ guarantees different QoSs through dividing the services into distinct QoS levels. According to IETF RFC 2474, each level is supported by dropping TCP packets of lower priority levels.

Similar approach can be taken in the context of request-initiated resource contentions in distributed systems. For this purpose, the resource management system presents different QoS levels for user requests. Then, requests are classified in one of these levels at the admission time. However, in this scheme there is no control on the number of requests assigned to each QoS level. As a result, QoS requirements of request cannot be guaranteed. Therefore, DiffServ scheme is appropriate for soft QoS requirements.

Variations of DiffServ technique can be applied when contention occurs due to imbalanced requests. Silberstein et al. [89] also sought to decrease the response time of short requests in a multigrid environment. For that purpose, they apply a multilevel feedback queue (MLFQ) scheduling. In their policy, Grids are placed in different categories based on their response speed. Requests are all sent to the first queue upon arrival and if they cannot get completed in the time limit of that level, then they are migrated to the lower level queue which is a larger grid. The process continues up until the task finishes or reaches down the hierarchy.

In the *Partitioning scheme*, the resources are reserved for requests with different QoS levels. Unlike DiffServ scheme, in this approach boundaries of the reservations (partitions) can adaptively

move, based on the demand in different QoS levels. This solution can also be considered as a type of DiffServ that is suitable for requests with hard QoS requirements.

Economic scheme solutions either work in an auction-based or utility-based manner. In the former, both resource provider and resource consumer have their own agents. Through an auctioneer the consumer bids on the resources and also provides a valuation function. Then, the provider agent tries to maximize the utility based on the valuation function and comes up with a set of resources for the user. In the latter, a utility function that generally reflects the revenue earned by running a request is calculated for all contentious requests. Then, the request that maximizes the utility function has the priority of accessing resources. These approaches are commonly applied in market-oriented scheduling [36].

Fair scheme that guarantees contentious requests receive their share of the system resources [3]. This scheme is used to resolve resource contentions resulting from imbalanced requests in the system and assures starvation-free scheduling of the requests.

Outsourcing scheme: Interconnection of distributed systems creates the opportunity to employ resources from other distributed systems in the case of resource contention. Outsourcing is applied for both causes of request-initiated resource contention (i.e., request imbalance and QoS levels). Specially, Cloud providers have been extensively employed for outsourcing requests [84]. This issue has helped in emergence of hybrid clouds, which are a combination of a private (organizational) resources and public Clouds [12]. Although we categorize outsourcing as a resolution for request-initiated contentions, it can be applied for interdomain and origin initiated contentions as will be discussed in the next parts.

57.3.2 Interdomain-Initiated Resource Contention

Interdomain-initiated resource contention occurs, when the proportion of shared resources to the consumed resources by a constituent distributed system is low. In other words, this resource contention happens when a resource provider contributes few resources while demand more resources from other resource providers in an interconnected distributed system. Unlike request-initiated contention, which merely roots in request characteristics and can take place in any distributed system, interdomain contention is based on the overall consumption and contribution of each resource provider.

There are several approaches for handling interdomain-initiated contentions, namely, global scheduling, incentive, and token-based schemes (see Figure 57.3). These approaches are discussed in detail in what follows .

Global schedulers: In this approach, which is appropriate for large-scale distributed systems, there are local (domain) schedulers and global (meta) schedulers. Global schedulers are in charge of routing user requests to local schedulers and, ultimately, local schedulers, such as Condor [96] or Sun Grid Engine (SGE) [16], allocate resources to the requests.

Global schedulers can manage the interdomain resource contention by admitting requests from different organizations based on the number of requests it has redirected to the resources of each organization. Since global schedulers usually are not aware of the instantaneous load condition in the local schedulers, it is difficult for them to guarantee QoS requirements of users [11]. Thus, this approach is useful for circumstances where requests have soft QoS requirements.

Incentive scheme: In this approach, which is mostly used in peer-to-peer systems [71], resource providers are encouraged to share resources to be able to access more resources. Reputation Index Scheme [58] is a type of incentive-based approach in which the organization cannot submit requests to another organization while it has less reputation than that organization. Therefore, in order to gain reputation, organizations are motivated to contribute more resources to the interdomain sharing environment.

Quality service incentive scheme [70] is a famous type of incentive-based approach. Quality service is an extension of Reputation Index Scheme. The difference is that depending on the number of QoS levels offered by a participant, a set of distinct ratings is presented where each level has its own reputation index.

Token-based scheme: Operates based on the principle where a certain amount of tokens, which are allocated to an organization, is proportional to its resource contribution. If a user wants to get access to another organization resources, its consumer agent must spend amount of tokens to get the access. This scheme encompasses request-initiated and interdomain resource contentions. To address the request-initiated resource contention, valuation functions can be used to translate the QoS demands of user to the number of tokens to be used for a request. The provider agent can then use its own valuation functions to compute the admission price for the request. Finally, the request will be admitted only if the admission price is less or equal to the number of tokens that the requesting organization is willing to pay [73].

57.3.3 Origin-Initiated Resource Contention

In interconnected distributed systems, users' requests originate from distinct organizations. More importantly, these systems are prone to resource contention between local requests of the organization and requests from other organizations (i.e., external requests). Typically, local requests of each organization have priority over external requests [5]. In other words, the organization that owns the resources would like to ensure that its community has priority access to the resources. Under such a circumstance, external requests are welcome to use resources if they are available. Nonetheless, external requests should not delay the execution of local requests.

In fact, origin-initiated resource contention is a specific case of interdomain-initiated and request-initiated resource contentions. Consequently, the approaches of tackling this type of resource contention is similar to the already mentioned approaches. Particularly, partitioning approach both in static and dynamic forms and global scheduling are applicable for origin-initiated resource contentions. There are also other approaches to cope with origin-initiated contentions that we discuss in this part.

Preemption scheme: This mechanism stops the running request and free the resources for another, possibly higher priority, or urgent request. The higher priority request can be a local request or a hard QoS request in an interconnected distributed system. The preempted request may be able to resume its execution from the preempted point. If suspension is not supported in a system, then the preempted request can be killed (canceled) or restarted. For parallel requests, *full preemption* usually is performed, in which whole request leaves the resources. However, some systems support *partial preemption*, in which part of resources allocated to a parallel request is preempted [86].

Although preemption mechanism is a common solution for origin-initiated contentions, it is also widely applied to solve request-initiated resource contentions. Due to the prominent role of preemption in resolving these types of resource contentions, in Section 57.4.5 we explain preemption in details.

Partitioning scheme: Both static and dynamic partitioning of resources, as mentioned in Section 57.3.1, can be applied to tackle origin-initiated contentions.

In dynamic partitioning of resources, the local and external partitions can borrow resources from each other when there is a high demand of local or external requests [11].

Several queues: In this approach when requests arrive [59], they are categorized in distinct queues, based on their origin. Each queue can independently have its own scheduling policy. Then, another scheduling policy determines the appropriate queue that can dispatch a request to the resources.

Combinations of the aforementioned contentions (mentioned as hybrid in Figure 57.3) can occur in an interconnected distributed system. The most common combination is the origin-initiated and request-initiated resource contentions. For instance, in federated Grids and federated Clouds, origin-initiated contention occurs between local and external requests. At the same time, external and local requests can also have distinct QoS levels, which is a request-initiated resource contention [5,6,81]. Generally, Resolution of hybrid resource contentions is a combination of different strategies mentioned earlier.

57.4 Contention Management

Resource management system is the main component of a distributed system that is responsible for resolving resource contentions. Various elements of a resource management system contribute in resolving different types of resource contentions. They apply different approaches in managing contentions. Different components of resource management systems and the way they deal with resource contention is presented in Figure 57.4.

57.4.1 Resource Provisioning

Resource provisioning component of a resource management system is in charge of procuring resources based on user application requirements. Resource provisioning is performed based on a provisioning model that defines the execution unit in a system. In fact, requests are allocated resources based on the resource provisioning model.

Resource provisioning models do not directly deal with resource contentions. However, the way other components of resource management system function strongly depends on the resource provisioning model.

Provisioning resources for users' requests in distributed systems has three dimensions as follows:

1. Hardware resources
2. Software available on the resources
3. Time during which the resources are available (availability)

Satisfying all of these dimensions in a resource provisioning model has been challenging. In practice, past resource provisioning models in distributed systems were unable to fulfill all of these dimensions [93]. Emergence of virtual machine (VM) technology as a resource provisioning model recently has posed an opportunity to address all of these dimensions. Over the next subsections, we discuss common resource provisioning models in current distributed systems.

57.4.1.1 Job Model

In this model, jobs are pushed or pulled across different schedulers in the system to reach the destination node, where they can run. In job-based systems, scheduling a job is the consequence of a request to run

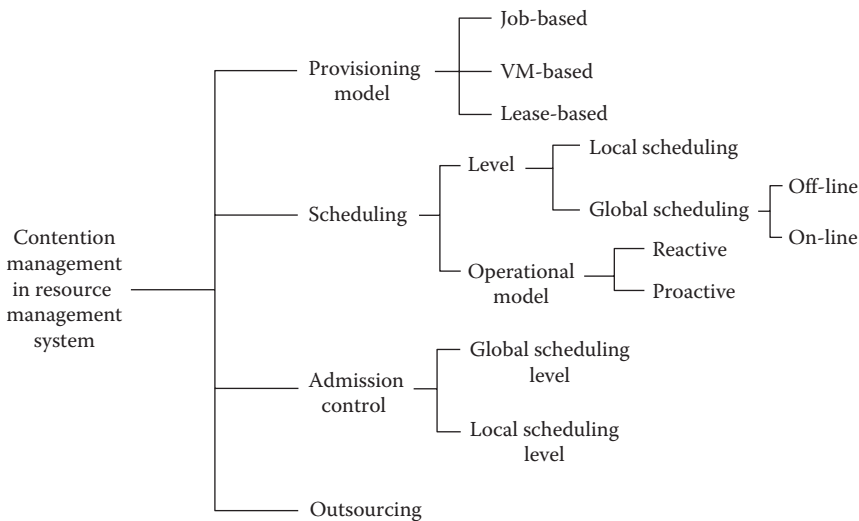

FIGURE 57.4 Components of a resource management system and their approach for dealing with contentions.

the job. Job model resource provisioning has been widely employed in distributed systems. However, this model cannot perfectly support all resource contention solutions.

Job-based systems provision hardware for jobs while they offer a limited support for software availability. In fact, in job-based model users do not have root access, therefore it is difficult to install and use required software packages. Many job-based systems support availability based on queuing theory along with scheduling algorithms. However, queue-based systems usually do not assure specific time availabilities.

To support availability and hardware dimensions, Nurmi et al. [68], present advance reservation (AR) model over the job-based provisioning model. They support AR through predicting waiting time of jobs in the queue. Hovestadt et al. [45] propose plan-based scheduling (opposite to queue-based) that finds the place of each job (instead of waiting in the queue) to be able to support AR model. In this system, on the arrival of each job the whole schedule is re-planned to optimize the resource utilization.

Falkon [75], Condor glidin [34], MyCluster [108], and Virtual Workspace [53] have applied a multilevel/hierarchical scheduling on top of a job-based system to offer other provisioning models (such as lease-based model, which is described in Section 57.4.1.3). In these systems, one scheduler allocates resources to another scheduler and the other scheduler runs the jobs on the allocated resources.

57.4.1.2 Virtual Machine Model

Virtual machines (VMs) are considered as an ideal vehicle for resource provisioning in distributed systems. The reason is that, in VM model, unlike the job model, hardware, software, and availability can be provisioned for user requests. Additionally, VMs' capability in getting suspended, resumed, or migrated without major utilization loss have proved to be useful in resource management. Therefore, VM-based provisioning model is commonly used in current distributed systems.

The VM-based resource provisioning model is used in creating virtual Clusters on top of an existing infrastructure. Virtual clusters (VC) are usually utilized for job-based batch processing. For example, in MOSIX [13], Clusters of VMs are transparently created to run high performance computing (HPC) applications. The Nimbus toolkit [52] provides "one-click virtual Cluster" automatically on heterogeneous sites through contextualizing disk images. Amazon EC2, provides VM-based Cluster instances* that offer supercomputing services to expedite execution of HPC applications, without delaying the user in a queue or acquire expensive hardware. Automatic VM creation and configuration in short time is also considered in In-VIGO [2] and VMplants [56]. An extension of Moab [29] creates VM-based virtual Clusters to run HPC batch applications.

Many commercial datacenters use VM-based provisioning model to provide their services to resource consumers. Such datacenters offer services such as Virtual Cluster, or hosting servers including web, email, and DNS.

Datacenters usually contain large scale computing and storage resources (order of 100s–1000s) and consume so much energy. A remarkable benefit of deploying VM-based provisioning model in datacenters is the consolidation feature of VMs that can potentially saves the energy consumption [105]. However, VM consolidation requires accurate workload prediction in the datacenters. Moreover, the consolidation impact on service level agreements (SLA) needs to be considered. VM consolidation can be performed in a static (also termed cold consolidation) or dynamic (hot consolidation) manner. In the former, VMs needs to be suspended and resumed on another resource that involves time overhead. In the latter approach, live migration [107] of VMs is used, thus, is transparent from the user.

Solutions such as VMware, Orchestrator, Enomalism, and OpenNebula [32] provide resource management for VM-based data centers.

There are also concerns in deploying VM-based provisioning model and Virtual Clusters. Networking and load balancing among physical Clusters is one of the challenges that is considered in Vio-Cluster [79]. Power efficiency aspect and effectively utilizing VMs capability in suspending and migrating are also

* <http://aws.amazon.com/hpc-applications/>

considered by many researchers [51,66,106]. Overhead and performance issues involved in applying VMs to run compute-intensive and IO-intensive jobs, fault tolerance, and security aspects of VMs are also of special importance in deploying VM-based provisioning model.

57.4.1.3 Lease Model

This model is considered as an abstraction for utility computing in which the user is granted a set of resources for specific interval and agreed quality of service [39]. In this model, job execution is independent from resource allocation, whereas in the job model resource allocation is the consequence of running a job.

Formally, a *lease* is defined by Sotomayor [93] as “a negotiated and renegotiable contract between a resource provider and a resource consumer, where the former agrees to make a set of resources available to the latter, based on a set of lease terms presented by the resource consumer.” If lease extension is supported by resource management system, then users would be able to extend their lease for a longer time. This is particularly useful in circumstances that users have inaccurate estimation of required time. Virtual machines are suitable vehicles to implement lease-based model. Depending on the contract, resource procurement for leases can be achieved from a single provider or from multiple providers.

57.4.2 Scheduling Unit

The way user requests are scheduled in an interconnected distributed system affects types of resource contentions occurring. Efficient scheduling decisions can prevent resource contention or reduce its impact whereas poor scheduling decisions can lead to more resource contentions.

In an interconnected distributed system, we can recognize two levels of scheduling, namely, local (domain level) scheduling and global scheduling (meta-scheduling). The global scheduler is generally in charge of assigning incoming requests to resource providers within its domain (e.g., Clusters or sites). In the next step, the local scheduler performs further tuning to run the assigned requests efficiently on resources.

From the resource contention perspective, scheduling methods can either react to resource contention or proactively prevent the resource contention to occur.

57.4.2.1 Local Scheduling

Local scheduler deals with scheduling requests within each distributed system (e.g., Cluster or site). Scheduling policies in this level can mainly deal with request-initiated and origin-initiated contentions. Indeed, there are few local schedulers that handle interdomain-initiated contention.

Backfilling is a common scheduling policy in local resource management systems (LRMS). The aims of backfilling are increasing resource utilization, minimizing average request response time, and reducing queuing fragmentation. In fact, backfilling is an improved version of FCFS in which requests that arrive later, possibly are allocated earlier in the queue, if there is enough space for them. Variations of backfilling policy are applied in local schedulers:

- Conservative: In which a request can be brought forward if it does not delay any other request in the queue.
- Aggressive (EASY): The reservation of the first element in the queue cannot be postponed. However, the arriving request can shift the rest of scheduled requests.
- Selective: If the slowdown of a scheduled request exceeds a threshold, then it is given a reservation, which cannot be altered by other arriving requests.

There are also variations of backfilling method that are specifically designed to resolve request-initiated resource contentions. Snell et al. [91] applied preemption on backfilling policy. They provide policies to select the set of requests for preemption in a way that the requests with higher

priority are satisfied and, at the same time, the resource utilization increases. The preempted request is restarted and rescheduled in the next available time slot.

Multiple resource partitioning is another scheduling approach for local schedulers by Lawson and Smirni [59]. In this approach, resources are divided into partitions that potentially can borrow resources from each other. Each partition has its own scheduling scheme. For example, if each partition uses EASY backfilling, then one request from another QoS level can borrow resources, if it does not delay the pivot request of that partition.

In FCFS or backfilling scheduling policies, the start time of a request is not predictable (not determined). Nonetheless, in practice, we need to guarantee timely access to resources for some requests (e.g., deadline-constraint requests in a QoS-based system). Therefore, many local schedulers support Advance Reservation (AR) allocation model that guarantees resource availability for a requested time period. Resource management systems such as LSF, PBSPRO, and MAUI support AR.

Advance Reservation is prone to low-resource utilization specially if the reserved resources are not used by the users. Additionally, it increases the response time of normal requests [63,90]. These side-effects of AR can be minimized by limiting the number of AR, and leveraging flexible AR (in terms of start time, duration, or number of processing elements needed).

57.4.2.2 Global Scheduling (Meta-Scheduling)

Global scheduler in an interconnected distributed system usually has two aspects. On the one hand, the scheduler is in charge of assigning incoming requests to resource providers within its domain (e.g., Clusters). On the other hand, it is responsible to deal with other distributed systems such as schedulers or gateways that delegate other peer distributed systems. This aspect of global schedulers can particularly resolve interdomain-initiated and origin-initiated resource contentions.

The global scheduler either works off-line (i.e., batches incoming requests and assigns each batch to a Cluster), or is online (i.e., assign each request to a local scheduler as it is received). The global schedulers can proactively prevent resource contentions.

57.4.3 Admission Control Unit

Controlling the admission of requests prevents the imbalanced deployment of resources. By employing an appropriate admission control policy different types of resource contentions can be avoided. An example of the situation without admission control in place is when two requests share a resource but one of them demands more time. In this situation, the other request will face low-resource availability and subsequently, high response time. Thus, lack of admission control can potentially lead to request-initiated contention.

Admission control behavior should depend on the workload condition in a resource provider. Applying a strict admission control in a lightly loaded system results in low resource utilization and high rejection of requests. Nonetheless, the consequence of applying less strict admission control in a heavily loaded resource is more QoS violation and less user satisfaction [112].

Admission control can function in different ways. To tackle request-initiated contention, admission control commonly carried out via introducing a valuation function. The valuation function relates the quality constrains of users to a single quantitative value. The value indicates the amount a user is willing to pay for a given quality of service (QoS). Resource management system use the valuation functions to allocate resources with the aim of maximizing aggregate valuation of all users.

Admission control also can be applied in interdomain-initiated contentions to limit the amount of admitted requests of each organization to be proportional to their resource contribution. Similarly, admission control can be applied to avoid origin-initiated resource contention. For this purpose, admission control policy would not admit external requests where there is peak load of local requests.

Placement of admission control component in a resource management system of a interconnected distributed system can be behind the local scheduler and/or behind the global scheduler. In the former, for rejecting a request there should be an alternative policy to manage the rejected request. In fact, rejecting by

a local scheduler implies that the request has already been admitted and, hence, has to be taken care. For instance, the rejected request can be redirected to another resource provider or even queued in a separate queue to be scheduled later. Deploying admission control behind the global scheduler is easier in terms of managing the rejected requests. However, the drawback of employing admission control with global scheduler is that the global scheduler may not have updated information about site's workload situation.

57.4.4 Outsourcing Unit

Interconnectivity of distributed systems creates the opportunity to resolve the resource contention via employing resources from other distributed systems. Therefore, resource management systems in interconnected distributed computing systems usually have a unit that decides about details of outsourcing requests (i.e., redirecting arriving requests to other distributed systems) such as when to outsource and which requests should be outsourced. In terms of implementation, in many systems, the outsourcing unit is incorporated into either admission control or scheduling unit. However, it is also possible to have it as an independent unit in the resource management system.

Outsourcing is generally applied when there is a peak demand or there is a resource contention (specially request-initiated contention). In this situation to serve requests without resource contention, some requests (e.g., starved requests) are selected to be redirected to other distributed systems.

Cloud computing providers have been of special interest to be employed for outsourcing (off-loading) requests [84]. This issue has pushed the emergence of hybrid clouds, which are a combination of a private (organizational) Cloud and public Clouds.

57.4.5 Preemption Mechanism

Preemption mechanism in a resource management system makes the resources free and available for another, possibly higher priority, request. Preemption is a useful mechanism to resolve request-initiated and origin-initiated contentions. Preemption of a running process can be performed manually or automatically through the resource management system.

The way preemption mechanism is implemented, depends on the way checkpointing operation is carried out. If the checkpointing is not supported, then the preempted process has to be killed and restarted at a later time. If checkpointing is supported (both by the running process and by the scheduler), then the preempted request can be suspended and resumed at a later time. However, checkpointing is not a trivial task in distributed systems. We will deal with checkpointing hurdles in Section 57.4.5.4.

Due to the critical role of preemption in solving different types resource contentions, in this section, we investigate preemption in distributed systems from different angles. Particularly, we consider various usages of preemption and the way they solve resource contentions. Then, we investigate possible side-effects of preemption. Finally, we discuss how a preempted request (i.e., job/VM/lease) can be resumed in a distributed system.

57.4.5.1 Applications of Preemption Mechanism

Preemption in distributed systems can be applied for reasons that are presented in Figure 57.5. As we can see, preemptions can be used to resolve resource contention. However, there are other usages of preemption in distributed systems that we will discuss them in this part.

Preemption is used to resolve request-initiated resource contentions. One approach is employing preemption in local scheduler along with the scheduling policy (e.g., backfilling) to prevent unfairness. For instance, when a backfilled request exceeds the allocated time slot and interferes with the reservation of other requests preemption mechanism can preempt the backfilled requests and therefore the reservations can be served on time. The preempted request can be allocated another time slot to finish its computation [40].

A preemptive scheduling algorithm is implemented in MOSIX [4] to allocate excess (unclaimed) resources to users that require more resources than their share. However, these resources will be released

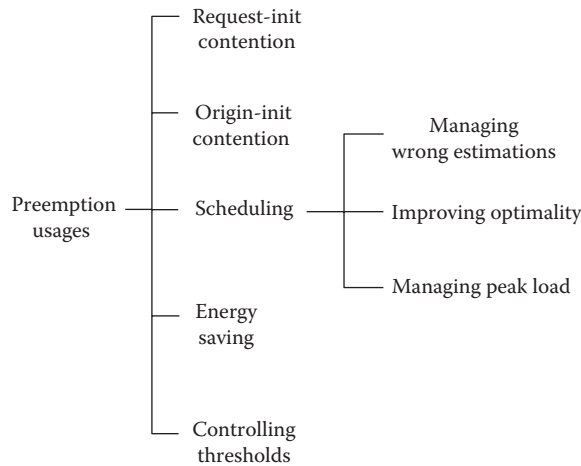

FIGURE 57.5 Different usages of preemption in distributed systems.

as soon as they are reclaimed. MOSIX also support situation that there are local and guest jobs and can consider priority between them (origin-initiated contention).

Scojo-PECT [92] provides a limited response time for several job classes within a virtualized Cluster. It employs DiffServ solution that is implemented via coarse-grained preemption to cope with the request-initiated resource contention. The preemptive scheduler aims at creating a fair-share scheduling between different job classes of a Grid. The scheduler works based on a coarse-grained time sharing and for preemption it suspends VMs on the disk.

Walters et al. [109] introduced a preemption-based scheduling policy for batch and interactive jobs within a virtualized Cluster. In this work, batch jobs are preempted in favor of interactive jobs. The authors introduce different challenges in preempting jobs including selecting a proper job to be preempted, checkpointing the preempted job, VM provisioning, and resuming the preempted job. Their preemption policy is based on weighted summation of factors such as the time spent in the queue.

Haizea [93] is a lease scheduler that schedules a combination of advanced reservation and best effort leases. Haizea preempts best effort leases in favor of advance reservation requests. Haizea also considers the overhead time imposed by preempting a lease (suspending and resuming included VMs).

Preemption of parallel jobs has also been implemented in the Catalina job scheduler [63] in San-Diego Supercomputer Center (SDSC). They have added preemption to conservative backfilling. The job preemption is carried out based on job priorities which is determined based on weighted summation of factors such as the time a request waits in the queue, the size (number of processing elements) required by the request, and expansion factor of the request. In general, the policy tries to preempt jobs that require fewer processing elements because they impose less overhead to the system for preemption. In fact, preempting jobs with larger size (wide jobs) implies more overhead because of the time needed for saving messages between nodes.

Isard et al. [49] have investigated the problem of optimal scheduling for data intensive applications, such as Map-Reduce, on the Clusters where the computing and storage resources are close together. To achieve the optimal resource allocation, their scheduling policy preempts the currently running job in order to maintain data locality for a new job.

Preemption can be applied to resolve the origin-initiated resource contentions. Ren et al. [76] have proposed a prediction method for unavailable periods in fine-grained cycle sharing systems where there are mixture of local jobs and global (guest) jobs. The prediction is used to allocate global requests in a way that do not disturb local requests.

Gong et al. [38] have considered preemption of external tasks in favor of local tasks in a Network of Workstations (NOW) where local tasks have preemptive priority over external tasks. They provided a performance model to work out the run time of an external task that is getting preempted by

local tasks in a single processor. The performance model also covers the average runtime of the whole external job which is distributed over NOW.

There are other research works such as [5,6,81,82] that apply preemption for removing origin-initiated contentions.

Apart from removing resource contention, preemption has other usages in resource management systems. More importantly, preemption can be applied to improve the quality of scheduling policies. In fact, preemption can be used as a tool by scheduler to enforce its policy.

Scheduling algorithms in distributed systems are highly dependent on user runtime estimation. There are studies (e.g., [99]) that demonstrate the inefficiency of these estimations and how these wrong estimation can compromise the scheduling performance. In the presence of inaccurate estimations, preemption can be deployed to help the scheduler in enforcing its decision through preempting the process that has wrong estimations. Particularly, this is critical for systems that support strict reservation model such as advanced reservation. In this situation, preemption abstracts the scheduling policy from the obstacles in enforcing that policy [44].

Preemption can be applied to improve the optimality of resource scheduling. Specifically, online scheduling policies are usually not optimal because jobs are constantly arriving over time and the scheduler does not have a perfect knowledge about them [4]. Therefore, preemption can potentially mitigate the nonoptimality of the scheduling policy.

Preemption mechanism can be employed for managing peak load. In these systems, resource-intensive applications or batch applications are preempted to free the resources during the peak time. Accordingly, when the system is not busy and the load is low, the preempted requests can be resumed [69].

Preemption can be employed to improve the system and/or user centric criteria, such as resource utilization and average response time. Kettimuthu et al. [54] have focused on the impact of preempting parallel jobs in supercomputers for improving the average and worst-case slowdown of jobs. They suggest a preemption policy, called *Selective Suspension*, where an idle job can preempt a running job if the suspension factor is adequately more than the running job.

A recent application of preemption is in energy conservation in datacenters. In fact, one prominent approach in energy conservation of virtualized datacenters is VM consolidation, which takes place when resources in the datacenter are not utilized efficiently. In VM consolidation, VMs running on under-utilized resources are preempted (suspended) and resumed on other resources. VM consolidation can also occur through live migration of VMs [107] to minimize the unavailability time of the VMs. When a resource is evacuated, it can be powered off to reduce the energy consumption of the datacenter.

Salahi et al. [83] have applied VM preemption to save energy in a datacenter that supports requests with different SLAs and priorities. They introduce an energy management component for Haizea [93] that determines how resources should be allocated for a high-priority request. The allocation can be carried out through preempting lower-priority requests or reactivating powered off resources. The energy management component can also decide about VM consolidation, in circumstances that powered on resources are not being utilized efficiently.

Preemption can be used for controlling administrative (predetermined) thresholds. The thresholds can be configured on any of the available metrics. For instance, the temperature threshold for CPUs can be established that leads to the system automatically preempts part of the load and reschedule on other available nodes. Bright Cluster Manager [1] is a commercial Cluster resource management system that offers the ability to establish preemption rules by defining metrics and thresholds.

57.4.5.2 Preemption Challenges

Operating systems of single processor computers have been applying preemption mechanism for a long time to offer interactivity to the end-user. However, since interactive requests are not prevalent in distributed systems, there has been less demand for preemption in these systems. More importantly, achieving preemption in distributed systems entails challenges that discourage researchers to investigate deeply on that. This challenges are different based on the resource provisioning model.

TABLE 57.1 Preemption Challenges in Different Resource Provisioning Models

Challenge	Resource Provisioning Model		
	Job-Based	VM-Based	Lease-Based
Coordination	✓	✓	✓
Security	✓	×	×
Checkpointing	✓	×	×
Time overhead	✓	✓	✓
Permission	✓	✓	×
Impact on queue	✓	✓	✓
Starvation	✓	✓	✓
Preemption candidates	✓	✓	✓

In this part, we present the detailed list of challenges that distributed systems encounter in preempting requests in various resource provisioning models. Moreover, a summary of preemption challenges based on different provisioning models is provided in Table 57.1.

- *Coordination*: Distributed requests (jobs/VMs/leases) are scattered on several nodes by nature. Preemption of the distributed requests have to be coordinated between the nodes that are executing them. Lack of such coordination leads to inconsistent situation (e.g., because of message loss) for the running request.
- *Security*: Preemption in job-based systems implies security concerns regarding files that remain open and swapping-in the memory contents before job resumption. In other words, in job-based systems operating system has to provide the security of not accessing files and data of the preempted processes. Since VM- and lease-based systems are self-contained (isolated) by nature, there is not usually security concern in their preemption.
- *Checkpointing*: Lack of checkpointing facilities is a substantial challenge in job-based resource provisioning model. Because of this problem, in job-based systems the preempted job is generally killed, which is a waste of resources [91]. Checkpointing problem is obviated in VM and lease-based resource provisioning models [94]. Due to the fundamental role of checkpointing for preemption mechanism, in Section 57.4.5.4 we discuss it in details.
- *Time overhead*: In VM- and lease-based resource provisioning models, time overhead imposed to the system to perform preemption is a major challenge. If preemption takes place frequently and the time overhead would not be negligible, then the resource utilization will be affected.

Additionally, disregarding the preemption time overhead in scheduling, prevents requests to start at the scheduled time [94]. In practice, resource management systems that support preemption, must have an accurate estimation of the preemption time overhead. Overestimating the preemption time overhead results in idling resources. However, underestimating the preemption time overhead ends up in starting leases with delay, which subsequently might violate SLA agreements.

Sotomayor et al. [94] have presented a model to predict the preemption time overhead for VMs. They identified that the size of memory that should be de-allocated, number of VMs mapped to each physical node, local or global memory used for allocating VMs, and the delay related to commands being enacted are effective on the time overhead of preempting VMs. To decrease the preemption overhead, the number of preemptions that take place in the system has to be reduced [87].

- *Permission*: In the lease-based resource provisioning model, preempting leases is not allowed by default. In fact, one difference between lease-based and other resource provisioning models is that jobs and VMs can be preempted without notifying the user (requester), whereas leases require the requester's permission for preemption [39]. Therefore, there must be regulations in the lease

terms to make lease preemption possible. These terms can be in the form of QoS constraints of the requests or can be bound to pricing schemes. For instance, requests with tight deadline, advance reservations, or requests with tight security possibly choose to pay more instead of getting preempted while they are running.

- *Impact on other requests:* Most of the current distributed systems use a variation of backfilling policy as the scheduling policy. In backfilling, future resource availabilities are reserved for other requests that are waiting in the queue. Preempting the running process and allocating resources to a new request affects the running job/lease as well as the reservations waiting in the queue. Re-scheduling of the preempted requests in addition to the affected reservations are side-effects of preemption in distributed systems.
- *Starvation:* Preemption leads to increasing the response time and, in the worst case, starvation for low-priority requests [5]. There is a possibility that low-priority requests get preempted as soon as they start running. This leads to unpredictable waiting time and unstable situation for low-priority requests. Efficient scheduling policies can prevent unstable and long waiting time situation. One approach to cope with the starvation challenge is restricting the number of requests admitted in a distributed system. Salehi et al. [82] have proposed a probabilistic admission control policy that restricts the queue length for low-priority requests in a way that they would not suffer from starvation.
- *Preemption candidates:* By allowing preemption in a distributed system, there is a possibility that several low priority requests have to be preempted to make sufficient vacant resources for the high-priority request. Therefore, there are several sets of candidate requests whose preemption can create adequate space for the high-priority request. As it is expressed in Figure 57.6, there are several candidate sets (Figure 57.6b) that their preemption can vacate resources for the required time interval (i.e., from t_1 to t_2 as indicated in Figure 57.6a).

Selecting distinct candidate sets affects the amount of unused space (also termed scheduling fragment) appear in the schedule. Furthermore, preempting different candidate sets imposes different time overhead to the system because of the nature of the requests preempted (e.g., being data-intensive). In this situation, choosing the optimal set of requests for preemption is a challenge that needs to be addressed.

To cope with this challenge, backfilling policy has been extended with preemption ability in Maui scheduler [91] to utilize scheduling fragments. Salehi et al. [5] have proposed a preemption policy that determines the best set of leases to be preempted with the objective of minimizing preemption

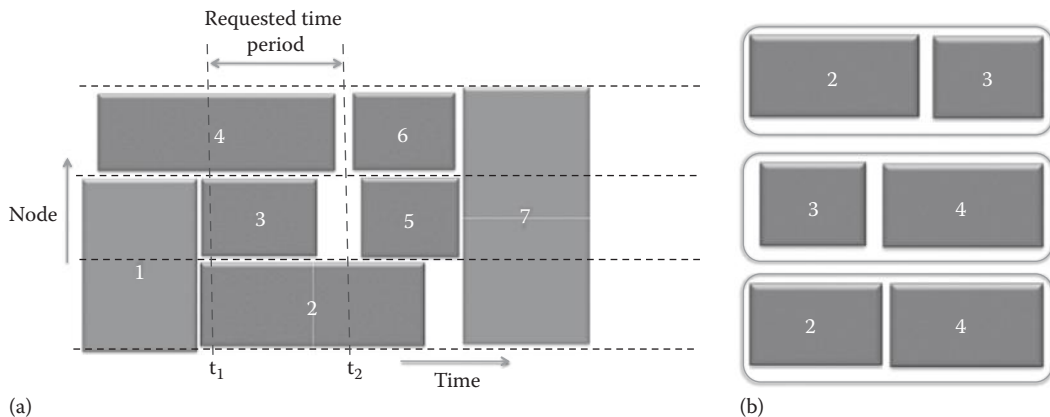

FIGURE 57.6 Preemption candidates for a request that needs two nodes. (a) Shows collision of the requested time interval with running requests within a scheduling queue. (b) Presents three different candidate sets that preempting any of them creates the required space for the new request.

time overhead. A preemption policy is also presented by Walter et al. [109] in a VM-based system with the objective of avoiding starvation for batch requests where a combination of batch and interactive requests co-exist in the system.

57.4.5.3 Possibilities for Preempted Requests

Issues discussed thus far are related to preemption mechanism and its challenges. However, making a proper decision for the preempted request is also important. This decision depends on the facilities provided by the resource management system of a distributed system. For example, migration is one choice that is viable in some distributed systems but not in all of them.

Thanks to the flexibility offered by deploying VM-based resource provisioning models, resource managers are capable of considering various possibilities for the preempted request. Nonetheless, in job-based systems, if preemption is possible, the possible action on the preempted job is usually limited to killing or suspending and resuming of the preempted job. Over the next paragraphs, we introduce various cases that can possibly happen for preempted VMs/leases. Additionally, in Figure 57.7 it is expressed that how different possibilities for the preempted VM affect the VMs' life cycle.

- *Cancelling*: VMs can be canceled (terminated) with/without notifying the request owner. VMs offered in this fashion are suitable for situation that the resource provider does not have to guarantee the availability of the resources for a specific duration. Spot instances offered by Amazon EC2 is an example of cancelling VMs. Isard et al. [49] have used cancelling VMs to execute map-reduce requests. Cancelling VMs imposes the minimum overhead time that is related to the time needed to terminate VMs allocated to the request.

In job-based systems, cancelling (killing) jobs is a common practice [91] because of the difficulty of performing other possible actions.

- *Restarting*: In both job-based and VM-based systems, the preempted request can be killed (similar to cancelling) and restarted either on the same resource or on another resource. The disadvantage of this choice is losing the preliminary results and wasting the computational power. Restarting can be applied for best-effort and deadline-constraint requests. In the former, restarting can be performed at any time whereas, in the latter, deadline of the request has to be taken into account for restarting.

FIGURE 57.7 VM life cycle by considering different possible preemption decisions in a resource management system.

- *Malleability (partial preemption)*: In this manner, the number of nodes/VMs allocated to a request might be changed while it is executing. In this approach, the request should be designed to adapt dynamically to the changes. This action can be applied on malleable jobs [72] in job-based systems. In VM and lease-based systems, frameworks such as Cluster-on-Demand (COD) [64], support this manner of preemption via cancelling some of the VMs of a lease. Malleability is also known as partial-preemption and can be used to implement dynamic partitioning (see Section 57.3.1).
- *Pausing*: When a VM is paused, it does not get any CPU share, however, it remains in the memory. Resumption of the VM, in this case, happens by getting CPU share and, thus, is very fast (Figure 57.7). Hence, we cannot consider pausing as a complete preemption action.

Nonetheless, the main usage of pausing is to perform lease-level preemption. In preempting a lease (several correlated VMs), to prevent inconsistency or message loss, first, all VMs are paused and then, suspension takes place [44] (link between pause state and sleep (suspended) state in Figure 57.7). In Section 57.4.5.4, we discuss how pausing VMs helps in preempting leases.

- *Suspending*: When a VM is suspended, the entire state of the VM (including the state of all processes running within the VM) is saved to the disk. At resumption time, the VM continues operating from the suspended point. The suspended request has to be rescheduled to find another free time slot for the remainder of its execution. In job-based systems, the operating system should retain the state of the preempted process and resume the job.

An important question after suspension is where to resume a VM/lease? Answering this question is crucial particularly for data-intensive applications. A suspended request can be resumed in one of the three following ways:

1. Resuming on the same resource; this case does not yield to optimal utilization of whole resources.
 2. Resuming on the same site but not essentially on the same resource; In this case, usually data transfer is not required.
 3. Resuming on different site: This case leads to migrating to another site, which entails data transfer. This is, particularly, not recommended for data-intensive requests.
- *Migrating*: VMs of the preempted request are moved to another resource provider to resume the computation (also called cold migration). According to Figure 57.7, migrating involves suspending, transferring, and resuming VMs. Transferring overhead in the worst case includes transferring the latest VM state in addition to the disk image of the VM. One solution to mitigate this overhead is migrating to another site within the same provider which has a high bandwidth connection available (e.g., within different Clusters of a datacenter). In terms of scheduling, multiple reservation strategies can be applied to assure that the request will access resources in the destination resource provider [93].
 - *Live Migration*: Using live migration preemption can be carried out without major interruption in running VMs involved in preemption (see live migration link in Figure 57.7). This is particularly essential in conditions that no interruption can be tolerated (e.g., Internet servers). For this purpose, the memory image of the VM is transferred over the network. There are techniques to decrease the live migration overhead, such as transferring just the dirty pages of the memory.

Apart from the aforementioned choices, there are requests that cannot be preempted (i.e., nonpreemptable requests). For example, critical tasks in workflows that have to start and finish at exact times to prevent delaying the execution of the workflow [57]. Another example is secure applications that cannot be moved to any other provider and cannot also be interrupted in the middle of execution.

In a particular resource management system, one or combination of the mentioned actions can be performed on the preempted request. The performed action can be based on the QoS constraints of the requests or restrictions that user declares in the request. Another possibility is that the resource management system dynamically decide the appropriate action on the preempted request.

57.4.5.4 Checkpointing in Distributed Systems

Checkpointing is the function of storing the latest state of a running process (e.g., job, VM, and lease). Checkpointing is an indispensable part of preemption, if the preempted request is going to resume its execution from the preempted point. In fact, checkpointing is the vehicle of implementing preemption. Apart from preemption, checkpointing has other usages including providing fault-tolerance for the requests.

Checkpointed process can be stored on a local storage, or carried over the network to a backup machine for future recovery/resume. Checkpointing has to be achieved in an *Atomic* way, which means either all or none of the modifications are checkpointed (transferred to the backup machine). There are various approaches to achieve checkpointing which are presented briefly in Figure 57.8. In this section, we explain checkpointing strategies for different provisioning models in distributed systems.

57.4.5.4.1 Checkpointing in Job-Based Provisioning Model

Checkpointing approaches are categorized as application-transparent and application-assisted (see Figure 57.8). In application-assisted (user-level) checkpointing, the application defines the necessary information (also called critical data area) that have to be checkpointed. The disadvantage of this approach is that it entails modifying the application by the programmer. However, this approach imposes little overhead to the system because it just checkpoints the necessary parts of the application; additionally, the frequency of performing checkpointing is determined by the user. User-level checkpointing can be further categorized as follows:

- Source-code level: In this manner, checkpointing codes are hard-coded by developers. However, there are some source code analysis tools [21,30] that can help developers to figure out the suitable places that checkpointing codes can be inserted.
- Library level: There are ready-made libraries for checkpointing, such as Libckpt [74] and Condor libraries [62]. To use this kind of checkpointing, developers have to recompile the source code by including the checkpointing library in their program.

As noted in Figure 57.8, checkpointing can also be done in application-transparent manner. This approach is also known as system level, Operating System level, or kernel level in the literature. As the name implies, in this approach the application is not aware of checkpointing process. Therefore, the application does not need to be modified to be checkpointable. Application-transparent checkpointing technique is particularly applied in preemption whereas application-assisted scheme is more used in fault-tolerance techniques. Examples of system level checkpointing in the system level are BLCR [41] and CRAK [111].

FIGURE 57.8 Checkpointing methods in distributed systems.

Since the application-transparent checkpointing methods have to checkpoint the whole application state, they impose significant time overhead to the system. Another drawback of this approach is that the system-level checkpointing methods are dependent on a specific version of the operating system that they are operating on and, hence, are not entirely portable.

In order to mitigate the checkpointing overhead, incremental checkpointing technique is used [43] in which just the changes since the previous state are checkpointed. Typically, a page-fault technique is used to find the dirty pages and write them to the backup [43,50].

Checkpointing of the distributed applications that run in a distributed system, such as a Cluster, is more complicated. For these applications, not only the state of the application on each running node should be checkpointed, but it has to be assured that the state of the whole application across several nodes remains consistent. Therefore, the checkpointing process across nodes that run the application must be synchronized in a way that there would be neither message loss nor message reordering. Checkpointing of the distributed applications (also termed coordinated checkpointing) traditionally is developed based on the global distributed snapshot concept [22]. These solutions are generally application-level, dependent on a specific version of operating system, and also dependent on the platform implementation (e.g., MPI implementation). Cocheck [95], BLCR [41], and MPICHV [24] are examples of these solutions.

There are various approaches for managing the connections between processes running on different nodes while the checkpointing is performed. In MPICHV [24], the connection among processes has to be disconnected before each process saves its local state to the checkpoint file. In this approach, connections should be re-established before processes can resume their computation. Another approach, which is used in LAM/MPI, uses bookmarking mechanism between sender and receiver processes to guarantee message delivery at the checkpointing time.

57.4.5.4.2 Checkpointing in VM-Based Systems

Virtualization technique provides application-transparent checkpointing as an inherent feature that involves saving (suspending) and restoring (resuming) of the VM state [14,20,55].

In a virtualized platform, hypervisor (also called virtual machine monitor) is an essential component that manages different VMs concurrently running on the same host. Generally, the hypervisor is in charge of VM checkpointing. To checkpoint a VM, its internal state including memory, cache, and data related to the virtual devices have to be stored on the disk. Disk image snapshot also has to be stored, specially when the checkpointed VM is transferred and sharing image is not possible. Current virtual machine monitors, such as VMware, Xen, and KVM, support saving/restoring the state of VMs to/from a file. However, taking a copy of the disk image is not practically possible because of the size of the disk [69]. Therefore, currently, checkpointing is mostly carried out within resources with a shared storage, such as NFS.

Accordingly, distributed applications running on VMs across several nodes within a Cluster can be checkpointed [46]. Checkpointing of such applications is complicated because of the possible correlations between VMs (e.g., TCP packets and messages exchanged between VMs). The checkpointing process should be aware of these correlations, otherwise the checkpointing process leads to inconsistency in running the distributed applications.

To handle the checkpointing, when a checkpointing event is initiated, all the nodes that run a process of the distributed application receive the event. Upon receiving the event, the hypervisor *pauses* computation within VMs in order to preserve the internal state of VM and also to stop submitting any new network message (see Figure 57.7). In the next step, checkpointing protocols save the in-flight messages (i.e., network packets). For this purpose, the hypervisor collects all the incoming packets and queue them. Finally, a local VM checkpointing is performed through which the VM's internal state, VM disk image, and queued messages for that VM are saved in the checkpoint file [44].

57.5 Contention Management in Practice

Various types of distributed systems for resource sharing and aggregation have been developed. They include Clusters, Grids, and Clouds. In this section, we study these systems from the resource contention perspective. We identify and categorize properties of the reviewed systems and summarize them in Table 57.2 for Clusters and in Table 57.3 for Grids and Clouds.

57.5.1 Contention Management in Clusters

Compute Clusters are broadly categorized as dedicated and shared Clusters. In dedicated Clusters a single application exclusively runs on the Cluster's nodes. Mail servers, and web servers are examples of dedicated Clusters.

By contrast, in a shared Cluster the number of requests is significantly higher than the number of Cluster nodes. Therefore, nodes have to be shared between the requests by means of a resource management system [100]. From the resource contention perspective, shared Clusters are generally prone to request-initiated contention.

Virtual Clusters are another variation of Clusters that work based on VMs. Although users of these Clusters are given root access to the VMs, these resources are not dedicated to one user in hardware level (i.e., several VMs on the same node can be allocated to different users).

A multicluster is an interconnected distributed system that consists of several Clusters possibly in different organizations. Multiclusters are prone to origin-initiated contentions as well as request-initiated contention.

TABLE 57.2 Role of Different Components of Cluster Management Systems in Dealing with Resource Contentions

System	Provisioning Model	Operational Model	Context	Contention Initiation	Contention Management	RMS Component
Haizea [93]	Lease	Reactive	Cluster	Request	Preemption	Local sched
VioCluster [79]	VM	Proactive and reactive	MultiCluster	Origin	Preemption	Local sched
Snell et al. [91]	Job	Reactive	Cluster	Request	Preemption	Local sched
Lawson Smirni [59]	Job	Proactive and reactive	Cluster	Request	Partitioning	Local sched
Walters et al. [109]	VM	Reactive	Cluster	Request	Preemption	Local sched

Shirako [48] is a lease-based platform for on-demand allocation of resources across several Clusters. In Shirako, a broker receives user's application and provides it tickets that are redeemable at the provider Cluster. In fact, Shirako brokers handles interdomain-initiated contentions by coordinating resource allocation across different Clusters. However, the user application should decide how and when to use the resources.

VioCluster [79] is a VM-based platform across several Clusters. It uses lending and borrowing policies to trade VMs between Clusters. VioCluster is equipped with a machine broker that decides when to borrow/lend VMs from/to another Cluster. Machine broker also has policies for reclaiming resources that reacts to origin-initiated contention by preempting a leased VM to another domain. Machine property policy monitors the machine properties that should be allocated to the VMs such as CPU, memory, and storage capacity. Location policy in the VioCluster proactively determines if it is better to borrow VMs from other Cluster or waiting for nodes on a single domain.

Haizea [93] is a lease manager that is able to schedule combination of Advanced Reservation, Best Effort, and Immediate leases. Haizea acts as a scheduling back-end for OpenNebula [32]. The advantage of Haizea is considering and scheduling the preparation overhead of deploying VM disk images. For scheduling Advanced Reservation and Immediate leases, leases with lower priority (i.e., Best Effort) are preempted (i.e., suspended and resumed after the reservation is finished). In fact, Haizea provides a reactive resource contention mechanism for request-initiated contentions.

Sharc [100] is a platform that works in conjunction with nodes' operating system and enables resource sharing within Clusters. Architecturally, Sharc includes two components, namely, *control plane* and *nucleus*. The former is in charge of managing Cluster-wide resources and removing request-initiated contentions, whereas the latter, interacts with the operating system of each node and reserves resources for requests. Control plane uses a tree structure to keep information of resources are currently in use in the Cluster. The root of the tree shows all the resources in the Cluster and each child indicates one job. The nucleus uses a hierarchy that keeps information about what resources are in use on a node and

by whom. The root of hierarchy shows all the resources on that node and each child represents a job on that node. In fact, there is a mapping between the control plane hierarchy and the nucleus hierarchy that helps Sharc to tolerate faults.

Cluster-on-Demand [64] (COD) is a resource management system for shared Clusters. COD supports lease-based resource provisioning in the form of virtual Clusters where each Virtual Cluster is an isolated group of hosts inside a shared hardware base. COD is equipped with a protocol that dynamically resizes Virtual Clusters in cooperation with middleware components. COD uses group-based priority and partial preemption scheme to manage request-initiated resource contention. Specifically, when resource contention takes place, COD preempts nodes from a low-priority Virtual Cluster. For preemption the selected Virtual Cluster returns those nodes that create minimal disruption to the Virtual Clusters.

Cluster Reserves [10] is a resource allocation for Clusters that provides services to the clients based on the notion of service class (partitioning). This is performed by allocating resource partitions to parallel applications and dynamically adjusting the partitions on each node based on the user demand. Indeed, Cluster Reserve applies partitioning scheme to cope with the request-initiated contention problems. The resource management problem is considered as a constrained optimization problem where the inputs of the problem are periodically updated based on the resource usage.

Muse [23] is an economy-based architecture for dynamic resource procurement within a job-based Cluster. Muse is prone to request-initiated contention and applies a utility-based, economic solution to resolve that. In the model, each job has a utility function based on its throughput that reflects the revenue earned by running the job. There is a penalty that the job charges the system when its constraints are not met. Resource allocation is worked out through solving an optimization problem that maximizes the overall profit. Muse considers energy as a driving issue in resource management of server Clusters.

MUSCLE [42] is an off-line, global scheduler for multiclusters that batches parallel jobs with high packing potential (i.e., jobs that can be packed into a resource space of a given size) to the same Cluster. In the next step, a local scheduler (called TITAN) performs further tuning to run the assigned jobs with minimized make span and idle times.

Lee et al. [60] have proposed a global and a local scheduler for a multicluster. The local scheduler is a variant of backfilling that grants priority to wide jobs to decrease their waiting time and resolves the request-initiated contention. The global dispatcher assigns requests to the proper Cluster by comparing the proportion of requests with the same size at each participant Cluster. Therefore, a fairly uniform distribution of requests in the Clusters is created which leads to a considerable impact on the performance.

Percival et al. [73] applied an admission control policy for shared Cluster. There is a request-initiated contention because some large jobs takes precedence over many small jobs that are waiting in the queue. Resource providers determine the resource prices based on the degree of contention and instantaneous utilization of resources. Consumers also bid for the resources based on their budget. In general, a job can get a resource if it can compensate the loss of earning resulting from not admitting several small jobs.

57.5.2 Contention Management in Desktop Grids

This form of distributed computing (also known as volunteer computing) inherently relies on participation of resources, mainly Personal Computers. In desktop Grids, participants become available during their idle periods to leverage the execution of long running jobs. They usually use specific events such as screen-saver as an indicator for idle cycles. SETI@home [8] is a famous desktop Grid project that works based on BOINC [7] software platforms and was originally developed to explore the existence of life out of the earth. Desktop Grids are prone to origin-initiated resource contentions that take place between the guest requests (come from the Grid environment) and local requests (initiated by the resource owner) in a node.

In desktop Grids, the guest applications are running in the user (owner) environment. Running the external jobs along with other owner's processes, raised the security concern in desktop Grids and became an obstacle in prevalence of these systems. However, using the emulated platforms, such as Java, and sand-boxing the security concern were mitigated.

Another approach in desktop Grids is rebooting the machine and run an entirely independent operating system for the guest request. As a result, the guest request does not have access to the user environment. Instances of this approach include HP's I-cluster [77] and vCluster [27]. However, this approach can potentially interrupt the interactive user (owner). Therefore, idle cycle prediction has to be done conservatively to avoid interrupting the interactive user (owner). Both of these approaches are heavily dependent on the efficient predicting and harvesting of the idle cycles. Indeed, these approaches function efficiently where there are huge idle cycles.

Recently, VM technology has been used in desktop Grids. The advantages of using VMs in these environments are threefolds. First and foremost is the security that VMs provide through an isolated execution environment. Second, VMs offer more flexibility in terms of the running environment demanded by the guest application. The third benefit is that by using VMs fragmented (unused) idle cycles, such as cycles at the time of typing or other light-weight processes, can be harvested.

NDDE [67] is a platform that utilizes VMs to exploit idle cycles for Grid or Cluster usage in corporations and educational institutions. This system is able to utilize idle cycles that appear even while the user is interacting with the computer. Indeed, in this system the guest and owner applications are run concurrently. This approach increases the harvested idle cycle to as many as possible with minor impact on the interactive user's applications. NDDE has more priority than idle process in the host operating system and, therefore, will be run instead of idle process when the system is idle. At the time the owner has a new request, the VM and all the processes belong to NDDE are preempted and changed to "ready-to-run" state.

Fine-grained cycle sharing system (FGCS) [76] runs a guest request concurrently with the local request whenever the guest process does not degrade the efficiency of the local request. However, FGCS are prone to unavailability because of the following reasons:

1. Guest jobs are killed or migrate off the resource because of a local request
2. Host suddenly discontinue contributing resource to the system

To cope with these problems, they define unavailabilities in the form a state diagram where each state is a condition that resource becomes unavailable (e.g., contention between users, and host unavailability). The authors have applied a Semi-Markov chain Process to predict the availability. The goal of this predictor engine is determining the probabilities of not transferring to unavailable states in a given time period of time in future.

57.5.3 Contention Management in Grids

Grids are initially structured based on the idea of the virtual organizations (VOs). A VO is a set of users from different organizations who collaborate towards a common objective. Several organizations constitute a VO by contributing share of their resources to that and as a result their users gain access to the VO resources. Contributing resources to a VO is carried out via an agreement upon that an organization gets access to the VO resources according to the amount of resources it offers to the VO.

Organizations usually retain part of their resources for their organizational (local) users. In other words, VO (external) requests are welcome to use resources if they are available. However, VO requests should not delay the execution of local requests.

Indeed, Grids are huge interconnected distributed systems that are prone to all kinds of resource contentions [85]. Particularly, interdomain-initiated resource contention arises when organizations need to access VO's resources based on their contributions. Origin-initiated resource contention occurs when there is a conflict between local and external users within the resources of an organization. Finally, request-initiated contention exists between different types of requests (short/long, parallel/serial, etc.).

Gruber/Di-Gruber [28] is a Grid broker that deals with the problem of resource procurement from several VOs and assigns them to different user groups. Gruber provides monitoring facilities that can be used for interdomain-initiated contentions. It also investigates the enforcing of usage policies (SLA) as well as monitoring the enforcement. Another component of Gruber sought to cope with request-initiated resource contention through monitoring resources' loads and outsource jobs to a suitable site (site selector component). Di-Gruber is the distributed version of Gruber which supports multiple decision points.

InterGrid [26] is a federation of Grid systems where each Grid receives lease requests from other Grids based on peering arrangements between InterGrid Gateways (IGG) of the Grids. Each Grid serves its own users (e.g., organizational/local users) as well as users coming from other Grids (external). InterGrid is prone to origin-initiated (between local and external requests) and interdomain-initiated (between different Grids) resource contentions.

Peering arrangements between Grids coordinate exchanging resources and functions based on peer-to-peer relations established among Grids. Each peer is built upon a predefined contract between Grids and handles interdomain-initiated contentions between the two Grids. Outsourcing unit of InterGrid is incorporated in the scheduling and determines when to outsource a request. Salehi et al. [6] have utilized probabilistic methods and proposed contention-aware scheduling that aims at minimizing the number of VM preemptions (and therefore minimizing contention) in a Grid.

They have also come up [82] with an admission control policy to reduce origin-initiated contention in InterGrid. The admission control policy works based on limiting queue length for external requests in a way that their deadline can be met. For that purpose they anticipate the average response time of external requests waiting in the queue by considering characteristics of local requests such as interarrival rate and size. In this situation, the external requests are accepted up until the response time is less than the average deadline.

Delegated-matchmaking [47] proposes an architecture that delegates the ownership of resources to users in a transparent and secure way. More specifically, when a site cannot satisfy its local users, the matchmaking mechanism of Delegated-matchmaking adds remote resources to the local resources. In fact, in Delegated-matchmaking the ownership of resources are delegated in different sites of Grids. From the resource contention perspective, matchmaking mechanism is in charge of dealing with request-initiated contentions through outsourcing scheme.

GridWay [103] is a project that creates loosely coupled connection between Grids via connecting to their meta-schedulers. GridWay is specifically useful when a job does not get the required processing power or the job waiting time is more than an appointed threshold. In these situation, GridWay migrates (outsources) the job to another Grid in order to provides the demanded resources to the job. We can consider GridWay as a global scheduler that deals with request-initiated resource contentions.

OurGrid [9] is a Grid that operates based on a P2P network between sites and share resources based on reciprocity. OurGrid uses network of favors as the resource exchange scheme between participants. According to this network, each favor to a consumer should be reciprocated by the consumer site at a later time. The more favor participants do, the more reward they expect. From the resource contention perspective, OurGrid uses incentive-based approach to figure out the problem of interdomain-initiated contentions in a Grid.

Sandholm et al. [86] investigated how admission control can increase user fulfillment in a computational market. Specifically, they considered the mixture of best effort (to improve resource utilization) and QoS-constrained requests (to improve revenue) within a virtualized Grid. They applied a reactive approach through partial preemption of best-effort requests to resolve request-initiated contentions. However, the admission control proactively accepts a new request if the QoS requirements of the current requests can still be met.

57.5.4 Contention Management in Clouds

Advances in virtual machine and network technologies has led to appearing commercial providers that offer numerous resources to users and charge them in a pay-as-you-go fashion. Since the physical

infrastructure is unknown to the users in these providers; they are known as Cloud Computing [18]. There are various fashions for delivering Cloud services, which are generally known as XaaS (X as a Service). Among these services Infrastructure as a Service (IaaS) offers resources in the form of VM to users.

From the availability perspective, Cloud providers are categorized as public, private, and hybrid Clouds [19]. To cope with the shortage of resource availability, particularly in private Clouds, the idea of federated Cloud has been presented [18]. Cloud federation is a possible solution for a Cloud provider in order to access to a larger pool of resources.

Similar to Grid environments, Clouds are also prone to different types of resource contentions. However, as Clouds are more commercialized in comparison with Grids, the resource contentions solutions are also mostly commercially driven.

Recently, Amazon started to offer spot instances to sell the unused capacity of their data centers [110]. Spot instances are priced dynamically based on users' bids. If the bid price is beyond the current spot instance price, the VM instance is created for the user. The spot instance's price fluctuates and if the current price goes beyond the bid price, the VM instance is canceled (terminated) or alternatively suspended up until the current price becomes lower than the bid. Indeed, the spot market presents a request-initiated resource contention where the contention is solved via an auction-based scheme. Kondo and Andryejak [110] have evaluated the dynamic checkpointing schemes, which is adaptive to the current instance price, and achieves cost efficiency and reliability in dealing with spot instances.

Van et al. [101] have proposed a multilayer, contention-aware resource management system for Cloud infrastructure. The resource management system takes into account both request's QoS requirements and energy consumption costs in VM placement. In the request (user) level, a local decision module (LDM) monitors the performance of each request and calculates a utility function that indicates the performance satisfaction of that request. LDM interacts with a global decision module (GDM) which is the decision-making component in the architecture. GDM considers the utility functions of all LDMs along with system-level performance metrics and decides about the appropriate action. In fact, GDM provides a global scheduling solution to resolve request-initiated contentions between requests. The output of the GDM can be management commands to the server hypervisor and notifications for LDMs. The notifications for LDM includes adding a new VM to the application, upgrading or downgrading an existing VM, preempting a VM belonging to a request. Management actions for hypervisors include the starting, stopping, or live migration of a VM.

RESERVOIR [78] is a research initiative that aims at developing the technologies required to address the scalability problems existing in the single provider Cloud computing model. To achieve this goal, Clouds with excess capacity offer their resources, based on an agreed price, to the Clouds that require extra resources. Decision making about where to allocate resources for a given request is carried out through an outsourcing component, which is called placement policy. Therefore, the aim of project is providing an outsourcing solution for request-initiated resource contention.

InterCloud [18] aims to create a computing environment that offers dynamic scaling up and down capabilities (for VMs, services, storage, and database) in response to users' demand variations. The central element in InterCloud architecture is the Cloud Exchange, which is a market that gathers service providers and users' requests. It supports trading of Cloud services based on competitive economic models, such as financial options [98]. Toosi et al. [18,97] consider circumstances that each Cloud offers on-demand and spot VMs. The admission control unit evaluates the cost-benefit of outsourcing an on-demand request to the InterCloud or allocating resource to that via terminating spot VMs (request-initiated contention). Their ultimate objective is to decrease the rejection rate and having access to seemingly unlimited resources for on-demand requests.

57.6 Conclusions and Future Research Directions

Due to resource shortage as well as surge in demand, distributed systems commonly face contention between requests to access resources. Resource contentions are categorized as *request-initiated*, when a user request cannot be admitted or cannot acquire sufficient resources because the resources are

occupied by other requests. *Origin-initiated* resource contention refers to circumstances that requests are from different sources with distinct priorities. *Interdomain-initiated* resource contentions take place when the proportion of shared resources to the consumed resources by a resource provider is low.

Resource contention can be handled by different components of resource management system. Therefore, solutions for resource contention depends on the structure of resource management in a distributed system. In this research, we recognized the role of resource provisioning model, local scheduling, global scheduling, and admission control unit in a resource management system on various types of resource contentions. We also realized that the emergence of VM-based resource provisioning model has posed the preemption as a predominant solution for different types of resource contentions. Therefore, in this survey we also investigated the challenges and opportunities of preempting VMs.

We reviewed systems in Clusters, Grids, and Clouds from the contention management perspective and categorized them based on their operational model, the type of contention they deal with, the component of resource management system involved in resolving the contention, and the provisioning model that contention is considered. We also closely investigated preemption mechanism as the substantial resolution for resource contention.

There are avenues of future research works in managing resource contentions that can be pursued by researchers. Proactive resource contention management methods are required specifically for interdomain-initiated contentions. This means that in an interconnected distributed system when resource management system decides to outsource a request, contention probability in the destination provider has to be considered.

Combination of different resource contentions (hybrid contention) requires further investigation. For example, resolving contention where there is a combination of origin-initiated and request-initiated contentions. Moreover, economical solutions can be taken into consideration to resolve the origin-initiated and interdomain-initiated resource contentions.

We also enumerated several options that can be considered for resuming a preempted request. Current systems usually choose one of these options. However, it will be interesting to come up with a mechanism that dynamically (e.g., based on the request condition) chooses one of the available options. A more specific case is when preemption via suspension happens. In this situation, determining the appropriate place to resume the preempted request is a challenge. For instance, if it is data-intensive request, then it might be better to wait in the queue instead of migrating to another resource.

58.1 Introduction

The discipline of real-time computing studies computer systems in which certain computations have both a logical and a temporal notion of correctness: the correct result must be produced, at the right time. As computer systems come to play an increasingly important role in monitoring and controlling ever more aspects of the physical world and our interactions with it, principles of real-time computing are fast becoming central to broad areas of computer science and engineering, including embedded systems, cyber-physical systems, electronic commerce, multimedia, communication and networking, and robotics.

This discipline grew out of a need to be able to ensure provably correct behavior in safety-critical embedded systems such as the ones found in aerospace and armaments applications. The focus initially was therefore on the worst-case analysis of very simple systems that are restricted to execute in tightly controlled environments, with the objective of ensuring that all timing constraints are always met. As more and more application domains have come to explicitly recognize the real-time nature of their requirements, the kinds of systems falling within the scope of the discipline of real-time computing have broadened considerably in many ways: systems subject to real-time analysis are no longer simple but display significant complexity and heterogeneity in composition and in requirements, and are expected to operate correctly in relatively unpredictable environments. This expansion in scope has considerably enriched the discipline, rendering it far more challenging and interesting.

58.2 Underlying Principles

A real-time system is specified by specifying a *workload*, and a *platform* upon which this workload is to execute. The workload is often modeled as consisting of a number of *jobs*, each of which has a *release time*, an *execution requirement*, and a *deadline*. The interpretation is that the job needs to execute for an amount equal to its execution requirement within a *scheduling window* that is the interval between its release time and its deadline. If a workload consists of a finite number of jobs that are all known beforehand, it may sometimes be specified explicitly. More commonly, however, real-time systems are *reactive* [26] in the sense that they maintain an ongoing interaction with their environment at a speed determined by the environment: they obtain information about the environment using sensors and may seek to change the environment via actuators. For such reactive systems, *constraints* of various kinds (such as precedence constraints, periodicity constraints, minimum inter-arrival separation constraints, and mutual exclusion constraints) are specified for the kinds of (potentially infinite) collections of jobs that are *legal* for a given system. Such constraints are typically specified within the context of a *formal model* for representing a real-time workload—some commonly used models are described in Section 58.2.4. A *schedule* for a real-time system specifies which jobs are to execute on each part of the platform at each instant in time. A *scheduling algorithm* generates a schedule.

58.2.1 Hard versus Soft Real-Time Systems

For a *hard real-time* (HRT) system, it is imperative that all deadlines always be met; in *soft real-time* (SRT) systems, it is acceptable to miss an occasional deadline (the consequences of doing so are usually quantitatively specified as part of the system model). A special kind of SRT system is a *firm real-time* system, in which there is a reward associated with completing each job by its deadline (but no penalty for failing to do so), and the objective of a scheduling algorithm is to maximize the cumulative reward obtained.

58.2.2 Pre-Run-Time Analysis

One of the salient features of the discipline of real-time computing is its strong emphasis on the analysis of systems prior to their deployment. This is particularly true for safety-critical systems: such systems must be demonstrated to always exhibit safe behavior during run time before they can be deployed. (In some application domains, including civilian aviation and medical devices, prior certification of such safe behavior may be required from statutory *certification authorities*.) Pre-run-time analysis may take different forms, including the use of theorem-provers, model-checking, and the application of rigorously derived properties of resource-allocation and scheduling algorithms. Most of the analysis techniques considered in this chapter fall into the latter of these possible approaches.

A given schedule is said to be *feasible* for a workload that is specified as a collection of jobs upon a specified platform if it provides sufficient execution for each job to complete within its scheduling window. A specified collection of jobs is feasible upon a specified platform if there exists a feasible schedule for it. A specified collection of jobs is said to be *schedulable* by a given scheduling algorithm if the algorithm produces a feasible schedule.

The aforementioned definitions generalize from workloads that are specified as collections of jobs to workloads that are specified using more general models in the natural way: a workload is feasible if there is a feasible schedule for every legal collection of jobs that is consistent with the specified constraints, and it is schedulable by a given algorithm if the algorithm finds a feasible schedule for every such legal collection of jobs.

With regard to workloads that are specified according to a particular model (see Section 58.2.4 for a listing of some such models) and that are to be implemented upon a specified platform, a *schedulability test* for a given scheduling algorithm is an algorithm that takes as input a workload specification and provides as output an answer as to whether the workload is schedulable by the given scheduling algorithm. A schedulability test is *exact* if it correctly identifies all schedulable and unschedulable task systems. It is *sufficient* if it correctly identifies all unschedulable task systems, but may misidentify some schedulable systems as being unschedulable.

For any scheduling algorithm to be useful for HRT applications, it must have at least a sufficient schedulability test that can verify that a given workload is schedulable. The quality of the scheduling algorithm and the schedulability test are thus inseparable for HRT systems.

58.2.3 Time-Triggered versus Event-Triggered Scheduling

In designing scheduling algorithms, two major alternative paradigms have emerged. In a *time-triggered* (TT) schedule, all scheduling activities are initiated by the progress of time. That is, the entire schedule is predetermined before the system is deployed, and all scheduling activities are initiated (“triggered”) at prespecified points in time. TT schedules are typically (although not always) stored as lookup tables and are suitable for use in highly deterministic systems, in which the entire real-time workload can be completely characterized as a particular collection of jobs prior to system run time. For systems that are not completely deterministic, the *event-triggered* (ET) paradigm is more appropriate. In an ET schedule, it is *events*, rather than the passage of time, that initiate scheduling activities. These events can be external (such as the release of a job or the arrival of an interrupt signal) or internal (e.g., the completion of the execution of a currently executing job). ET scheduling is able to deal with some kinds of incompletely specified workloads in a more resource-efficient manner than TT scheduling.

58.2.4 Models for Recurrent Tasks

The workload of a real-time system is often modeled as consisting of a finite number of recurrent *tasks* or processes. Each such task usually represents code embedded within an infinite loop: each iteration of the loop gives rise to one or more jobs.

The *periodic task model* [39] is the simplest model for representing such recurrent tasks. Each task τ_i in this model is characterized by a *worst-case execution time* (WCET) parameter C_i and a *period* T_i , with the interpretation that this task releases a job at each integer multiple of T_i , with this job having a deadline that is T_i time units after its release and needing to execute for up to C_i time units by this deadline. A generalization to the model allows for the specification of an additional parameter O_i called the *initial offset*, with the interpretation that the first job is released at time O_i and subsequent jobs T_i time units apart. A further generalization [36,37] allows for the specification of a *relative deadline* parameter D_i ; the deadline of a job is D_i time units after its release (rather than T_i time units). In this most general form, thus, each task $\tau_i = (O_i, C_i, D_i, T_i)$ releases a job with WCET equal to C_i at time instant $O_i + k \cdot T_i$, and deadline at time-instant $O_i + k \cdot T_i + D_i$, for each integer $k \geq 0$.

Recall that the release of a job may be triggered by the occurrence of an external event. In many real-time systems, such external events may not occur periodically (i.e., exactly T_i time units apart); modeling the task that is responsible for processing such events as a periodic task therefore results in a loss of accuracy. If it is, however, possible to provide a *lower bound* on the minimum amount of time that must occur between the occurrence of successive events, the *sporadic task model* [42] is able to model the processing of these events. In this model, a task τ_i is again characterized by the same four-tuple of parameters: $\tau_i = (O_i, C_i, D_i, T_i)$; however, the interpretation of the first and fourth parameters (O_i and T_i) is different. Specifically, such a task generates a sequence of jobs with the release time of the first job $\geq O_i$,

and the release times of successive jobs separated by an interval of duration $\geq T_i$; each job has a WCET C_i and a deadline D_i time units after its release time.*

There is a classification of real-time systems consisting entirely of sporadic tasks, depending on the relationship between the D_i and T_i parameters. In this classification,

- Any task system consisting entirely of sporadic tasks is called an *arbitrary-deadline* sporadic task system
- In *constrained-deadline* sporadic task systems, $D_i \leq T_i$ for all tasks τ_i
- In *implicit-deadline* sporadic task systems, $D_i = T_i$ for all tasks τ_i

(It is evident from these definitions that each implicit-deadline sporadic task system is also a constrained-deadline sporadic task system, and each constrained-deadline sporadic task system is also an arbitrary-deadline sporadic task system.)

Several models that are more general than the ones described earlier have also been proposed for representing recurrent real-time task systems; these include the multiframe model [43], the generalized multiframe model [8], the recurring real-time task model [7], and the digraph task model [54]. Models incomparable to the ones discussed earlier include the pinwheel model [28], and various models used for representing firm-real-time task systems such as the imprecise computation model [38] and the (m, k) -task model [25].

58.2.5 Priority-Driven Scheduling Algorithms

Most run-time scheduling algorithms are implemented as follows. At every instant during run time, each job that is eligible to execute is assigned a *priority* (either explicitly or implicitly), and the highest-priority jobs are selected for execution. Depending upon the manner in which priorities are assigned, algorithms for scheduling recurrent tasks can be classified [17] into three major categories:

1. In fixed-task-priority (FTP) scheduling algorithms, each recurrent task gets assigned a distinct priority and each job gets the priority of the task that generated it. Common examples of FTP scheduling algorithms include the *rate-monotonic* (RM) algorithm, in which tasks are assigned priorities according to their period parameters (tasks with smaller periods get greater priority), and the *deadline monotonic* (DM) algorithm, in which priorities are assigned according to the relative deadline parameters (tasks with smaller relative deadline are assigned greater priority).
2. In fixed-job-priority (FJP) scheduling algorithms, different jobs of the same task may be assigned different priorities; however, each job gets assigned exactly one priority upon its release and this priority may not change until the job has completed execution. The *earliest deadline first algorithm* (EDF), in which jobs with earlier deadlines are assigned greater priority (with ties broken arbitrarily), is a common example of an FJP scheduling algorithm.
3. There are no restrictions on the priority-assignment procedure for dynamic priority (DP) scheduling algorithms: different jobs of the same task may have different priorities and the priority of a job may change arbitrarily often. The *least laxity* (LL) algorithm, in which the priority assigned to a job depends upon the difference between the amount of time remaining to its deadline and its remaining execution, is an example of a DP scheduling algorithm: under LL scheduling, an executing job does not have its priority change, whereas a job that is awaiting execution sees its priority increase.

* In specifying sporadic task systems, the first parameter—the initial offset O_i —is often left unspecified; it seems that knowledge of this parameter does not significantly help in determining scheduling algorithms for systems of sporadic tasks.

58.2.6 Synchronous Real-Time Systems

The synchronous paradigm of real-time computation [24] posits that all actions execute instantaneously. In practice, this requires that *the program reacts rapidly enough to perceive all external events in suitable order* [24, p. 6]. For this paradigm to be applicable, it is therefore necessary that an atomic time-slice be sufficiently large (equivalently, that the clock used be sufficiently coarse-grained to allow any action that begins execution at a clock-tick to complete execution, and have its results communicated to where it may be needed, by the next clock-tick). Synchronous programming languages such as ESTEREL [12] have been developed for implementing real-time systems when these conditions are satisfied.

Although synchronous programming is an extremely powerful programming technique for specifying and proving the correctness of complex real-time systems, it is difficult to obtain implementations of such systems that make efficient use of platform resources; in essence, this is because the time-granularity at which platform resources may be allocated corresponds to the maximum amount of time needed for any action to complete execution. In their purest forms, the synchronous paradigm and the priority-driven one (which is the focus of much of this chapter) can be thought of as representing two alternative approaches: by using the synchronous paradigm it is easier to specify a real-time application but more difficult to obtain a resource-efficient implementation, whereas specifying an application using the task system models discussed in this chapter may be more difficult, but the resulting abstract model can be implemented in a very resource-efficient manner.

58.2.7 Execution Platform

In large part, the discipline of real-time systems has focused on optimizing the use of the processor (often called the CPU); additional platform components (memory, bandwidth, energy, etc.) have received much less attention. This is beginning to change; in Section 58.4, we will see how some of these additional resources give rise to a number of important and interesting research directions.

The execution model can be preemptive or nonpreemptive. In *preemptive* scheduling, an executing job may have its execution interrupted in order to execute some other job, with the interrupted job resuming execution later. In nonpreemptive scheduling, by contrast, an executing job may not be interrupted until it has completed execution.

With regard to the processing resource, both uniprocessor and multiprocessor platforms have been considered. A uniprocessor platform consists of a single CPU upon which the entire real-time workload is required to execute. Real-time systems were initially primarily implemented on uniprocessor platforms, but the advent of multicore technologies prompted many real-time researchers to begin investigating multiprocessor-related resource allocation problems. Given a system of recurrent tasks and a number of processors, it is possible to divide the processors into clusters and assign each task to a cluster. A scheduling algorithm is then applied locally in each cluster to the jobs generated by the tasks that are assigned to the cluster. The following two extremes of clustering have attracted the most attention from the real-time research community:

- *Partitioned scheduling*: Each processor is a cluster of size one. Historically, this has been the first step in extending single-processor analysis techniques to the multiprocessor domain.
- *Global scheduling*: There is only one cluster containing all the processors.

When resources other than the processors are taken into consideration, it is sometimes useful to consider cluster sizes other than these two extremes. For example, many multicore CPUs have on-chip multilevel cache memory that is shared among different sets of processing cores; it may be beneficial to consider cores that share a common cache as a single cluster.

A classification of multiprocessor platforms considers the relationship between the different processors:

- *Identical multiprocessors*: All the processors exhibit the same characteristics.
- *Uniform multiprocessors*: Some processors are “faster” than others, in the sense that a job would require less time to execute on the faster processor. All jobs experience the same speedup upon the faster processor.

The uniform multiprocessor model is useful for modeling platforms in which all the processors are of the same family of processors, but some may be of a newer generation than others. Alternatively, it may be the case that only a fraction of the computing capacity of each processor is available to the real-time workload (and this fraction is not the same for all the processors).

- *Unrelated multiprocessors*: Different jobs experience different speedups on different processors.

The unrelated multiprocessor model models multiprocessor platforms consisting of different kinds of processors (such as DSPs and GPUs). Depending on what they are doing, different jobs may be expected to have different execution rates on different processors—for example, a graphics-intensive job would probably experience greater speedup on a GPU than some other jobs. As such platforms become ever more common (particularly on multicore CPUs), the unrelated multiprocessor model is expected to become more important for the modeling of real-time application systems.

58.3 Best Practices

58.3.1 Scheduling on Uniprocessors

The scheduling of recurrent task systems on uniprocessor platforms is a well-studied subject. Much of the work has focused on preemptive scheduling; however, there are also several interesting and important results concerning nonpreemptive scheduling.

58.3.1.1 Earliest Deadline First

One of the seminal results in uniprocessor scheduling is that *EDF is optimal for scheduling collections of independent jobs on a preemptive uniprocessor*, in the sense that if a given collection of jobs can be scheduled on a preemptive processor such that each job will complete by its deadline, then scheduling jobs according to their deadlines will also complete each job by its deadline [18,39]. This optimality result also holds for real-time workloads modeled using any of the models described in Section 58.2.4.

58.3.1.2 FTP Scheduling

EDF is an example of a FJP scheduling algorithm (see Section 58.2.5). A couple of FTP algorithms are also very widely used: *rate-monotonic (RM)* and *deadline-monotonic (DM)*. In RM scheduling [39], a task is assigned a priority depending on its period parameter T_i ; the smaller the period, the greater the priority (with ties broken arbitrarily). In DM scheduling [37], priorities are assigned depending on the relative deadline parameter D_i ; the smaller the relative deadline, the greater the priority (with ties again broken arbitrarily). Observe that for *implicit-deadline* sporadic task systems, RM and DM assign priorities in an identical manner (since $T_i = D_i$ for all tasks in such systems). The following results are known concerning RM and DM scheduling:

1. DM is an optimal FTP algorithm for scheduling constrained-deadline sporadic task systems on a preemptive uniprocessor, in the sense that if a given collection of constrained-deadline sporadic task is schedulable by any FTP algorithm then it is also schedulable by DM [37].
2. DM is also an optimal FTP algorithm for scheduling periodic task systems satisfying the additional properties that (a) all the offset parameters (the O_i 's) are equal—periodic task systems satisfying this property are called *synchronous* periodic task systems; and (b) $D_i \leq T_i$ for each task τ_i .

3. A direct corollary of the aforementioned results is that RM is optimal for implicit-deadline sporadic task systems and for synchronous periodic task systems with $D_i = T_i$ for all τ_i ; this result was previously proved in [39].
4. DM and RM are *not* optimal for asynchronous periodic task systems, and for sporadic task systems in which D_i may exceed T_i for some tasks τ_i .

58.3.1.3 Shared Nonpreemptable Resources

The uniprocessor platforms upon which real-time systems execute may include nonpreemptable serially reusable resources in addition to the shared processor; these could be software resources such as shared data structures or hardware resources such as sensors and actuators. Access to such shared resources is typically made within critical sections of code that are guarded using mutual-exclusion primitives such as semaphores.

Priority-based scheduling algorithms have been extended to handle resource-sharing of this kind. Under *priority inheritance* protocols [49] for resource-sharing, a *blocking job*—that is, a job that holds a nonpreemptable resource and thereby prevents the execution of a higher-priority job—has its scheduling priority temporarily elevated to the priority of the blocked job. A particular kind of a priority inheritance protocol, called the *priority ceiling protocol (PCP)*, restricts the conditions under which a job is eligible to begin execution. Another version—the *Stack Resource Policy (SRP)* [3]—defines a different set of restrictions. It has been shown that PCP is optimal for the FTP scheduling and that SRP is optimal for the FJP scheduling (and, therefore, also for FTP scheduling), of sporadic task systems on a platform consisting of a single preemptive processor and additional nonpreemptive serially reusable resources.

58.3.2 Scheduling on Multiprocessors

There has recently been a considerable amount of effort devoted to obtaining better algorithms for scheduling real-time systems on platforms containing multiple processors. Much of this work studies partitioned and global preemptive scheduling of HRT workloads represented using the sporadic task model (Section 58.2.4) and implemented upon identical multiprocessors; a few results concerning scheduling on uniform and unrelated multiprocessors have also been obtained.

58.3.2.1 Partitioned Scheduling on Identical Multiprocessors

The partitioned scheduling of a collection of recurrent tasks can be thought of as a two-step process. The first step occurs prior to run time: during this step, each task in the collection needs to be assigned to one of the processors. This step reduces the multiprocessor problem to a series of uniprocessor problems, one on each processor—the subsequent step solves these uniprocessor problems using, for example, the techniques discussed in Section 58.3.1.1. In the following, we therefore focus on the partitioning step.

It is evident that the partitioning step is a generalization of the *bin-packing* problem, which is known to be NP-hard in the strong sense. Therefore, most positive results concerning partitioned scheduling concern approximation algorithms. Several such positive results have been obtained for partitioning implicit-deadline sporadic task systems. Lopez et al. [41] have proposed a partitioning algorithm based on the first-fit decreasing bin-packing heuristic and have obtained a sufficient schedulability condition when the subsequent partitioning step is done using EDF; similar sufficient schedulability conditions for RM scheduling have also been obtained [40,44]. In more theoretical work, a polynomial-time approximation scheme (PTAS) for partitioned EDF scheduling is easily derived from the results in [27], while a 3/2-approximation algorithm for partitioned RM scheduling was presented in [29].

The partitioned scheduling of constrained- and arbitrary-deadline sporadic task systems is less well studied. A polynomial-time partitioning algorithm called *first-fit with increasing deadline (FFID)* was proposed in [10] for partitioned EDF scheduling; a variant for partitioned DM scheduling was derived in [21].

58.3.2.2 Global Scheduling on Identical Multiprocessors

The global scheduling of implicit-deadline sporadic task systems can be done optimally using a dynamic priority (DP) scheduling algorithm called *pfair* [9] and its variants and refinements.

As stated in Section 58.3.1, upon preemptive uniprocessors EDF is an optimal FJP algorithm, and DM is an optimal FTP algorithm for constrained-deadline task systems. These optimality results do not hold for global multiprocessor scheduling; in fact, a phenomenon commonly called *Dhall's effect* [20] means that such algorithms can perform arbitrarily poorly when used for global scheduling. Phillips et al. [46] studied the global preemptive EDF scheduling of collections of independent jobs; their results have spawned a host of results scheduling algorithms and schedulability tests for the FJP and FTP global scheduling of implicit-deadline, constrained-deadline, and arbitrary-deadline sporadic task systems on identical multiprocessor platforms. These include FTP algorithms in which priorities are assigned using strategies other than RM or DM (see, e.g., [1,2]), as well as *hybrid* scheduling algorithms in which some tasks' jobs are assigned highest priority while remaining tasks' jobs have priorities assigned according to EDF (e.g., [23]). Various sufficient schedulability conditions for EDF and FTP scheduling (with a given priority assignment) have been derived [4,5,13,45].

58.3.2.3 Scheduling on Uniform and Unrelated Multiprocessors

As is evident from the earlier sections, considerable progress has been made on better understanding the scheduling of sporadic task systems on identical multiprocessors. Far less work has been done concerning real-time scheduling in uniform and unrelated multiprocessors. Funk's PhD dissertation [22] has a series of results for global and partitioned scheduling of implicit-deadline sporadic task systems on uniform multiprocessors. On unrelated multiprocessors, results from [33,34,51] can be applied to obtain polynomial-time approximation algorithms for partitioned scheduling of implicit-deadline sporadic task systems on unrelated multiprocessors; results from [31] can be used to obtain a polynomial-time algorithm for global scheduling of implicit-deadline sporadic task systems on unrelated multiprocessors. Global scheduling of arbitrary-deadline sporadic task systems on uniform processors is considered in Ref. [11].

58.3.3 Verification and Certification

As stated in Section 58.2.2, pre run-time analysis is often very important in real-time computing, particularly for safety-critical systems. Considerable effort has been devoted to the design of tools and methodologies for the formal verification of safety-critical real-time systems; these may involve the use of logic-based theorem provers, model-checking, automata-based tools, etc.

In safety-critical systems, *certification* refers to the process of demonstrating the correctness (or at least, safety) of a safety-critical system to a statutory authority. For example, aircraft are generally required to obtain an *airworthiness certificate* from the Federal Aviation Administration in order to be authorized to operate within US civilian airspace. Certification authorities (CAs) are entrusted by governments or other entities with certification responsibility over specified application domains; these CAs establish standards that must be met in order to obtain certification. Coming up with real-time system design processes that ameliorate the effort needed to obtain certification is an active ongoing research area, particularly for *mixed criticality* [6] systems: real-time systems in which different tasks perform functions that are of different degrees of importance (or criticality) to the overall performance of the system and are therefore subject to different certification requirements.

58.3.4 Operating Systems Issues

A real-time operating system (RTOS) provides system support for predictably satisfying real-time constraints. An RTOS differs from a traditional OS in that the time dimension is elevated to a central

principle; in contrast, traditional OSeS tend to abstract real time away to facilitate specification, design, and verification of systems. An RTOS needs to have a highly integrated time-cognizant resource allocation approach that provides support for meeting deadlines and for predictability; such a resource allocation approach must be built upon the foundational principles described in Sections 58.3.1 and 58.3.2. Some features typically found in current RTOSs* include the following:

- A real-time clock
- A priority scheduling mechanism
- A fast and predictable context switch
- A fast and predictable response to external interrupts
- Provides for special alarms and timeouts
- Permits tasks to invoke primitives to delay by a fixed amount of time and to pause/resume execution

Current RTOSs can be placed in one of two broad categories: those that are specifically built for real-time use and those that are obtained by adding some support for real time to general-purpose operating systems (various flavors of real-time Linux typically fall within this second category). A further classification of purpose-built RTOSs is proposed in [14, Section 2.5.1]:

- *Deeply embedded RTOSs*, for use in applications where resources are at a premium and mostly static, single-purpose workloads are prevalent. Such RTOS kernels are also sometimes called “executives.”
- *Full-featured RTOSs*, for applications where UNIX-like OS abstractions and multitasking are desirable, and the system design can afford the additional resources required to support them (e.g., extra memory and faster processors). Such RTOSs may find use in, for example, factory automatization and telecommunication infrastructure.
- *Certification compliant RTOSs*, for use in safety-critical applications that are subject to mandatory certification requirements. RTOSs in this category, also called *separation kernels*, are commonly used in avionics applications, where government-mandated standards such as the DO-178B standard for avionics impose strict isolation of safety-critical subsystems from faults in non- or less-safety-critical subsystems. The RTOS itself may have obtained certification, thereby facilitating its adoption in applications subject to certification.

There are hundreds of small and large RTOS products and projects; see, for example, [53] and [14, Chapter 2.5] for discussions concerning some of them.

58.4 Research Issues

As real-time embedded systems become ever more important, time plays an increasingly more central role in the specification, design, implementation, and validation of computing systems. This phenomenon has led to some prominent researchers in real-time computing making a case (see, e.g., [32,52]) that the entire foundations of computing, starting from the Turing abstraction, need to be revisited to place time in a more central role. Of course, such a radical rethink of the discipline of computing gives rise to a host of deep open questions; these questions, although important, will not be addressed further in this section—the interested reader is encouraged to read the cogent and convincing arguments put forth by Lee [32] and Sifakis [52], and consider their proposed avenues toward solving the problems identified.

Even from a less radical perspective, though, there are many interesting and important unresolved research issues in many areas of real-time computing. We list some of these areas next.

* The term RTOS is often applied to minimal custom-designed run-time environments that are developed for use in specific embedded systems; the discussion during the remainder of this section does exclude such RTOSs.

58.4.1 Scheduling

In *real-time scheduling theory*, researchers are working on developing algorithms and techniques for implementing real-time workloads on *heterogeneous* platforms that consist of different kinds of processing elements. Determining efficient scheduling strategies for meeting specified *end-to-end deadlines* on distributed platforms is also an active research area.

58.4.2 Programming Languages

The design of *specification formalisms* and *programming languages* for specifying and implementing real-time systems is an active research area. This research aims to resolve the ongoing tension between the need for a formalism to be adequately expressive and easy to use, while simultaneously being implementable in a resource-efficient manner. If a programming model is too close to an abstract specification, then it is difficult to obtain an efficient implementation. On the other hand, if a programming model is too close to the execution platform, then programming becomes a challenge. (This tension was highlighted in Section 58.2.6 with respect to the synchronous paradigm of real-time computing, which is easier to program in vis a vis a priorities-based programming model, but typically results in less efficient use of platform resources.)

58.4.3 Real-Time Networking

Since embedded real-time systems are typically implemented upon distributed platforms, it is imperative that communication between the different nodes of the platform be guaranteed to occur in real time. The discipline of *real-time networking* studies the challenges associated in providing such communication.

58.4.4 Energy and Thermal Issues

There was initially an expectation that Moore's law would eventually render resource-efficiency less of an issue, but that expectation has not been realized; instead, resources *other* than processing or memory capacity have become the scarce ones. One particularly important resource in this regard is the *energy* consumed by the real-time system, particularly in mobile embedded systems that are not tethered to the electricity grid. A related concern is ensuring that *temperature* does not rise too much, since the overheating of hardware components can change their behavioral characteristics and compromise their reliability and longevity. *Energy-aware* and *thermal-aware* real-time computing are very active research areas today.

58.4.5 Real-Time Operating Systems

New approaches for implementing RTOSs that are more general (i.e., offer services closer to those offered by general-purpose OSs) and are known to be correct to a high level of assurance (e.g., by being certified correct) are another active research area. There is much work on adapting the server or container abstraction, which allows for multiple applications of different criticalities to coexist on a shared platform, for use in RTOSs.

58.4.6 Soft Real-Time Computing

Much of the discussion in this chapter has been about HRT systems; this reflects the current focus of the community. However, SRT considerations are becoming increasingly more significant, as ever more SRT applications (such as multimedia and gaming) pay increasing attention to temporal issues.

Many different notions of SRT have been explored in some depth; the *time-utility function* approach [48] and the *bounded tardiness* approach [19,35] merit special mention for the comprehensive nature of the research that has been done and the results that have been obtained.

Further Information

The textbooks by Burns and Wellings [15], and Buttazzo [16], provide further information about many of the concepts introduced in this chapter. Kopetz [30] provides in-depth coverage of the concepts and results on time-triggered scheduling; the text by Halbwachs [24] is an introduction to the synchronous paradigm of real-time computing.

Proceedings of research conferences serve to provide an up-to-date snapshot of the current state of knowledge in the discipline and can be a useful source for recent results. The *IEEE Real-Time Systems Symposium* (RTSS), which has been held annually since 1980, is one of the flagship academic research conferences in real-time computing. The *EuroMicro Conference on Real-Time Systems* (ECRTS) and the *ACM International Conference in Embedded Software* (EMSOFT) are other important annual conferences. The archival journal *Real-Time Systems* is, as its name suggests, devoted to publishing research and survey articles on real-time computing principles and applications. The November 2004 issue of this journal is a special anniversary issue containing invited survey papers on a number of important topics in real-time computing, including scheduling theory [50], the issue of predictability in real-time computing [55], real-time databases [47], and real-time operating systems [53].

59.1 Introduction

In this chapter, *scheduling* is defined as the activity that consists in mapping a task graph onto a target platform. The task graph represents the application, nodes denote computational tasks, and edges model precedence constraints between tasks. For each task, an assignment (choose the processor that will execute the task) and a schedule (decide when to start the execution) are determined. The goal is to obtain an efficient execution of the application, which translates into optimizing some objective function.

The traditional objective function in the scheduling literature is the minimization of the total execution time, or *makespan*. Section 59.2 provides a quick background on task graph scheduling, mostly to recall some definitions, notations, and well-known results.

In contrast to pure makespan minimization, this chapter aims at discussing scheduling problems that arise at large scale and involve one or several different optimization criteria, that depart from, or complement, the classical makespan objective. Section 59.3 assesses the importance of key ingredients of modern scheduling techniques: (1) multicriteria optimization; (2) memory management; and (3) reliability. These concepts are illustrated in the following sections, which cover four case studies. Section 59.4 is devoted to illustrate multicriteria optimization techniques that mix throughput, energy; and reliability. Sections 59.5 and 59.6 illustrate different memory management techniques to schedule large task graphs. Finally, Section 59.7 discusses the impact of checkpointing techniques to schedule parallel jobs at very large scale. We conclude this chapter by stating some research directions in Section 59.8, defining terms in key terms, and pointing to additional sources of information in further information.

59.2 Background on Scheduling

59.2.1 Makespan Minimization

Traditional scheduling assumes that the target platform is a set of p identical processors, and that no communication cost is paid. In that context, a task graph is a directed acyclic vertex-weighted graph $G = (V, E, w)$, where the set V of vertices represents the tasks, the set E of edges represents precedence constraints between tasks ($e = (u, v) \in E$ if and only if $u < v$), and the weight function $w : V \rightarrow \mathbb{N}^*$ gives the weight (or duration) of each task. Task weights are assumed to be positive integers. A schedule σ of a task graph is a function that assigns a start time to each task: $\sigma : V \rightarrow \mathbb{N}^*$ such that $\sigma(u) + w(u) \leq \sigma(v)$ whenever $e = (u, v) \in E$. In other words, a schedule preserves the *dependence constraints* induced by the precedence relation $<$ and embodied by the edges of the dependence graph; if $u < v$, then the execution of u begins at time $\sigma(u)$ and requires $w(u)$ units of time, and the execution of v at time $\sigma(v)$ must start after the end of the execution of u . Obviously, if there was a cycle in the task graph, no schedule could exist, hence the restriction to acyclic graphs (DAGs).

There are other constraints that must be met by schedules, namely, *resource constraints*. When there is an infinite number of processors (in fact, when there are as many processors as tasks), the problem is *with unlimited processors*, and denoted $P_{\infty} | prec | C_{max}$ in the literature [25]. We use the shorter notation $Pb(\infty)$ in this chapter. When there is only a fixed number p of available processors, the problem is *with limited processors*, and denoted $Pb(p)$. In the latter case, an allocation function $alloc : V \rightarrow \mathcal{P}$ is required, where $\mathcal{P} = \{1, \dots, p\}$ denotes the set of available processors. This function assigns a target processor to each task. The resource constraints simply specify that no processor can be allocated more than one task at the same time:

$$alloc(T) = alloc(T') \Rightarrow \begin{cases} \sigma(T) + w(T) \leq \sigma(T') \\ \text{or} & \sigma(T') + w(T') \leq \sigma(T). \end{cases}$$

This condition expresses the fact that if two tasks T and T' are allocated to the same processor, then their executions cannot overlap in time.

The *makespan* $MS(\sigma, p)$ of a schedule σ that uses p processors is its total execution time: $MS(\sigma, p) = \max_{v \in V} \{\sigma(v) + w(v)\}$ (assuming that the first task(s) is (are) scheduled at time 0). The makespan is the total execution time, or finish time, of the schedule. Let $MS_{opt}(p)$ be the value of the makespan of an optimal schedule with p processors: $MS_{opt}(p) = \min_{\sigma} MS(\sigma, p)$. Because schedules respect dependences, we have $MS_{opt}(p) \geq w(\Phi)$ for all paths Φ in G (weights extend to paths in G as usual). We also have $Seq \leq p \times MS_{opt}(p)$, where $Seq = \sum_{v \in V} w(v) = MS_{opt}(1)$ is the sum of all task weights.

While $Pb(\infty)$ has polynomial complexity (simply traverse the graph and start each task as soon as possible using a fresh processor), problems with a fixed amount of resources are known to be difficult.

Letting $Dec(p)$ be the decision problem associated with $Pb(p)$, and $Indep - tasks(p)$ the restriction of $Dec(p)$ to independent tasks (no dependence, i.e., when $E = \emptyset$), well-known complexity results are summarized next:

- $Indep - tasks(2)$ is NP-complete but can be solved by a pseudo-polynomial algorithm. Moreover, $\forall \epsilon > 0$, $Indep - tasks(2)$ admits a $(1 + \epsilon)$ -approximation whose complexity is polynomial in $1/\epsilon$.
- $Indep - tasks(p)$ is NP-complete in the strong sense.
- $Dec(2)$ (and hence $Dec(p)$) is NP-complete in the strong sense.

Because $Pb(p)$ is NP-complete, heuristics are used to schedule task graphs with limited processors. The most natural idea is to use greedy strategies: at each instant, try to schedule as many tasks as possible onto available processors. Such strategies deciding *not to deliberately keep a processor idle* are called *list scheduling* algorithms. Of course, there are different possible strategies to decide which tasks are given priority in the (frequent) case where there are more free tasks than available processors. Here a *free* task is a task whose predecessors have all been executed, hence which is available and ready for execution itself. But a key result due to Graham [26] is that any list algorithm can be shown to achieve at most twice the optimal makespan. More precisely, the approximation factor with p processors is $2p-1/p$, and this bound is tight.

A widely used list scheduling technique is *critical path scheduling*. The selection criterion for ready tasks is based on the value of their bottom level, defined as the maximal weight of a path from the task to an exit task of the graph. Intuitively, the larger the bottom level, the more “urgent” the task. The *critical path* of a task is defined as its bottom level and is used to assign priority levels to tasks. Critical path scheduling is list scheduling where the priority level of a task is given by the value of its critical path. Ties are broken arbitrarily.

59.2.2 Dealing with Communication Costs

Thirty years ago, communication costs have been introduced in the scheduling literature. Because the performance of network communication is difficult to model in a way that is both precise and conducive to understanding the performance of algorithms, the vast majority of results hold for a very simple model, which is defined as follows.

The target platform consists of p identical processors that are part of a fully connected clique. All interconnection links have same bandwidth. If a task T communicates data to a successor task T' , the cost is modeled as

$$\text{cost}(T, T') = \begin{cases} 0 & \text{if } \text{alloc}(T) = \text{alloc}(T') \\ c(T, T') & \text{otherwise,} \end{cases}$$

where $\text{alloc}(T)$ denotes the processor that executes task T , and $c(T, T')$ is defined by the application specification. The time for communication between two tasks running on the same processor is negligible. A schedule σ must still preserve dependences, a condition that now writes

$$\forall e = (T, T') \in E, \begin{cases} \sigma(T) + w(T) \leq \sigma(T') & \text{if } \text{alloc}(T) = \text{alloc}(T') \\ \sigma(T) + w(T) + c(T, T') \leq \sigma(T') & \text{otherwise.} \end{cases}$$

This so-called *macro-dataflow* model makes two main assumptions: (1) communication can occur as soon as data are available and (2) there is no contention for network links. Assumption (1) is reasonable as communication can overlap with (independent) computations in most modern computers. Assumption (2) is much more questionable (although it makes sense in a shared-memory environment). Indeed, there is no physical device capable of sending, say, 1000 messages

to 1000 distinct processors, at the same speed as if there were a single message. In the worst case, it would take 1000 times longer (serializing all messages). In the best case, the output bandwidth of the network card of the sender would be a limiting factor. In other words, assumption (2) amounts to assuming infinite network resources. Nevertheless, this assumption is omnipresent in the traditional scheduling literature.

Including communication costs in the model makes everything difficult, including solving $P_b(\infty)$, which becomes NP-complete in the strong sense. The intuitive reason is that a trade-off must be found between allocating tasks to either many processors (hence balancing the load but communicating intensively) or few processors (leading to less communication but less parallelism as well). Even the problem in which all task weights and communication costs have the same (unit) value, the so-called UET-UCT problem (unit execution time-unit communication time) is NP-hard [40].

With limited processors, list heuristics can be extended to take communication costs into account, but Graham's bound does not hold any longer. For instance, the *Modified Critical Path (MCP)* algorithm proceeds as follows. First, bottom levels are computed using a pessimistic evaluation of the longest path, accounting for each potential communication (this corresponds to the allocation where there is a different processor per task). These bottom levels are used to determine the priority of free tasks. Then each free task is assigned to the processor that allows its earliest execution, given previous task allocation decisions. It is important to explain further what "previous task allocation decisions" means. Free tasks from the queue are processed one after the other. At any moment, it is known which processors are available and which ones are busy. Moreover, for the busy processors, it is known when they will finish computing their currently allocated tasks. Hence, it is always possible to select the processor that can start the execution of the task under consideration the earliest. It may well be the case that a currently busy processor is selected.

The last extension of the "classical" line of work has been to handle heterogeneous platforms, that is, platforms that consist of processors with different speeds and interconnection links with different bandwidths. The main principle remains the same, namely, to assign the free task with highest priority to the "best" processor, given already given decisions. Now the "best" processor is the one capable to finish the execution of the task at the earliest, rather than starting the execution of the task, because computing speeds are different. These ideas have led to the design of the list heuristic called HEFT, for *Heterogeneous Earliest Finish Time* [51]. We refer the reader to [13] for a complete description of HEFT because we have omitted many technical (but important) implementation details. We stress that HEFT has received considerable acceptance and is the most widely used heuristic to schedule a task graph on a modern computing platform.

59.2.3 Realistic Communication Models

Assuming an application that runs threads on, say, a node that uses multicore technology, the network link could be shared by several incoming and outgoing communications. Therefore, the sum of the bandwidths allotted by the operating system to all communications cannot exceed the bandwidth of the network card. The *bounded multiport model* proposed by Hong and Prasanna [28] assesses that an unbounded number of communications can thus take place simultaneously, provided that they share the total available bandwidth.

A more radical option than limiting the total bandwidth is simply to forbid concurrent communications at each node. In the *one-port model*, a node can either send data or receive data, but not simultaneously. This model is thus very pessimistic as real-world platforms can achieve some concurrency of communication. On the other hand, it is straightforward to design algorithms that follow this model and thus to determine their performance a priori.

There are more complicated models such as those that deal with bandwidth sharing protocols [35,36]. Such models are very interesting for performance evaluation purposes, but they almost always prove too complicated for algorithm design purposes. For this reason, when scheduling task graphs, one prefers

to deal with the bounded multiport or the one-port model. As stated earlier, these models represent a good trade-off between realism and tractability, and we use them for all the examples and case studies of this chapter.

59.3 Underlying Principles

As stated in the introduction, the case studies provided in this chapter depart from pure makespan minimization. In this section, we briefly overview the main objectives that can be addressed instead of, or in complement to, the total execution time.

59.3.1 Multicriteria Optimization

The first case study (Section 59.4) deals with energy consumption. Processors can execute tasks at different frequencies, and there is a trade-off to achieve between fast execution (which implies high frequencies) and low-energy consumption (which requests low frequencies). To complicate matters, running at low frequencies increases the probability of a fault during the execution. Altogether, one faces a tri-criteria problem, involving makespan, energy, and reliability.

How to deal with several objective functions? In some approaches, one would form a linear combination of the different objectives and treat the result as the new objective to optimize for. But it is not natural for the user to maximize a quantity like $0.6M + 0.3E + 0.1R$, where M is the makespan, E the energy consumption, and R the reliability. Instead, one is more likely to fix an execution deadline and a reliability threshold, and to search for the execution that minimizes the energy consumption under these makespan and reliability constraints. One single criterion is optimized, under the condition that the constraints on the other criteria are not violated.

59.3.2 Memory Management

The second and third case studies (Sections 59.5 and 59.6) both deal with memory management issues. In Section 59.5, the goal is to traverse a task graph (an out-tree) and execute it with a prescribed amount of main memory. To execute a task, one needs to load the files produced by the parent of the task, the object code of the task itself, and all the files that it produces for its children. If there is not enough main memory available, secondary (out-of-core) memory must be used, at the price of a much slower execution. The ordering of the tasks chosen by the scheduler will have a dramatic impact on the peak amount of memory that is needed throughout the execution.

The problem investigated in Section 59.6 also deals with out-trees and is expressed as follows: How to partition the leaves of the tree in fixed-size parts so that the total memory load is minimized? Here the load of a part is the sum of the weights of the subtree formed by the leaves in the part. Intuitively, the goal is to construct parts whose leaves share many ancestors, so that the cost of loading these ancestors is paid for only a reduced number of times. Both case studies arise from scientific applications (such as multifrontal method for sparse linear algebra) that deploy large collections of tasks, and an efficient memory management is the key component to efficiency.

59.3.3 Reliability

The fourth case study (Section 59.7) addresses a completely different problem. Instead of dealing with task graphs, it deals with a single job that must be executed by one or several processors. This (large) job is divisible, meaning that it can be split arbitrarily into chunks of different sizes. Processors are subject to failures, which leads to take a checkpoint after each successful execution of a chunk. Indeed, after a failure, the execution can resume at the state of the last checkpoint. Frequent checkpoints avoid to lose (in fact, re-execute) a big fraction of the work when a failure occurs, but they induce a big overhead.

What is the optimal checkpointing policy? In some way, this problem can be viewed as a trade-off between makespan and reliability, but the framework is totally different from that of Section 59.4. The goal here is to minimize the expected makespan on a platform subject to failures. With the advent of future exascale machines that gather millions of processors, the problem has become central to the community.

59.4 Case Study: Tri-Criteria (Makespan, Energy, and Reliability) Scheduling

In this section, we are interested in energy-aware scheduling: the aim is to minimize the energy consumed during the execution of the target application. Energy-aware scheduling has proven an important issue in the past decade, both for economical and environmental reasons. This holds true for traditional computer systems, not even to speak of battery-powered systems. More precisely, a processor running at frequency f dissipates f^3 watts per unit of time [7,9,15], hence it consumes $f^3 \times d$ joules when operated during d units of time. To help reduce energy dissipation, processors can run at different frequencies, that is, different speeds. A widely used technique to reduce energy consumption is *dynamic voltage and frequency scaling (DVFS)*, also known as speed scaling [7,9,15]. Indeed, by lowering supply voltage, hence processor clock frequency, it is possible to achieve important reductions in power consumption; faster speeds allow for a faster execution, but they also lead to a much higher (supra-linear) power consumption. Processors can have arbitrary speeds, and can vary them continuously in the interval $[f_{\min}, f_{\max}]$. This model of continuous speeds is unrealistic (any possible value of the speed, say $\sqrt{e^\pi}$, cannot be obtained), but it is theoretically appealing [9].

Obviously, minimizing the energy consumption makes sense only when coupled with some performance bound to achieve, otherwise, the optimal solution always is to run each processor at the slowest possible speed. We consider a directed acyclic graph (DAG) of n tasks with precedence constraints, and the goal is to schedule such an application onto a fully homogeneous platform consisting of p identical processors. This problem has been widely studied with the objective of minimizing the total execution time, or *makespan*, and it is well known to be NP-complete [12]. Since the introduction of DVFS, many papers have dealt with the optimization of energy consumption while enforcing a deadline, that is, a bound on the makespan [5,7,9,15].

There are many situations in which the mapping of the task graph is given, say by an ordered list of tasks to execute on each processor, and we do not have the freedom to change the assignment of a given task. Such a problem occurs when optimizing for legacy applications, or accounting for affinities between tasks and resources, or even when tasks are pre-allocated [45], for example for security reasons. While it is not possible to change the allocation of a task, it is possible to change its speed. This technique, which consists in exploiting the slack due to workload variations, is called *slack reclaiming* [32,43]. In our previous work [5], assuming that the mapping and a deadline are given, we have assessed the impact of several speed variation models on the complexity of the problem of minimizing the energy consumption. Rather than using a local approach such as backfilling [43,54], which only reclaims gaps in the schedule, we have considered the problem as a whole.

While energy consumption can be reduced by using speed scaling techniques, it was shown in [17,57] that reducing the speed of a processor increases the number of transient fault rates of the system; the probability of failures increases exponentially, and this probability cannot be neglected in large-scale computing [39]. In order to make up for the loss in *reliability* due to the energy efficiency, different models have been proposed for fault-tolerance. In this section, we consider *re-execution*: a task that does not meet the reliability constraint is executed twice. This technique was also studied in [42,56,57], or in the case study of Section 59.7. The goal is to ensure that each task is reliable enough, that is, either its execution speed is above a threshold, ensuring a given reliability of the task, or the task is executed twice to enhance its reliability. There is a clear trade-off between energy consumption

and reliability, since decreasing the execution speed of a task, and hence the corresponding energy consumption, is deteriorating the reliability. This calls for tackling the problem of considering the three criteria (makespan, reliability, and energy) simultaneously. This tri-criteria optimization brings dramatic complications: in addition to choosing the speed of each task, as in the makespan/energy bi-criteria problem, we also need to decide which subset of tasks should be re-executed (and then choose both execution speeds).

Given an application with dependence constraints and a mapping of this application on a homogeneous platform, we present in this section theoretical results for the problem of minimizing the energy consumption under the constraints of both a reliability threshold per task and a deadline bound.

59.4.1 Tri-Criteria Problem

Consider an application task graph $\mathcal{G} = (V, \mathcal{E})$, where $V = \{T_1, T_2, \dots, T_n\}$ is the set of tasks, $n = |V|$, and where \mathcal{E} is the set of precedence edges between tasks. For $1 \leq i \leq n$, task T_i has a weight w_i , that corresponds to the computation requirement of the task. We also consider particular class of task graphs, such as *linear chains* where $\mathcal{E} = \bigcup_{i=1}^{n-1} \{T_i \rightarrow T_{i+1}\}$, and *forks* with $n + 1$ tasks $\{T_0, T_1, T_2, \dots, T_n\}$ and $\mathcal{E} = \bigcup_{i=1}^n \{T_0 \rightarrow T_i\}$.

We assume that tasks are mapped onto a parallel platform made up of p identical processors. Each processor has a set of available speeds that is continuous (in the interval $[f_{\min}, f_{\max}]$). The goal is to minimize the energy consumed during the execution of the graph while enforcing a deadline bound and matching a reliability threshold. To match the reliability threshold, some tasks are executed once at a speed high enough to satisfy the constraint, while some other tasks need to be re-executed. We detail next the conditions that are enforced on the corresponding execution speeds. The problem is therefore to decide which task to re-execute and at which speed to run each execution of a task.

In this section, for the sake of clarity, we assume that a task is executed at the same (unique) speed throughout execution, or at two different speeds in the case of re-execution. In Section 59.4.2, we show that this strategy is indeed optimal. We now detail the three objective criteria (makespan, reliability, and energy), and then define formally the problem.

The *makespan* of a schedule is its total execution time. We consider a *deadline bound* D , which is a constraint on the makespan. Let $\mathcal{E}xe(w_i, f)$ be the execution time of a task T_i of weight w_i at speed f . We assume that the cache size is adapted to the application, therefore ensuring that the execution time is linearly related to the frequency [37]: $\mathcal{E}xe(w_i, f) = w_i/f$. When a task is scheduled to be re-executed at two different speeds $f^{(1)}$ and $f^{(2)}$, we always account for both executions, even when the first execution is successful, and hence $\mathcal{E}xe(w_i, f^{(1)}, f^{(2)}) = \frac{w_i}{f^{(1)}} + \frac{w_i}{f^{(2)}}$. In other words, we consider a worst-case execution scenario, and the deadline D must be matched even in the case where all tasks that are re-executed fail during their first execution.

To define the *reliability*, we use the fault model of Zhu et al. [56,57]. *Transient* failures are faults caused by software errors for example. They invalidate only the execution of the current task and the processor subject to that failure will be able to recover and execute the subsequent task assigned to it (if any). In addition, we use the reliability model introduced by Shatz and Wang [48], which states that the radiation-induced transient faults follow a Poisson distribution. The parameter λ of the Poisson distribution is then

$$\lambda(f) = \tilde{\lambda}_0 e^{\tilde{d} \frac{f_{\max} - f}{f_{\max} - f_{\min}}}, \quad (59.1)$$

where

$f_{\min} \leq f \leq f_{\max}$ is the processing speed, the exponent $\tilde{d} \geq 0$ is a constant, indicating the sensitivity of fault rates to DVFS
 $\tilde{\lambda}_0$ is the average fault rate corresponding to f_{\max}

We see that reducing the speed for energy saving increases the fault rate exponentially. The reliability of a task T_i executed once at speed f is $R_i(f) = e^{-\lambda(f) \times \text{Exe}(w_i, f)}$. Because the fault rate is usually very small, of the order of 10^{-6} per time unit in [8,42], 10^{-5} in [4], we can use the first-order approximation of $R_i(f)$ as

$$R_i(f) = 1 - \lambda(f) \times \text{Exe}(w_i, f) = 1 - \lambda_0 e^{-df} \times \frac{w_i}{f},$$

where

$$d = \frac{\tilde{d}}{f_{\max} - f_{\min}}$$

$$\lambda_0 = \tilde{\lambda}_0 e^{df_{\max}}$$

This equation holds if $\varepsilon_i = \lambda(f) \times w_i / f \ll 1$. With, say, $\lambda(f) = 10^{-5}$, we need $w_i / f \leq 10^3$ to get an accurate approximation with $\varepsilon_i \leq 0.01$: the task should execute within 16 min. In other words, large (computationally demanding) tasks require reasonably high processing speeds with this model (which makes full sense in practice).

We want the reliability R_i of each task T_i to be greater than a given threshold, namely $R_i(f_{\text{re1}})$, hence enforcing a local constraint dependent on the task $R_i \geq R_i(f_{\text{re1}})$. If task T_i is executed only once at speed f , then the reliability of T_i is $R_i = R_i(f)$. Since the reliability increases with speed, we must have $f \geq f_{\text{re1}}$ to match the reliability constraint. If task T_i is re-executed (speeds $f^{(1)}$ and $f^{(2)}$), then the execution of T_i is successful if and only if one of the attempts do not fail, so that the reliability of T_i is $R_i = 1 - (1 - R_i(f^{(1)}))(1 - R_i(f^{(2)}))$, and this quantity should be at least equal to $R_i(f_{\text{re1}})$.

The *total energy consumption* corresponds to the sum of the energy consumption of each task. Let E_i be the energy consumed by task T_i . For one execution of task T_i at speed f , the corresponding energy consumption is $E_i(f) = \text{Exe}(w_i, f) \times f^3 = w_i \times f^2$, which corresponds to the dynamic part of the classical energy models of the literature [5,7,9,15]. Note that we do not take static energy into account, because all processors are up and alive during the whole execution.

If task T_i is executed only once at speed f , then $E_i = E_i(f)$. Otherwise, if task T_i is re-executed at speeds $f^{(1)}$ and $f^{(2)}$, it is natural to add up the energy consumed during both executions, just as we add up both execution times when enforcing the makespan deadline. Again, this corresponds to the worst-case execution scenario. We obtain $E_i = E_i(f_i^{(1)}) + E_i(f_i^{(2)})$. In this work, we aim at minimizing the total energy consumed by the schedule in the worst case, assuming that all re-executions do take place. This worst-case energy is $E = \sum_{i=1}^n E_i$.

Some authors [56] consider only the energy spent for the first execution, which seems unfair: re-execution comes at a price both in the deadline and in the energy consumption. Another possible approach would be to consider the expected energy consumption, which would require to weight the energy spent in the second execution of a task by the probability of this re-execution to happen. This would lead to a less conservative estimation of the energy consumption by averaging over many execution instances. However, the makespan deadline should be matched in all execution scenarios, and the execution speeds of the tasks have been dimensioned to account for the worst-case scenario, so it seems more important to report for the maximal energy that can be consumed over all possible execution instances.

We are now ready to define the optimization problem: given an application graph $\mathcal{G} = (V, \mathcal{E})$, mapped onto p homogeneous processors with continuous speeds, TRI-CRIT is the problem of deciding that tasks should be re-executed and at which speed each execution of a task should be processed, in order to minimize the total energy consumption E , subject to the deadline bound D and to the local reliability constraints $R_i \geq R_i(f_{\text{re1}})$ for each $T_i \in V$.

We also introduce variants of the problems for particular application graphs: TRI-CRIT-CHAIN is the same problem as TRI-CRIT when the task graph is a linear chain, mapped on a single processor;

and TRI-CRIT-FORK is the same problem as TRI-CRIT when the task graph is a fork, and each task is mapped on a distinct processor.

59.4.2 Complexity Results

Note that the formal proofs for this section can be found in [6]. As stated in Section 59.4.1, we start by proving that there is always an optimal solution where each task is executed at a unique speed:

Lemma 59.1

It is optimal to execute each task at a unique speed throughout its execution.

The idea is to consider a task whose speed changes during the execution; we exhibit a speed such that the execution time of the task remains the same, but where both energy and reliability are maybe improved, by convexity of the functions.

Next we show that not only a task is executed at a single speed, but that its re-execution (whenever it occurs) is executed at the same speed as its first execution:

Lemma 59.2

It is optimal to re-execute each task (whenever needed) at the same speed as its first execution, and this speed f is such that $f_i^{(inf)} \leq f < \frac{1}{\sqrt{2}} f_{rel}$, where

$$\lambda_0 w_i \frac{e^{-2df_i^{(inf)}}}{(f_i^{(inf)})^2} = \frac{e^{-df_{rel}}}{f_{rel}}. \quad (59.2)$$

Similarly to the proof of Lemma 59.1, we exhibit a unique speed for both executions, in case they differ, so that the execution time remains identical but both energy and reliability are improved. If this unique speed is greater than $\frac{1}{\sqrt{2}} f_{rel}$, then it is better to execute the task only once at speed f_{rel} , and if f is lower than $f_i^{(inf)}$, then the reliability constraint is not matched. Note that both lemmas can be applied to any solution of the TRI-CRIT problem, not just optimal solutions. We are now ready to assess the problem complexity:

Theorem 59.1

The TRI-CRIT-CHAIN problem is NP-hard, but not known to be in NP.

Note that the problem is not known to be in NP because speeds could take any real values. The completeness comes from SUBSET-SUM [22]. The problem is NP-hard even for a linear chain application mapped on a single processor (and any general DAG mapped on a single processor becomes a linear chain).

Even if TRI-CRIT-CHAIN is NP-hard, we can characterize an optimal solution of the problem:

Proposition 59.1

If $f_{re1} < f_{max}$, then in any optimal solution of TRI-CRIT-CHAIN, either all tasks are executed only once, at constant speed $\max\left(\frac{\sum_{i=1}^n w_i}{D}, f_{re1}\right)$; or at least one task is re-executed, and then all tasks that are not re-executed are executed at speed f_{re1} .

In essence, Proposition 59.1 states that when dealing with a linear chain, we should first slow down the execution of each task as much as possible. Then, if the deadline is not too tight, that is, if $f_{re1} > \frac{\sum_{i=1}^n w_i}{D}$, there remains the possibility to re-execute some of the tasks (and of course it is NP-hard to decide which ones). Still, this general principle “*first slow-down and then re-execute*” can guide the design of efficient heuristics (see [6]).

While the general TRI-CRIT problem is NP-hard even with a single processor, the particular variant TRI-CRIT-FORK can be solved in polynomial time:

Theorem 59.2

The TRI-CRIT-FORK problem can be solved in polynomial time.

The difficulty to provide an optimal algorithm for the TRI-CRIT-FORK problem comes from the fact that the total execution time must be shared between the source of the fork, T_0 , and the other tasks that all run in parallel. If we know D' , the fraction of the deadline allotted for tasks T_1, \dots, T_n once the source has finished its execution, then we can decide which tasks are re-executed and all execution speeds. Indeed, if task T_i is executed only once, it is executed at speed $f_i^{(once)} = \min(\max(w_i/D', f_{re1}), f_{max})$. Otherwise, it is executed twice at speed $f_i^{(twice)} = \min(\max(2w_i/D', f_{min}, f_i^{(inf)}), f_{max})$, where $f_i^{(inf)}$ is the minimum speed at which task T_i can be executed twice (see Lemma 59.2). The energy consumption for task T_i is finally $E_i = \min(w_i \times f_i^{(once)}, 2w_i \times f_i^{(twice)})$, and the case that reaches the minimum determines whether the task is re-executed or not. There remains to find the optimal value of D' , which can be obtained by studying the function of the total energy consumption, and bounding the value of D' to a small number of possibilities. Note however that this algorithm does not provide any closed-form formula for the speeds of the tasks, and that there is an intricate case analysis due to the reliability constraints.

If we further assume that the fork is made of identical tasks (i.e., $w_i = w$ for $0 \leq i \leq n$), then we can provide a closed-form formula. However, Proposition 59.2 illustrates the inherent difficulty of this *simple* problem, with several cases to consider depending on the values of the deadline, and also the bounds on speeds ($f_{min}, f_{max}, f_{re1}$, etc.). First, since the tasks all have the same weight $w_i = w$, we get rid of the $f_i^{(inf)}$ introduced earlier, since they are all identical (see Equation 59.2): $f_i^{(inf)} = f^{(inf)}$ for $0 \leq i \leq n$. Therefore we let $f_{min} = \max(f_{min}, f^{(inf)})$ in the following proposition below:

Proposition 59.2

In the optimal solution of TRI-CRIT-FORK with at least three identical tasks (and hence $n \geq 2$), there are only three possible scenarios: (1) no task is re-executed; (2) the n successors are all re-executed but not

the source; and (3) all tasks are re-executed. In each scenario, the source is executed at speed f_{src} (once or twice), and the n successors are executed at the same speed f_{leaf} (once or twice).

For a deadline $D < \frac{2w}{f_{max}}$, there is no solution. For a deadline $D \in \left[\frac{2w}{f_{max}}, \frac{w}{f_{rel}} \frac{(1+2n^{\frac{1}{3}})^{\frac{3}{2}}}{\sqrt{1+n}} \right]$, no task is re-executed (scenario (1)) and the values of f_{src} and f_{leaf} are the following:

- If $\frac{2w}{f_{max}} \leq D \leq \min \left(\frac{w}{f_{max}} (1+n^{\frac{1}{3}}), w \left(\frac{1}{f_{rel}} + \frac{1}{f_{max}} \right) \right)$, then $f_{src} = f_{max}$ and $f_{leaf} = \frac{w}{Df_{max} - w} f_{max}$
- If $\frac{w}{f_{max}} (1+n^{\frac{1}{3}}) \leq w \left(\frac{1}{f_{rel}} + \frac{1}{f_{max}} \right)$, then
 - if $\frac{w}{f_{max}} (1+n^{\frac{1}{3}}) < D \leq \frac{w}{f_{rel}} \frac{1+n^{\frac{1}{3}}}{n^{\frac{1}{3}}}$, then $f_{src} = \frac{w}{D} (1+n^{\frac{1}{3}})$ and $f_{leaf} = \frac{w}{D} \frac{1+n^{\frac{1}{3}}}{n^{\frac{1}{3}}}$
 - if $\frac{w}{f_{rel}} \frac{1+n^{\frac{1}{3}}}{n^{\frac{1}{3}}} < D \leq \frac{2w}{f_{rel}}$, then $f_{src} = \frac{w}{Df_{rel} - w} f_{rel}$ and $f_{leaf} = f_{rel}$
- If $\frac{w}{f_{max}} (1+n^{\frac{1}{3}}) > w \left(\frac{1}{f_{rel}} + \frac{1}{f_{max}} \right)$, then
 - if $w \left(\frac{1}{f_{rel}} + \frac{1}{f_{max}} \right) < D \leq \frac{2w}{f_{rel}}$, then $f_{src} = \frac{w}{Df_{rel} - w} f_{rel}$ and $f_{leaf} = f_{rel}$
- If $\frac{2w}{f_{rel}} < D \leq \frac{w}{f_{rel}} \frac{(1+2n^{\frac{1}{3}})^{\frac{3}{2}}}{\sqrt{1+n}}$, then $f_{src} = f_{leaf} = f_{rel}$

Note that for larger values of D , depending on f_{min} , we can move to scenarios (2) and (3) with partial or total re-execution. The case analysis becomes even more painful, but remains feasible. Intuitively, the property that all tasks have the same weight is the key to obtaining analytical formulas, because all tasks have the same minimum speed $f^{(inf)}$ dictated by Equation 59.2. Beyond the case analysis itself, the result of Proposition 59.2 is interesting: we observe that in all cases the source task is executed faster than the other tasks. This shows that Proposition 59.1 does not hold for general DAGs and suggests that some tasks may be more critical than others. A hierarchical approach that categorizes tasks with different priorities may guide the design of efficient heuristics (see [6]).

59.4.3 Conclusion

In this case study, we have accounted for the energy cost associated to task re-execution in a more realistic and accurate way than the best-case model used in [56]. Coupling this energy model with the classical reliability model used in [48], we have been able to formulate a tri-criteria optimization problem: How to minimize the energy consumed given a deadline bound and a reliability constraint? The “antagonistic” relation between energy and reliability renders this tri-criteria problem much more challenging than the standard bi-criteria (makespan, energy) version. We have assessed the intractability of this tri-criteria problem, even in the case of a single processor. In addition, we have provided several complexity results for particular instances. Note that several polynomial time heuristics are discussed in [6].

Further work could tackle the design of efficient approximation algorithms. However, this is quite a challenging work for arbitrary DAGs, and one may try to focus on special graph structures, for example, series-parallel graphs. However, looking back at the complicated case analysis needed for an elementary fork-graph with identical weights (Proposition 59.2), we cannot underestimate the difficulty of this problem. Also, it could be interesting to study the expected energy consumption, instead of the worst-case energy consumption. However, the complexity of the problems is likely

to increase drastically. Finally, we point out that energy reduction and reliability will be even more important objectives with the advent of massively parallel platforms, made of a large number of clusters of multicores. More efficient solutions to the tri-criteria optimization problem (makespan, energy, and reliability) could be achieved through combining replication with re-execution. A promising (and ambitious) research direction would be to search for the best trade-offs that can be achieved between these techniques that both increase reliability, but whose impact on execution time and energy consumption is very different. The comprehensive set of theoretical results presented in this case study provides solid foundations for further studies and constitutes a partial yet important first step for solving the problem at very large scale.

59.5 Case Study: Memory-Aware Scheduling

In this section, we review the latest results in memory-aware scheduling. When processing an application on a computational grid, it is likely that the involved data will have a very high volume. Such large data sizes may prevent the processing of some task on given resources, and more often, may prevent the processing of two data-intensive tasks on the same resource, because of the input and output data needed for these tasks. In this case, some of the data may need to be discarded from the main storage system (such as memory) and to be written to a secondary storage system (such as disk), to be able to proceed with the execution.

In grid computing, workflows are usually modeled as Directed Acyclic Graph (DAG), where nodes represent computational tasks and edges represent the dependencies among tasks. The dependencies are in the form of input and output files: each node accepts a set of (large) files as input, and produces a set of (large) files as output, each of them accepted by different child tasks. The execution scheme of such a workflow corresponds to a traversal of the DAG, where visiting a node translates into reading the associated input files and producing output files. Even on a single machine, finding a way to traverse the DAG to minimize the needed storage is a difficult problem: when restricting the problem to uniform sizes, it is similar to the pebble game problem, which has been proven NP-hard by Sethi [47] (the general problem allowing recomputation, that is, re-pebbling a vertex that has been pebbled before, has been proven PSPACE complete by Gilbert, Lengauer and Tarjan [24]). Latest studies focus on the restricted problem of traversing tree-shaped DAGs to minimize the memory demand on a single machine.

For convenience we refer to the two levels of storage as *main memory* and *secondary memory*, and also as *in-core* and *out-of-core*. Many combinations such as cache and RAM, or RAM and disk, or even disk and tape, lead to the same association of a faster but smaller storage device together with a larger but slower device. The difficulty remains the same for all combinations: find an execution scheme that makes the best use of *main memory*, and minimizes accesses to *secondary memory*.

Throughout the case study we consider *out-trees* where a task can be executed only if its parent has already been executed. However, all results equivalently apply to *in-trees*, where tasks are processed from the leaves up to the root, as explained later. Each task (or node) i in the tree is characterized by the size f_i of its input file (data needed before the execution and received from its parent), and by the size n_i of its execution file. During execution, nonleaf nodes generate several output files, one for each child, which can have different sizes. A task can be processed only in-core; its execution is feasible only if all its files (input, output, and execution) fit in currently available memory. More formally, let M be the size of the main memory, and S the set of files stored in this memory when the scheduler decides to execute task i . Note that S must contain the input file of task i . The processing of task i is possible if we have

$$MemReq(i) = f_i + n_i + \sum_{j \in Children(i)} f_j \leq M - \sum_{j \in S, j \neq i} f_j \quad (59.3)$$

where $MemReq(i)$ denotes the memory requirement of task i (and $Children(i)$ its child nodes in the tree). Once i has been executed, its input file and execution file can be discarded, and replaced by other files in main memory; the output files can either be kept in main memory, in order to execute some child of the task, or they can temporarily be stored into secondary memory (and retrieved later when the scheduler decides to execute the corresponding child of i). The volume of accesses (reads or writes) to secondary memory is referred to as the *I/O volume*.

Clearly, the traversal, that is, the order chosen to execute the tasks, plays a key role in determining which amount of main memory and I/O volume are needed for a successful execution of the whole tree. More precisely, there are two main problems that the scheduler must address

MINMEMORY Determine the minimum amount of main memory that is required to execute the tree without any access to secondary memory.

MINIO Given the size M of the main memory, determine the minimum I/O volume that is required to execute the tree.

Obviously, a necessary condition for the execution to be successful is that the size M of main memory exceeds the largest memory requirement over all tasks:

$$\max_i MemReq(i) \leq M$$

However, this condition is not sufficient, and a much larger main memory size may be needed for the **MINMEMORY** problem.

This problem has two main motivations. The first one (chronologically) arose from numerical linear algebra. Tree workflows (assembly or elimination trees) appear during the factorization of sparse matrices, and the huge size of the files involved makes it absolutely necessary to reduce the memory requirement of the factorization. The trees arising in this context are in-trees (as said before, there is no difference between in-trees and out-trees). Liu [33] discusses how to find the best traversal for the **MINMEMORY** problem when the traversal is required to correspond to a postorder traversal of the tree. In the follow-up study [34], an exact algorithm is proposed to solve the **MINMEMORY** problem, without the postorder constraint on the traversal. Another exact algorithm has been proposed recently [29]. Although its theoretical worst-case complexity is similar to Liu's algorithm, it performs better on elimination trees arising from real sparse matrix factorizations.

The second motivation for this problem comes from computations and simulations involving large objects, such as the accurate modeling of the electronic structure of atoms and molecules in quantum chemistry, or in some computational physics code. In this context, Liu's exact algorithm has been recently rediscovered by Lam et al. [31]. In the following, we first propose a formal model for the problem. Then we review state-of-the-art results and algorithms for the **MINMEMORY** and **MINIO** problems.

59.5.1 Problem Modeling

We consider a tree workflow \mathcal{T} composed of p nodes, or tasks, numbered from 1 to p . Nodes in the tree have an input file, an execution file (or program), and several output files (one per child). More precisely the following conditions hold true:

- Each node i has an input file of size f_i . If i is not the root, its input file is produced by its parent $parent(i)$; if i is the root, its input file can be of size zero, or contain input from the outside world.
- Each node i in the tree has an execution file of size n_i .
- Each nonleaf node i in the tree, when executed, produces a file of size f_j for each $j \in Children(i)$. Here $Children(i)$ denotes the set of the children of i . If i is a leaf node, then $Children(i) = \emptyset$ and i produces a file of null size: we then consider that the terminal data produced by leaves are directly written to the secondary memory or sent to the outside world, independently from the I/O mechanism.

The memory requirement $MemReq(i)$ of node i is the total amount of main memory that is needed to execute node i , as underlined in Equation 59.3. After i has been processed, its input file and program can be discarded, while its output files can either be kept in main memory (to process the children of i) or be stored in secondary memory temporarily.

59.5.2 In-Core Traversals and the MINMEMORY Problem

For the MINMEMORY problem, we are given a tree \mathcal{T} with p nodes and an initial amount of memory M . A traversal is an ordering of the p nodes that specifies at which step they are executed. A traversal must obey precedence constraints (a node is always scheduled after its parent) and must never exceed the available memory. A formal definition of a traversal is given next.

Definition 59.1 (INCORETRAVERSAL)

Given a tree \mathcal{T} and a amount M of available memory, the problem INCORETRAVERSAL(\mathcal{T} , M) consists in finding a feasible in-core traversal σ described by a permutation of the nodes of a tree \mathcal{T} such that

$$\forall i \neq \text{root}, \quad \sigma(\text{parent}(i)) < \sigma(i) \quad (59.4)$$

$$\forall i \quad \sum_{\sigma(j) < \sigma(i)} \left(\sum_{k \in \text{Children}(j)} f_k - f_j \right) + n_i + \sum_{k \in \text{Children}(i)} f_k \leq M \quad (59.5)$$

In this definition, Equation 59.4 accounts for precedence constraints and Equation 59.5 deals with memory constraints. A postorder traversal is a traversal where nodes are visited according to some top-down postorder ordering of the tree nodes. Hence, in a postorder traversal, after processing a vertex i , the whole subtree rooted in i is completely processed.

Definition 59.2 (MINMEMORY)

Given a tree \mathcal{T} , determine the minimum amount of memory M such that INCORETRAVERSAL(\mathcal{T} , M) has a solution. MINMEMORY-POSTORDER is the same problem restricted to postorder traversals.

Here, we have chosen to define the problem for out-trees and top-down traversals. However, it is possible to define a similar problem for in-trees and bottom-up traversals. Both problems are equivalent. Consider an in-tree \mathcal{T} and the out-tree \mathcal{T}' obtained when reversing all its edges. Then, from any traversal of \mathcal{T} we can obtain a valid traversal of \mathcal{T}' with same memory footprint simply by reversing the order of visited nodes. Thus, all results mentioned in the following apply both for in-trees and out-trees.

59.5.2.1 Postorder Traversals

Postorder traversals are very natural for the MINMEMORY problem, and they are widely used in sparse matrix software like MUMPS [2,3]. Liu [33] has characterized the best postorder traversal, leading to a fast but suboptimal solution for MINMEMORY. In a nutshell, the best postorder is obtained by guaranteeing that in the resulting order the children of a node are listed in the increasing order of the memory requirement of their respective subtrees. This can be done with a recursive algorithm, which computes

a memory-optimal schedule for each subtree: at each level subtrees are sorted in nonincreasing order of $\max_{i \in \text{subtree}} (\text{MemReq}(i) - f_{\text{subroot}})$ (where *subroot* is the root of the current subtree). In the following, we denote this algorithm by *PostOrder*. Although it has a low time complexity ($O(p \log(p))$) and it is widely used in practice, it may require arbitrarily more main memory than the optimal traversal.

Theorem 59.3

Given any arbitrarily large integer K , there exist trees for which the best postorder traversal requires at least K times the amount of main memory needed by the optimal traversal for MINMEMORY.

The proof of this results relies on the family of trees illustrated in Figure 59.1, where all branches are identical and all tasks have a zero length execution file. On the single-level tree of Figure 59.1a, any postorder traversal requires an amount of $M + \epsilon + (b - 1)M/b$ main memory, while the optimal traversal (which alternates between branches) only requires $M_{\min} = M + \epsilon$. Now replace each leaf by a copy of the harpoon graph, as shown in Figure 59.1b. The value of M_{\min} is unchanged, while a postorder traversal requires $M + \epsilon + 2(b - 1)M/b$. Iterating the process K times leads to the desired result.

The tree used to prove that postorder may require an arbitrarily large memory compared from the optimal is very different to usual trees encountered in practice: it has many edges with zero weight, and on a path from the root, the edge weights alternate between large and small values. It is thus interesting to compare the actual performance of *PostOrder* in terms of the memory requirement of the resulting traversal with respect to the optimal value on realistic trees. To this goal, one can use assembly trees that arise from the factorization of matrices obtained from the University of Florida Sparse Matrix Collection (see [29] for details on the experimental dataset). The optimal memory requirement of a traversal is computed using the exact algorithms presented later. The experiments show that in 95.8% of the cases, *PostOrder* is optimal. In the nonoptimal cases, *PostOrder* requires up to 18% more memory than the optimal solution (the average increase in memory is around 1%).

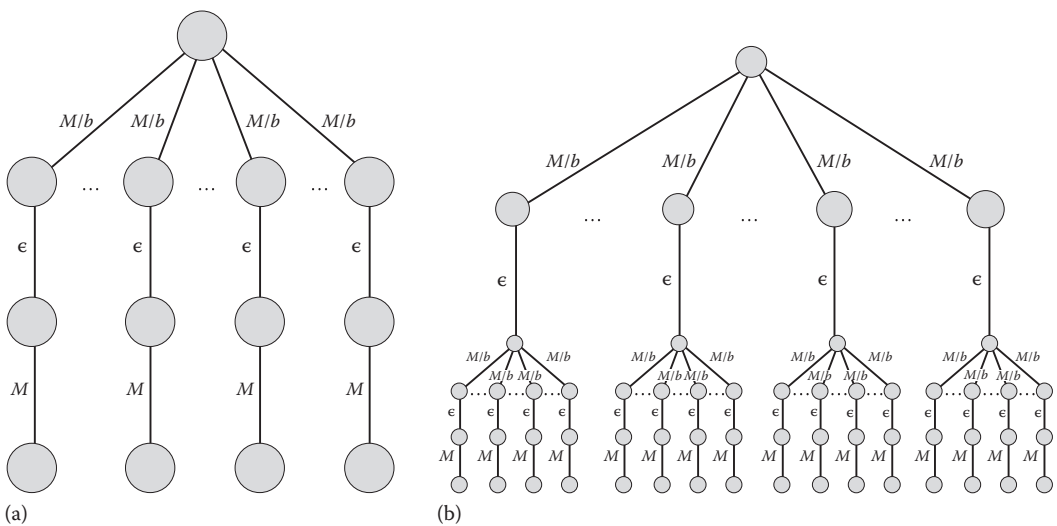

FIGURE 59.1 First levels of the graph for the proof of Theorem 59.3. Here b is the number of children of the nodes with more than one child: (a) One level and (b) two levels.

59.5.2.2 Exact Algorithms

Liu [34] proposes an algorithm for MINMEMORY that is optimal among all possible traversals, not only postorder ones. It is a recursive bottom-up traversal of the tree that, at each node of the tree, combines the optimal traversals built for all subtrees (see Algorithms 59.1 and 59.2). The combination is based on the notion of *Hill-Valley Segments*: the schedule corresponding to a subtree is split into a sequence of segments. Each segment ends at a (local) minimum memory: to minimize the memory, it is better to totally process a segment before switching to the processing of another subtree. Then, the sequence of segments computed for all subtrees are ordered by nonincreasing *hill - valley* value and merged. The motivation is then to process first segments with high memory peak (hill) but small residual memory requirement (valley).

Liu provides a complex proof for the optimality of the obtained schedule. It also states that the worst-case complexity of this algorithm is $O(p^2)$ using some sophisticated multiway merging algorithm.

Algorithm 59.1 *LiuMinMem(T)*

Input: tree T rooted at r

if r is a leaf **then**

return the sequence consisting of the node r

else

Let T_1, \dots, T_k be the subtrees rooted at the children of r **for** $i = 1, \dots, k$ **do**

$S_i \leftarrow \text{LiuMinMem}(T_i)$

return $S = \text{Combine}(T, S_1, \dots, S_k)$

Algorithm 59.2 *Combine (T, S₁, ..., S_k)*

for $i = 1, \dots, k$ **do**

Compute the memory occupation at each step of S_i when processing subtree T_i

Split S_i into a series of m segments such that:

- the memory occupation at the end of the first segment is the minimum memory (valley) in S_i
- the memory occupation at the end of the i th segment is the minimum memory in S_i restricted to segments i to m

For each segment s , compute its hill (maximum memory) and valley (minimum memory) values

Sort all segments by hill-valley value

return this ordering of the nodes

Another optimal algorithm, the *MinMem* has been proposed in [29] to minimize memory during the tree traversal. It is based on an advanced tree exploration routine: the *Explore* algorithm described in Algorithm 59.3. The *Explore* algorithm requires a tree T to explore and an amount of available memory M_{avail} . With these parameters, the algorithm computes the state with minimal residual memory that can be reached with memory M_{avail} . If the whole tree can be processed, then the minimal residual memory is zero. Otherwise, the algorithm stops before reaching the bottom of the tree, because some parts of the tree require more memory than what is available. In this case, the state with minimal residual memory corresponds to a *cut* in the tree: some subtrees are not yet processed, and the input files of their root nodes are still stored in memory. The *Explore*

algorithm outputs the cut with minimal memory occupation, as well as a possible traversal to reach this state with the provided memory.

When called on a tree T , the algorithm first checks if the current node can be executed. If not, the algorithm stops. Otherwise, it recursively proceeds in its subtree. The optimal cut is initialized with its children, and iteratively improved. All the nodes in the cut are explored: if the cut L_j found in the subtree of a child j has a smaller memory occupation than the child itself, the cut is updated by removing child j , and by adding the corresponding cut L_j . When no more nodes in the cut can be improved, then the algorithm outputs the current cut.

The *Explore* algorithm can be used to check whether a given tree can be processed using a given memory. A possible way to compute the minimum memory to process the tree is then to perform a binary search on the available memory. However, there are several ways to speed-up such an algorithm (for details, see [29]):

- We can transform the *Explore* algorithm so that it also returns the minimum increment in the available memory needed to explore more nodes. This helps to reduce the number of calls to *Explore*.

Algorithm 59.3 *Explore*(T, M^{avail})

Input: tree T rooted at r and available memory M^{avail}

Output: $\langle L, m, S \rangle$ where L is a state (described by the input files it contains) with minimum memory m which can be reached with memory M , and S a schedule to reach it.

if r is a leaf and there is enough memory for its processing **then**

return $\langle \emptyset, 0, (r) \rangle$

if there is not enough memory to process r **then**

return $\langle \emptyset, \infty, \emptyset \rangle$

$S \leftarrow (r)$

$\text{CurrentCut} \leftarrow \{\text{Children of } r\}$

$\text{stopped} \leftarrow 0$

while $\text{stopped} \neq 1$ **do**

$\text{stopped} \leftarrow 1$

foreach $j \in \text{CurrentCut}$ **do**

Compute the available memory for the processing of the subtree at j :

$$M_j^{\text{avail}} \leftarrow M_j^{\text{avail}} - \sum_{k \in \text{CurrentCut} \setminus \{j\}} f_k$$

$$\langle L_j, m_j, S_j \rangle \leftarrow \text{Explore}(T, M_j^{\text{avail}})$$

if exploring the subtree at j leads to state with less memory: $m_j \leq f_j$ **then**

$\text{stopped} \leftarrow 0$

$\text{CurrentCut} \leftarrow \text{CurrentCut} \setminus \{j\} \cup L_j$

append traversal S_j to the end of S : $S \leftarrow S \oplus S_j$

$$m \leftarrow \sum_{j \in \text{CurrentCut}} f_j$$

return $\langle \text{CurrentCut}, m, S \rangle$

- When calling *Explore* several times on the same subtree with an increasing memory, the beginning of the subtree will be explored many times. To avoid this, it is possible to store the current state of exploration, as well as the current schedule. This ensures that nodes are not visited several times.

Using these optimizations, it is possible to prove that the *MinMem* algorithm based on the *Explore* procedures has a similar time complexity with *LiuMinMem* ($O(p^2)$). Although both exact algorithms have the same worst-case time complexity, it is interesting to note that *MinMem* is faster than *LiuMinMem* on realistic trees: Experiments on the same set of trees described earlier show that *MinMem* is the fastest algorithm in 80% of the cases. This is explained by the fact that *LiuMinMem* has to sort segments when merging schedules obtained for subtrees. On the contrary, *MinMem* does not use sorting. This can make a significant difference if, for example, for each node, the size of the input file is larger than the size of the output files, *MinMem* will run in $O(n)$ for a tree of n nodes.

59.5.3 Out-of-Core Traversals and the MINIO Problem

Out-of-core processing enables solving large problems, when the size of the data cannot fit into the main memory. In this case, some temporary data are copied into the secondary memory, and unloaded from the main memory, so as to leave room for other computations. Since secondary memory has a smaller access rate, the usual objective is to limit the volume of I/O operations.

Defining traversals that perform I/O operations is more complicated than defining in-core traversals: in addition to determining the ordering of the nodes (the permutation σ), at each step we have to identify which files are written into secondary memory (if necessary). When a task i is scheduled for execution but its input file was moved to secondary memory, that file must be read and loaded back into the main memory before processing task i . Thus, a given file is written at most once in the secondary memory. Moreover, if a file is to be written in the secondary memory, it is always beneficial to write it as soon as it is created. Thus, we can model the I/O operations via a binary function δ_{IO} such that $\delta_{IO}(i) = 1$ if and only if the input file of task i (of size f_i) should be moved to secondary memory. Formally, a valid out-of-core traversal can be defined as follows.

Definition 59.3 (OUTOF CORE TRAVERSAL)

Given a tree \mathcal{T} and a fixed amount of main memory M , the problem $\text{OUTOF CORE TRAVERSAL}(\mathcal{T}, M)$ consists in finding an out-of-core traversal, described by a permutation σ of the nodes in \mathcal{T} (corresponding to the schedule of computations), and a binary function δ_{IO} (corresponding to I/O operations), such that:

$$\forall i \neq \text{root}, \quad \sigma(\text{parent}(i)) < \sigma(i) \quad (59.6)$$

$$\forall i, \quad \sum_{\sigma(j) < \sigma(i)} \left(\sum_{k \in \text{Children}(j)} f_k - f_j \right) - \sum_{\substack{\sigma(\text{parent}(j)) \\ < \sigma(i) < \sigma(j) \\ \delta_{IO}(j)=1}} f_j + n_i + \sum_{k \in \text{Children}(i)} f_k \leq M \quad (59.7)$$

Then the amount of data written in secondary memory is given by

$$IO = \sum_{\delta_{IO}(i)=1} f_i$$

In Equation 59.7, the term $\sum_{\substack{\sigma(\text{parent}(j)) < \sigma(i) < \sigma(j) \\ \delta_{IO}(j)=1}} f_j$ corresponds to the files that have been written into secondary memory at step $\sigma(i)$. The MINIO problem, which asks for an out-of-core traversal with the minimum amount of I/O volume, can be defined as follows.

Definition 59.4 (MINIO)

Given a tree \mathcal{T} , and a fixed amount of main memory M , determine the minimum I/O volume IO needed by a solution of $OUTOFCORETRAVERSAL(\mathcal{T}, M)$.

The following three variants of the problem are NP-complete.

Theorem 59.4

Given a tree \mathcal{T} with p nodes, and a fixed amount of main memory M , consider the following problems:

- (i) Given a postorder traversal σ of the tree, determine the I/O schedule so that the resulting I/O volume is minimized.
- (ii) Determine the minimum I/O volume needed by any postorder traversal of the tree.
- (iii) Determine the minimum I/O volume needed by any traversal of the tree.

The (decision version of) each problem is NP-complete.

Note that (iii) is the original MINIO problem. Also note that the NP-completeness of (i) does not a priori imply that of (ii), because the optimal postorder traversal could have a particular structure. The same comment applies for (ii) not implying (iii). The proof of these three results all relies on a reduction from 2-Partition problem [22], using the tree illustrated in Figure 59.2. Scheduling this tree with a memory $M = 2S$ an maximum amount IO of $IO = 2/S$ requires to process first task T_{big} , and thus to select a subset of a_i s (the input file of tasks T_i), which sums exactly to $S/2$. For more details on the proofs for all variants, see [29].

59.5.4 Perspectives and Open Problems

We have gathered in this section existing results on the problem of scheduling trees under memory constraints. Many problems are still open. The first one concerns splittable files. Indeed, the NP-completeness

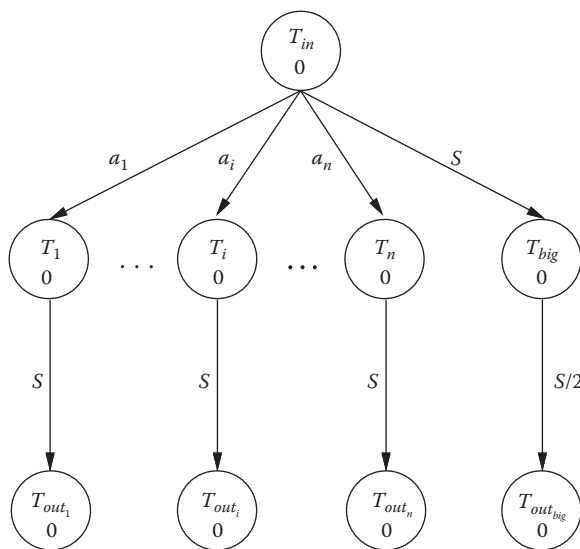

FIGURE 59.2 Reduction of an instance of the 2-Partition problem for the NP-completeness proof of MINIO.

of the MINIO problem comes from the difficulty to find a subset of files whose sizes sum up to a given bound. However, most memory systems nowadays are paginated and allows to write only portions of files to secondary memory. Therefore, studying the complexity of the MINIO problem with splittable files is very relevant. This problem is still open.

The results presented here only concern the processing of trees on a single machine. It is crucial to extend these results for other type of graphs (like series-parallel graphs, or any DAGs), and for parallel machines. It is likely that most problems will be NP-complete, but the results on trees may be useful to derive good heuristics, in the best case with approximation bounds. Even if approximation algorithms seem out of reach for general traversals, there is hope to derive an approximation algorithm for post-order traversals of trees, which are simpler to analyze than arbitrary traversals.

59.6 Case Study: Partitioning Tree Structured Computations

The problem addressed in this case study arises in the solution of linear systems with a direct method, and with an out-of-core environment [1]. In order to make the section self-contained, we investigate the combinatorial problem (in Sections 59.6.1 through 59.6.3) without linear algebra notions and refer the curious reader to the related reference items. We briefly discuss the mentioned application and one more related scenario in Section 59.6.4.

59.6.1 Definitions

Let $T = (V, E)$ be a rooted tree where all the edges are toward the root node r . Each node u , except the root, has a parent. Each node u , except the leaves, has a set of children, which are the nodes whose parent is u . For each node u , the vertices in the unique path from u to r are called the ancestors of u , and they are denoted by $P(u)$. The nodes u and r are included in $P(u)$. A subtree of T rooted at a node u contains all nodes v for which $u \in P(v)$; we use $T(u)$ to denote that subtree and use $L(u)$ to denote the leaf nodes in the subtree $T(u)$. A topological ordering of a tree $T = (V, E)$ is an ordering of the nodes V in such a way that any node is numbered before its parent; the root node is ordered last. A postorder traversal of a tree is a topological ordering where the nodes in each subtree are numbered consecutively.

There is a weight associated with each internal node of T . We use $w(u)$ to denote the weight of the node u . Leaf nodes are special and have zero weight. We are given a set of n tasks t_1, t_2, \dots, t_n . Each task is associated with a unique leaf node. In order to execute the task t_i , one starts from a leaf node ℓ_i and visits all the internal nodes in $P(\ell_i)$. Visiting an internal node u entails a cost, $w(u)$. A task requires a unit amount of memory storage throughout its execution. The task executions are nonpreemptive, that is, when a task is started, it continues until the root node. One can execute two or more tasks concurrently at each internal node, where the cost payed at a node u is always $w(u)$, irrespective of the number of concurrent tasks. As each task requires a unit amount of memory storage, the number of concurrent tasks is limited. In such a case, one takes as many tasks as possible and executes them concurrently till the root node. The problem then becomes that of partitioning the tasks into groups so that each group can be stored in the memory while the total cost is minimized.

We now define the problem formally. The cost associated with a task t_i is

$$\text{cost}(t_i) = \sum_{u \in P(\ell_i)} w(u). \quad (59.8)$$

If we execute a set S of tasks concurrently, the associate cost is

$$\text{cost}(S) = \sum_{u \in P(S)} w(u) \quad \text{where } P(S) = \bigcup_{t_i \in S} P(t_i).$$

Let B be the maximum number of tasks one can execute concurrently. Then we have the following TREEPARTITIONING problem. Given a tree T , a set of tasks $S = \{t_1, t_2, \dots, t_n\}$, and an integer $B \leq n$, partition S into a number of subsets S_1, S_2, \dots, S_K such that $|S_k| \leq B$, for $k = 1, \dots, K$ and the total cost

$$\sum_{k=1}^K \text{cost}(S_k) \quad (59.9)$$

is minimum. The number of parts K is not specified (but for feasibility we have $K \geq \lceil n/B \rceil$).

59.6.2 Complexity Results

Before introducing the complexity results (and algorithms), we present a lower bound for the cost of an optimal partition.

Theorem 59.5

Let T be a node weighted tree, $w(u)$ be the weight of node u , B be the maximum allowed size of a partition, and $L(u)$ be the number of leaf nodes in the subtree rooted at u . Then we have the following lower bound, denoted by η , on the optimal solution c^* of the TREEPARTITIONING problem:

$$\eta = \sum_{u \in T} w(u) \times \left\lceil \frac{L(u)}{B} \right\rceil \leq c^*.$$

Proof. Follows easily by noting that the leaf nodes of the subtree $T(u)$ will be partitioned among at least $\left\lceil \frac{L(u)}{B} \right\rceil$ parts.

Each internal node is on a path from (at least) one leaf node, therefore $\left\lceil L(u)/B \right\rceil$ is at least 1, and we have $\sum_u w(u) \leq c^*$.

Theorem 59.6

The TREEPARTITIONING problem is NP-complete.

Proof. We consider the associated decision problem: given a tree T with n leaves, a value of B , and a cost bound c , does there exist a partitioning S of the n leaves into subsets whose size does not exceed B , and such that $\text{cost}(S) \leq c$? It is clear that this problem belongs to NP since if we are given the partition S , it is easy to check in polynomial time that it is valid and that its cost meets the bound c . We now have to prove that the problem is in the NP-complete subset.

To establish the completeness, we use a reduction from 3-PARTITION [22], which is NP-complete in the strong sense. Consider an instance \mathcal{I}_1 of 3-PARTITION: given a set $\{a_1, \dots, a_{3p}\}$ of $3p$ integers, and an integer Z such that $\sum_{1 \leq j \leq 3p} a_j = pZ$, does there exist a partition of $\{1, \dots, 3p\}$ into p disjoint subsets K_1, \dots, K_p , each with three members, such that for all $1 \leq i \leq p$, $\sum_{j \in K_i} a_j = Z$?

We build the following instance \mathcal{I}_2 of our problem: the tree is a three-level tree composed of $N = 1 + 3p + pZ$ nodes: the root v_r , of cost w_r , has $3p$ children v_i , of the same cost w_r , for $1 \leq i \leq 3p$. In turn, each v_i has a_i children, each being a leaf node of zero cost. This instance \mathcal{I}_2 of the TREEPARTITIONING

FIGURE 59.3 The instance of the TREEPARTITIONING problem corresponding to a given 3-PARTITION PROBLEM. The weight of each node is shown next to the node. The minimum cost of a solution for $B = Z$ to the TREEPARTITIONING problem is $p \times w_r + 3p \times w_v$, which is only possible when the children of each internal node are all in the same part, and when the children of three different internal nodes, say v_i, v_j, v_k , are put in the same part. This corresponds to putting the numbers a_i, a_j, a_k into a set for the 3-PARTITION problem, which sums up to Z .

problem is shown in Figure 59.3. We let $B = Z$ and ask whether there exists a partition of leaf nodes of cost $c = pw_r + 3pw_v$. Here w_r and w_v are arbitrary values (we can take $w_r = w_v = 1$). We note that the cost c corresponds to the lower bound shown in Theorem 59.5; in this lower bound, each internal node v_i is loaded only once, and the root is loaded p times, since it has $pZ = pB$ leaves below it. Note that the size of \mathcal{I}_2 is polynomial in the size of \mathcal{I}_1 . Indeed, because 3-PARTITION is NP-complete in the strong sense, we can encode \mathcal{I}_1 in unary, and the size of the instance is $O(pZ)$.

Now we show that \mathcal{I}_1 has a solution if and only if \mathcal{I}_2 has a solution. Suppose first that \mathcal{I}_1 has a solution K_1, \dots, K_p . The partition of leaf nodes corresponds exactly to the subsets K_i ; we build p subsets S_i whose leaves are the children of vertices v_j with $j \in K_i$. Suppose now that \mathcal{I}_2 has a solution. To meet the cost bound, each internal node has to be loaded only once, and the root at most p times. This means that the partition involves at most p subsets to cover all leaves. Because there are pZ leaves, each subset is of size exactly Z . Because each internal node is loaded only once, all its leaves belong to the same subset. Altogether, we have found a solution to \mathcal{I}_1 , which concludes the proof.

We can further show that we cannot get a close approximation to the optimal solution in polynomial time.

Theorem 59.7

Unless $P = NP$, there is no $1 + o\left(\frac{1}{m}\right)$ polynomial approximation for trees with m nodes in the TREEPARTITIONING problem.

Proof. Assume that there exists a polynomial $1 + \frac{\epsilon(m)}{m}$ approximation algorithm for trees with m nodes, where $\lim_{m \rightarrow \infty} \epsilon(m) = 0$. Let $\epsilon(m) < 1$ for $m \geq m_0$. Consider an arbitrary instance \mathcal{I}_0 of 3-PARTITION with a set $\{a_1, \dots, a_{3p}\}$ of $3p$ integers, and an integer Z such that $\sum_{1 \leq j \leq 3p} a_j = pZ$. Without loss of generality, assume that $a_i \geq 2$ for all i (hence $Z \geq 6$). We ask if we can partition the $3p$ integers of \mathcal{I}_0 into p triplets of the same sum Z . Now we build an instance \mathcal{I}_1 of 3-PARTITION by adding X times the integer $Z - 2$ and $2X$ times the integer 1 to \mathcal{I}_0 , where $X = \max\left(\left\lfloor \frac{(m_0 - 1)}{(Z + 3)} \right\rfloor - p, 1\right)$. Hence, \mathcal{I}_1 has $3p + 3X$ integers and we ask whether these can be partitioned into $p + X$ triplets of the same sum Z . Clearly, \mathcal{I}_0 has a solution if and only if \mathcal{I}_1 does (the integer $Z - 2$ can only be in a set with two 1s).

We build an instance \mathcal{I}_2 of TREEPARTITIONING from \mathcal{I}_1 exactly as we did in the proof of Theorem 59.6, with $w_r = w_v = 1$, and $B = Z$. The only difference is that the value p in the proof has been replaced by

$p + X$ here, therefore the three-level tree now has $m = 1 + 3(p + X) + (p + X)Z$ nodes. Note that X has been chosen so that $m \geq m_0$. Just as in the proof of Theorem 59.6, \mathcal{I}_1 has a solution if and only if the optimal cost for the tree is $c^* = 4(p + X)$, and otherwise the optimal cost is at least $4(p + X) + 1$.

If \mathcal{I}_1 has a solution, and because $m \geq m_0$, the approximation algorithm will return a cost at most

$$\left(1 + \frac{\varepsilon(m)}{m}\right) c^* \leq \left(1 + \frac{1}{m}\right) 4(p + X) = 4(p + X) + \frac{4(p + X)}{m}.$$

But $\frac{4(p + X)}{m} = \frac{4(m - 1)}{(Z + 3)m} \leq \frac{4}{9} < 1$, so that the approximation algorithm can be used to determine whether \mathcal{I}_1 , and hence \mathcal{I}_0 , has a solution. This is a contradiction unless $P = NP$.

59.6.3 Approximation Algorithm

Consider the heuristic **POPART** shown in Algorithm 59.4 for the **TREEPARTITIONING** problem. As seen in Algorithm 59.4, the **POPART** heuristic first orders the leaf nodes according to their rank in the postorder. It then puts the first B leaves in the first part, the next B leaves in the second part, and so on. This simple partitioning approach results in $\lceil n / B \rceil$ parts, for a tree with n leaf nodes, and puts B nodes in each part, except maybe in the last one. We have the following theorem, which states that this simple heuristic obtains results that are at most twice the cost of an optimum solution.

Algorithm 59.4 *POPART: A postorder-based partitioning*

Input $T = (V, E)$ with n leaves; each requested entry corresponds to a leaf node.

Input B : the maximum allowable size of a part.

Output $\Pi_{PO} = \{S_1, \dots, S_K\}$ where $K = \lceil n / B \rceil$, a partition on the leaf nodes.

- 1: compute a postorder of the nodes of T
- 2: $\mathcal{L} \leftarrow$ sort the leaf nodes according to their rank in the postorder
- 3: $S_k = \{\mathcal{L}(i) : (k - 1) \times B + 1 \leq i \leq \min\{k \times B, n\}, \text{ for } k = 1, \dots, \lceil n / B \rceil\}$

Theorem 59.8

Let Π_{PO} be the partition obtained by the algorithm **POPART** and c^* be the cost of an optimum solution. Then

$$\text{cost}(\Pi_{PO}) \leq 2 \times c^*.$$

Proof. Consider node u . Since the leaves of the subtree rooted at u are sorted consecutively in \mathcal{L} , the contribution of node u to the cost will be at most $\left\lceil \frac{L(u)}{B} \right\rceil + 1$. Therefore, the overall cost is at most

$$\begin{aligned} \text{cost}(\Pi_{PO}) &\leq \sum_u w(u) \times \left(\left\lceil \frac{L(u)}{B} \right\rceil + 1 \right) \\ &\leq \eta + \sum_u w(u) \\ &\leq 2 \times c^* \end{aligned}$$

59.6.4 Application Scenarios

In the application of the TREEPARTITIONING problem described by Amestoy et al. [1], each task corresponds to a sparse triangular solve operation with a right-hand-side (RHS) vector containing a single nonzero. There is a tree that describes the data requirements for each solve operation. Each internal node of the tree corresponds to parts of the triangular matrices stored in a file at disk. Solve operation for a given RHS vector starts from a leaf node and climbs up to the root. At each internal node, the matrix parts associated with that node are read from a file, and their inverse are applied to the RHS vector. All the RHS vectors are of the same size, and there is a huge number of them. Due to the limited memory size, one can hold only a certain number of RHS vectors at once in memory. In this setting, one organizes the solve operations in epochs where at each epoch a set of RHS vectors are solved for. Any internal node is accessed at most once during an epoch, but it can be accessed in multiple epochs. The solution time of an epoch is dominated by the time spent in reading the files containing the parts of the triangular matrices. In order to minimize the completion time of the application, one has to minimize the total size of the files read in. This is an instance of the TREEPARTITIONING problem where the tasks are solve operations; B is the number of unit size RHS vectors that one can hold in memory; the cost associated with an internal node is the size of the corresponding file; and the objective function is the total size of the files read in.

Consider a hypothetical application whose tasks correspond to paths from a leaf node to the root in a given tree. Assume that each internal node is associated with a data. Consider the following parallelization approach. Each task is to be executed by a single processor. This necessitates replicating the nodes of the tree at different processors so that each task can be executed by the owner processor. This can be again described as an instance of the TREEPARTITIONING problem, where this time B is a function of the available processors. Consider again the same application, where we do not want to replicate the data. In a possible parallelization approach, the data should be partitioned, and the tasks should be migrated from one processor to the other whenever needed (e.g., when the parent of a node and the node itself are at different processors). This time, one partitions the internal nodes of a tree so that the leaf-to-root paths are split among as few parts as possible. This seemingly different problem is addressed elsewhere [23] with techniques that are very different than what we saw in this section. However, it is possible to express both problems using hypergraph models and use a common algorithm to obtain effective solutions [52].

59.7 Case Study: Checkpointing Strategies

Any hardware component may be subject to faults. The Mean Time Between Failures (MTBF) of a processor is typically of the order of 100 years. The reader can thus very safely bet that his laptop processor will not fail within the next month. Therefore, she does not need any fault-tolerance technique to safely run a computation on his laptop for, say, 12 h. Things are completely different if the 12-h computation is performed using a large number of processors. Indeed, the probability that one of the processors used by the application will fail during the 12 h of the application execution dramatically increases with the number of processors enrolled in the execution. For instance, the 45,208-processor Jaguar platform is reported to experience on the order of one failure per day [10,38]. In other words, during any execution that would run for 12 h using the entire Jaguar platform, there is one chance out of two that a fault will occur. Faults that cannot be automatically detected and corrected in hardware lead to application failures. Using fault-tolerance techniques is thus mandatory when using a large number of processors for a significant amount of time. Resilience—the ability to resist to failures—is thus a key challenge for modern and future high-performance computing (HPC) systems [18,46].

The most used fault-tolerance technique is rollback recovery: after a failure, job execution is resumed from a previously saved fault-free execution state, or *checkpoint*. Rollback recovery implies frequent (usually periodic) *checkpointing* events at which the job state is saved to resilient storage. More frequent

checkpoints lead to higher overhead during fault-free execution, but less frequent checkpoints lead to a larger loss when a failure occurs. The design of efficient *checkpointing strategies*, which specify when checkpoints should be taken, is thus key to high performance.

In this case study, we consider a single job to be executed on a predefined number of processors. The scheduling problem, here, is then to decide when (and how many times) to checkpoint the job in order to minimize its expected execution time.

59.7.1 Problem Statement

We consider an application, or *job*, that executes on p processors. The job must complete \mathcal{W} units of (divisible) work: there are no constraints on when the job state can be checkpointed. We assume coordinated checkpointing [53], that is, that all processors checkpoint the job state simultaneously. We call *chunk* the fraction of the whole job that is executed between two consecutive checkpoints. Defining the sequence of chunk sizes is therefore equivalent to defining the checkpointing dates. We use C to denote the time needed to perform a checkpoint. The processors are subject to *failures*, each causing a *downtime* period, of duration D , followed by a *recovery* period, of duration R . The downtime accounts for software rejuvenation (i.e., rebooting [14,30]) or for the replacement of the failed processor by a spare. Regardless, we assume that after a downtime the processor that failed is fault-free and begins a new lifetime at the beginning of the recovery period. This period corresponds to the time needed to restore the last checkpoint. Note that although C and R can fluctuate depending on cluster and network load, as in most works in the field we assume they are constant. Finally, we assume that failures can happen during recovery or checkpointing, but not during a downtime (otherwise, the downtime period could be considered part of the recovery period).

We consider the processors from time t_0 onward. We use $P_{suc}(x|\tau_1, \dots, \tau_p)$ to denote the probability that none of the processors fail for the next x units of time, knowing that the last failure of processor P_i occurred τ_i units of time ago, for $1 \leq i \leq p$. The failure interarrival times on the different processors are defined by independent and identically distributed random variables. Let X_i be the random variable for the interarrival time on processor P_i between the last failure (that happened τ_i units of time ago) and the next one. Then we have

$$P_{suc}(x|\tau_1, \dots, \tau_p) = \mathbb{P}(X_1 \geq \tau_1 + x, \dots, X_p \geq \tau_p + x \mid X_1 \geq \tau_1, \dots, X_p \geq \tau_p).$$

Note that we do *not* assume that the failure stochastic process is memoryless.

59.7.2 Minimizing the Expected Makespan

Our aim is to minimize the job execution time. However, as we are trying to execute the job on a failure-prone platform, this execution time cannot be known beforehand: it depends on whether and when failures will impact the job execution. Therefore, our objective will not be the minimization of the makespan, like for instance in Section 59.4, but the *expectation* of the makespan, that is, the average makespan, the average being taken over all possible failure scenarios.

59.7.2.1 Formal Problem Definition

A solution to our scheduling problem is fully defined by a function $f(\omega|\tau_1, \dots, \tau_p)$ that returns the size of the next chunk to execute given the amount of work ω that has not yet been executed successfully ($f(\omega|\tau_1, \dots, \tau_p) \leq \omega \leq \mathcal{W}$) and the amount of time τ_i elapsed since the last failure of processor P_i , $1 \leq i \leq p$. f is invoked at each decision point, that is, after each checkpoint or recovery. Our goal is to determine a function f that defines an optimal solution. Assuming unit-speed processors without loss of generality, the time needed to execute a chunk of size w is $w + C$ if no failure occurs.

For a given amount of work ω and a time elapsed since the last failure τ , we define $T(\omega|\tau_1, \dots, \tau_p)$ as the random variable that quantifies the time needed for executing ω units of work. Given a solution function f , let $\omega_1 = f(\omega|\tau_1, \dots, \tau_p)$ denote the size of the first chunk. We can write the following recursion:

$$T(0|\tau_1, \dots, \tau_p) = 0$$

$$T(\omega|\tau_1, \dots, \tau_p) = \begin{cases} \omega_1 + C + T(\omega - \omega_1|\tau_1 + \omega_1 + C, \dots, \tau_p + \omega_1 + C) & \text{if no processor fails during next } \omega_1 + C \text{ units of time,} \\ T_{wasted}(\omega_1 + C|\tau_1, \dots, \tau_p) + T(\omega|\tau'_1, \dots, \tau'_p) & \text{otherwise.} \end{cases} \quad (59.10)$$

These two cases are explained as follows:

- If none of the processors fail during the execution and checkpointing of the first chunk (i.e., for $\omega_1 + C$ time units), there remains to execute a work of size $\omega - \omega_1$ and the time since the last failure is incremented on each processor by $\omega_1 + C$.
- If at least one processor fails before the successful completion of the first chunk and of its checkpoint, then some additional delays are incurred, as captured by the variable $T_{wasted}(\omega_1 + C|\tau_1, \dots, \tau_p)$. The time wasted corresponds to the execution up to the failure, a downtime, and a recovery during which some additional failures (and downtimes) may happen. Regardless, once a successful recovery has been completed, there still remain ω units of work to execute, and the time since the last failure of a processor depends on whether it fails (and when) during the attempt to process the first chunk, or the subsequent downtime and recovery.

We define **MAKESPAN** formally as find f that minimizes $\mathbb{E}\left(T(\mathcal{W}|\tau_1^0, \dots, \tau_p^0)\right)$, where $\mathbb{E}(X)$ denotes the expectation of the random variable X , and τ_i^0 the time elapsed since the last failure of processor P_i that happened before t_0 .

59.7.2.2 Solving **MAKESPAN** for the Exponential Distribution

In this section, we assume that the failure inter-arrival times of any processor follow an Exponential distribution with parameter λ , i.e., each $X_i = X$ has probability density $f_X(t) = \lambda e^{-\lambda t}$ and cumulative distribution $F_X(t) = 1 - e^{-\lambda t}$ for all $t \geq 0$. The advantage of the Exponential distribution, exploited time and again in the literature, is its “memoryless” property: the time at which the next failure occurs does not depend on the time elapsed since the last failure occurred. Therefore, in this section, we simply write $T(\omega)$, $T_{wasted}(\omega)$, and $P_{suc}(\omega)$ instead of $T(\omega|\tau_1, \dots, \tau_p)$, $T_{wasted}(\omega|\tau_1, \dots, \tau_p)$, and $P_{suc}(\omega|\tau_1, \dots, \tau_p)$.

A challenge for solving **MAKESPAN** is the computation of $T_{wasted}(\omega_1 + C)$. We rely on the following decomposition:

$$T_{wasted}(\omega_1 + C) = T_{lost}(\omega_1 + C) + T_{rec}$$

Where

$T_{lost}(x)$ is the amount of time spent computing before a failure, knowing that the next failure occurs within the next x units of time

T_{rec} is the amount of time needed by the system to recover from the failure (accounting for the fact that other failures may occur during recovery)

The expectation of the makespan can then be expressed as a “simple” recursion:

Lemma 59.3

Let \mathcal{W} be the amount of work to execute on p processors whose failure inter-arrival times follow *iid* Exponential distributions with parameter λ . The MAKESPAN problem is equivalent to finding a function f minimizing the following quantity:

$$\begin{aligned} \mathbb{E}(T(\mathcal{W})) &= P_{suc}(\omega_1 + C) \left(\omega_1 + C + \mathbb{E}(T(\mathcal{W} - \omega_1 + \omega_1 + C)) \right) \\ &\quad + (1 - P_{suc}(\omega_1 + C)) \left(\mathbb{E}(T_{lost}(\omega_1 + C)) + \mathbb{E}(T_{rec}) + \mathbb{E}(T(\mathcal{W})) \right) \end{aligned}$$

where $\omega_1 = f(\mathcal{W})$ and where $\mathbb{E}(T_{lost}(\omega))$ is given by

$$\mathbb{E}(T_{lost}(\omega)) = \frac{1}{p\lambda} - \frac{\omega}{e^{p\lambda\omega} - 1}.$$

The memoryless property makes it possible to solve the MAKESPAN problem analytically:

Theorem 59.9

Let \mathcal{W} be the amount of work to execute on p processors whose failure inter-arrival times follow *iid* Exponential distributions with parameter λ . Let $K_0 = \frac{p\lambda\mathcal{W}}{1 + \mathbb{L}(-e^{-p\lambda C - 1})}$, where \mathbb{L} , the Lambert function, is defined as $\mathbb{L}(z)e^{\mathbb{L}(z)} = z$. Then the optimal strategy to minimize the expected makespan is to split \mathcal{W} into $K^* = \max(1, \lfloor K_0 \rfloor)$ or $K^* = \lceil K_0 \rceil$ same-size chunks, whichever minimizes $\psi(K^*) = K^* \left(e^{p\lambda \left(\frac{\mathcal{W}}{K^*} + C \right)} - 1 \right)$.

The checkpointing strategy in Theorem 59.9 can be shown to be optimal among all deterministic and nondeterministic strategies, as a consequence of Proposition 4.4.3 in [44].

Interestingly, although we know the optimal solution with p processors, we are not able to compute the optimal expected makespan analytically. Indeed, $\mathbb{E}(T_{rec})$, for which there is a closed form in the case of sequential jobs [11], becomes quite intricate in the case of parallel jobs. This is because during the downtime of a given processor another processor may fail. During the downtime of that processor, yet another processor may fail, and so on. We would need to compute the expected duration of these “cascading” failures until all processors are simultaneously available. However, as the value of $\mathbb{E}(T_{rec})$ is independent of the choice of the chunk sizes, not knowing its value does not forbid to find the optimal chunk size function.

59.7.2.3 MAKESPAN and Arbitrary Distributions

Solving the MAKESPAN problem for arbitrary distributions is difficult because, unlike in the memoryless case, there is no reason for the optimal solution to use a single chunk size [50]. In fact, the optimal solution is very likely to use chunk sizes that depend on additional information that becomes available during the execution (i.e., failure occurrences to date). For sequential jobs, approximated dynamic programming solutions have been proposed [11]. They cannot be extended to the parallel case as this would require to memorize the evolution of the time elapsed since the last failure for all possible failure scenarios for each processor, leading to a number of states exponential in p . As we cannot attempt to solve directly MAKESPAN, we introduce a new related optimization problem.

This is especially important as failures in real-world computer systems are recognized not to follow exponential distributions but rather distributions like the Weibull distribution.

59.7.3 Maximizing the Expectation of the Amount of Work Completed

Rather than directly minimizing the job expected makespan, as in the `MAKESPAN` problem, in the `NEXTFAILURE` optimization problem we try to maximize the expected amount of work completed before the next failure occurs. `NEXTFAILURE` amounts to optimizing the makespan on a “failure-by-failure” basis, selecting the next chunk size as if the next failure were to imply termination of the execution. Intuitively, solving `NEXTFAILURE` should lead to a good approximation of the solution to `MAKESPAN`, at least for large job sizes \mathcal{W} . Therefore, we use the solution of `NEXTFAILURE` in cases for which we are unable to solve `MAKESPAN` directly.

59.7.3.1 Formal Problem Definition

For a given amount of work ω and a set of times elapsed since the last failure τ_1, \dots, τ_p , we define $W(\omega | \tau_1, \dots, \tau_p)$ as the random variable that quantifies the amount of work successfully executed before the next failure. Given a solution function f , let $\omega_1 = f(\omega | \tau_1, \dots, \tau_p)$ denote the size of the first chunk. We can write the following recursion:

$$W(0 | \tau_1, \dots, \tau_p) = 0$$

$$W(\omega | \tau_1, \dots, \tau_p) = \begin{cases} \omega_1 + W(\omega - \omega_1 | \tau_1 + \omega_1 + C, \dots, \tau_p + \omega_1 + C) & \text{if no processor fails during the next } \omega_1 + C \text{ units of time,} \\ 0 & \text{otherwise.} \end{cases} \quad (59.11)$$

This recursion is simpler than the one for `MAKESPAN` because a failure during the computation of the first chunk means that no work (i.e., no fraction of ω) will have been successfully executed before the next failure. We define `NEXTFAILURE` formally as find f that maximizes $\mathbb{E}\left(\mathcal{W} \left(\mathcal{W} | \tau_1^0, \dots, \tau_p^0 \right)\right)$.

59.7.3.2 Solving `NEXTFAILURE`

Weighting the two cases in Equation 59.11 by their probabilities of occurrence, we obtain the expected amount of work successfully computed before the next failure:

$$\mathbb{E}\left(W(\omega | \tau_1, \dots, \tau_p)\right) = P_{suc}(\omega_1 + C | \tau_1, \dots, \tau_p) \left(\omega_1 + \mathbb{E}\left(W(\omega - \omega_1 | \tau_1 + \omega_1 + C, \dots, \tau_p + \omega_1 + C)\right) \right).$$

Here, unlike for `MAKESPAN`, the objective function to be maximized can easily be written as a closed form, even for arbitrary distributions. Developing the expression above leads to the following result:

Proposition 59.3

The `NEXTFAILURE` problem is equivalent to maximizing the following quantity:

$$\mathbb{E}\left(W(\mathcal{W} | \tau_1^0, \dots, \tau_p^0)\right) = \sum_{i=1}^K \omega_i \times \prod_{j=1}^i P_{suc}(\omega_j + C | t_1^j, \dots, t_p^j),$$

where $t_i^j = \tau_i^0 + \sum_{\ell=1}^{j-1} (\omega_\ell + C)$ is the total time elapsed (without failure) before the start of the execution of chunk ω_j , and since the last failure of processor P_i prior to the beginning of the application processing, and K is the (unknown) target number of chunks.

Unfortunately, there does not seem to be an exact solution to this problem. However, the recursive definition of $\mathbb{E}(W(\mathcal{W} | \tau_1, \dots, \tau_p))$ lends itself naturally to a dynamic programming algorithm. Formally:

Proposition 59.4

Using a time quantum u , and for any failure inter-arrival time distribution, `DPNEXTFAILURE` (Algorithm 59.5), called with parameters $(\mathcal{W}, \tau_1^0, \dots, \tau_p^0)$, computes an optimal solution to `NEXTFAILURE` in time $O\left(\frac{\mathcal{W}^3}{u}\right)$.

Algorithm 59.5: `DPNEXTFAILURE` (W, τ_1, \dots, τ_p)

```

1 if  $W = 0$  then return 0
2  $best \leftarrow 0$ 
3  $chunksize \leftarrow 0$ 
4 for  $\omega = \min\{\text{quantum}, W\}$  to  $W$  step quantum do
5   ( $expected\_work, 1st\_chunk$ )  $\leftarrow$  DPNEXTFAILURE( $W - \omega, \tau_1 + \omega + C, \dots, \tau_p + \omega + C$ )
6    $cur\_exp\_work \leftarrow P_{suc}(\tau_1 + \omega + C, \dots, \tau_p + \omega + C | \tau_1, \dots, \tau_p) \times (\omega + expected\_work)$ 
7   if  $cur\_exp\_work > best$  then  $best \leftarrow cur\_exp\_work$ 
8    $chunksize \leftarrow \omega$ 
9 return ( $best, chunksize$ )

```

59.7.4 Conclusion

In this case study, we have considered the problem of deciding when to save the execution state of an application, that is, when to take a checkpoint, in order to minimize the expectation of the execution time of an application in a failure-prone environment. We have showed that the optimal solution was to take periodic checkpoints when failures follow an exponential distribution. In the general case, it is not known how to solve the problem analytically. Instead, we have built an approximation of the optimal solution through a dynamic programming algorithm.

We have considered the problem in a simple setting where all checkpointing and recovery times were constant. Furthermore, we have analyzed the simplest checkpointing protocol, namely, *coordinated checkpointing*. More complex protocols have been designed in order to (try to) alleviate the cost of the coordination [19,20].

Rollback-recovery, as studied here, is only one of several fault-tolerance mechanisms. Another often used mechanism is *replication* (see [21] for a coupling of replication with rollback recovery). The question with replication is to decide which task should be replicated and how many times. The optimization objective could be the minimization of the expectation of the execution time (as in this study), or the maximization of the probability that the computation succeeds (reliability), or a multicriteria optimization mixing reliability and performance.

59.8 Conclusion

In this chapter, we have presented several case studies that we believe to be representative of modern scheduling problems that arise at large scale. Energy consumption, fault-tolerance, and memory management are important objectives that must be taken into account in addition to pure makespan minimization.

The case studies are also representative of the increased level of difficulty of modern scheduling problems, which typically involve multicriteria optimization. A variety of mathematical tools and algorithmic techniques are used to solve such problems, and we hope to have convincingly illustrated many of them in this chapter. In addition, many bibliographical items have been provided within the text, and in further information.

Key Terms

Checkpoint and rollback recovery: The technique of saving the current state of the execution at different points in time; when a failure occurs, the application can rollback to, and recover from, the most recently saved state: execution resumes from that state instead of from the very beginning.

Dynamic voltage and frequency scaling (DVFS): By lowering supply voltage, hence processor clock frequency, it is possible to achieve important reductions in power consumption; faster speeds allow for a faster execution, but also lead to a much higher (supra-linear) power consumption.

Heterogeneity: Resources are said to be heterogeneous when they do not have all the exact same characteristics. For instance, the set of processors in a grid is heterogeneous if they do not all have the same processing capabilities or the same amount of memory.

Makespan: The makespan of an application is the time at which the application execution is completed.

Re-execution: A task whose execution is not reliable enough (for instance, because its execution speed is below a threshold) is executed twice (or more) to enhance its reliability.

Resource selection: Is the problem of deciding which, among all available resources, should be used to solve a given problem.

Scheduling: Is the problem of deciding at what time (when), and on which resource (where), to execute each of the (atomic) tasks that must be executed on the given platform.

Further Information

There is a very abundant literature on scheduling and load balancing strategies for parallel and/or distributed systems. The survey [49] is a good starting point to this work. The most famous heuristic to schedule a task graph on an heterogeneous platform is HEFT [51].

A good introduction to multicriteria optimization is the book by Pinedo [41]. Section 59.4 is mainly based on [6]. Section 59.5 is mainly based on [29]. Liu proposes two optimal algorithms for optimal memory traversal of trees, the first one restricted to postorder traversals [33], the second one for any traversal [34]. For more information on the pebble game model such as complexity results for general DAGs, see the seminal work of Sethi [47] and Gilbert, Lengauer and Tarjan [24].

The problem discussed in Section 59.6 is mainly based on a recent work by Amestoy et al. [1]. The paper includes some improved algorithms for the TREEPARTITIONING problem, as well as a hyper-

graph partitioning based formulation. The postorder-based algorithm discussed in Section 59.6.3 is implemented and incorporated in Mumps [2], a sparse direct solver.

Young is the author of a seminal study of periodic checkpointing policies [55]. His work was later extended by Daly [16]. Section 59.7 is mainly based on [11], which contains references to many studies of checkpointing policies. For noncoordinated checkpointing protocols, [27] by Guermouche et al. is a good starting point.

Distributed file systems (DFSs) provide common file access to a collection of computers; all in the collection can access files as if they were local, even though the files do not reside in their local file systems. The need for such a distributed system grew out of the switch in the 1980s from multiuser time-shared systems to networks of workstations (or personal computers). A community of people using a time-sharing system shared a single file system, all files were accessed identically by programs, and files were shared trivially. Furthermore, the file systems were easily administered—they were all attached to one machine and could be easily backed up. A DFS provides all the benefits of the file system on a time-sharing system and opens them up to users of collection of personal computers.

The history of DFSs goes back to the late 1970s and early 1980s. The first commercially successful DFS came as part of the Apollo Domain system, released in 1982, soon followed by Sun’s network file system (NFS). What motivated both these systems was the desire not only to share files but also, since disks were fairly expensive, to support relatively cheap, diskless workstations.

To a certain extent, the ideal DFS behaves as if all parties were on the same computer—in other words, as if it really were not a distributed system. Programs designed to work using a local file system should work just as well using a DFS. Coming close to this ideal is possible, but most existing systems do not—they make trade-offs so as to improve performance and reduce complexity.

Things get complicated when we consider failures: client crashes, server crashes, and communication failures. In the single-computer case, either the entire system is up or the entire system is down; we typically do not worry about file-system semantics on “partially up” or “partially down” systems since these cases simply do not arise. In a DFS, though, what should happen if a server crashes but its clients remain up? Or suppose clients and servers are up, but the network connections between them are down. Or suppose a client crashes while the rest of the system remains up.

The most obvious benefit of the DFS is that files are shared. If I want to let you work with one of my files, I simply give you its pathname. You see everything I’ve done to the file. If you make any modifications to

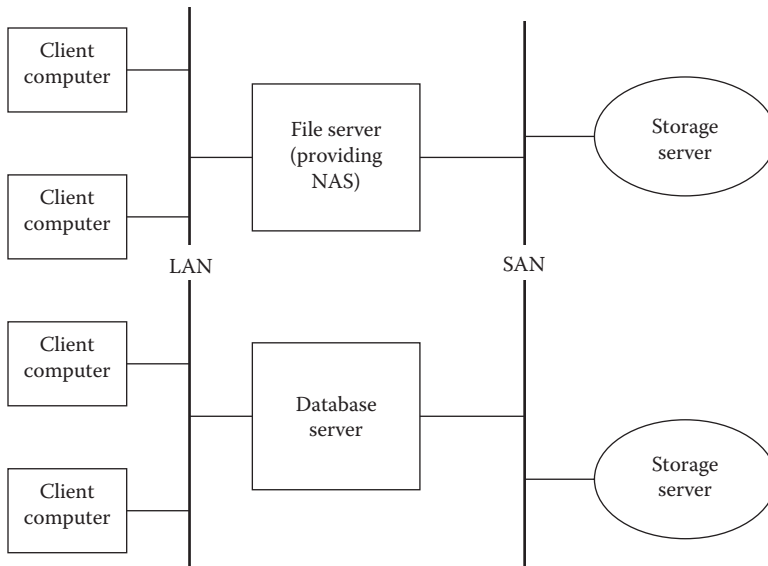

FIGURE 60.1 The relationship between *network attached storage* (NAS) and a *storage area network* (SAN).

it, I see those modifications. Neither of us needs to worry about synchronizing the contents of multiple copies of a file. Without the DFS, we would have to exchange files by e-mail or use applications such as the Internet's file transfer protocol.

A related benefit of a DFS is that my programs can access remote files as if they were local. The remote files have no special application-program interface; they are accessed just like local ones. With this property, known as *access transparency*, programs need not be aware whether a file is remote or local.

Finally, a DFS is easier to administer than multiple local file systems. Typically in such a system, a small number of server machines provide files to a large number of clients. Rather than having to back up files on each of the clients, only the servers' files need to be backed up.

Another term for DFS is *network attached storage*, referring to attaching to the network servers that provide file systems. A similar-sounding term that refers to a very different approach is *storage area network*. Here, the intent is to make available over the network not file systems but storage devices. For example, an organization might own a few large-capacity redundant array of independent disks (RAID) devices, each providing many terabytes of storage. The total capacity might be split into a number of logical storage devices, each assigned to a specific server. Some of the servers might be file servers, which use their logical storage devices to hold a file system. Others might be database systems, which use their logical storage devices to hold databases. The capacity can be shuffled among logical devices as needed to meet new requirements; the redundancy provided by RAID is shared by all. See Figure 60.1.

60.1 Basics

The ideal DFS should not give its users any unpleasant surprises: it should behave as much as possible as if it and its users were all on the same computer. The semantics of file operations should be exactly the same for DFSs as for local file systems. When multiple applications access the same file, the result should be the same on the distributed system as if all parties, clients and server, were on the same system. Failures, such as communication problems and crashes of client and server computers, should be minimally disruptive. And to top it all off, performance should be good.

Designing such a system entails determining how its various components are distributed—what resides on the servers, what resides on the clients. We categorize this information as follows:

- The *data state*: this is the contents of files.
- The *attribute state*: this is information about each file, such as its size, most recent modification time, and access-control information.
- The *open-file state*: this is the information indicating which files are open or otherwise in use as well as describing how files are locked. For example, in both Unix and Windows systems, opening a file adds to its reference count, and a file cannot be deleted unless its reference count is zero. A range of bytes of a file can have a shared (or read) lock or an exclusive (or write) lock applied to it.

As shown in Figure 60.2, each of these components might be kept on the server or on the clients, either in volatile storage (which is lost if a machine crashes) or in non-volatile storage (which is not lost after a crash). We think of the data state as permanently residing on the server's local (disk) file system, but recently accessed or modified information might reside in volatile storage in server or client caches (or both). Some systems even cache data on client disks. Similarly, the attribute state resides permanently on the server's local file system, but might be cached on servers and clients. The open-file state is transitory; it changes as processes open and close files. Thus, it makes sense for this to reside in volatile storage, but, as we discuss in the subsequent sections, for crash-recovery purposes, some systems keep a portion of it in non-volatile storage.

Three basic concerns govern this placement:

1. *Access speed*: Access is slow if the information resides on the server, yet is accessed and modified by clients. Caching such information on clients improves performance considerably. Information stored in volatile storage can be accessed and modified much more quickly than information stored in non-volatile storage.
2. *Consistency*: If clients cache information, do all parties share the same view of it?
3. *Recovery*: If one or more computers crash, to what extent are the others affected? How much information is lost?

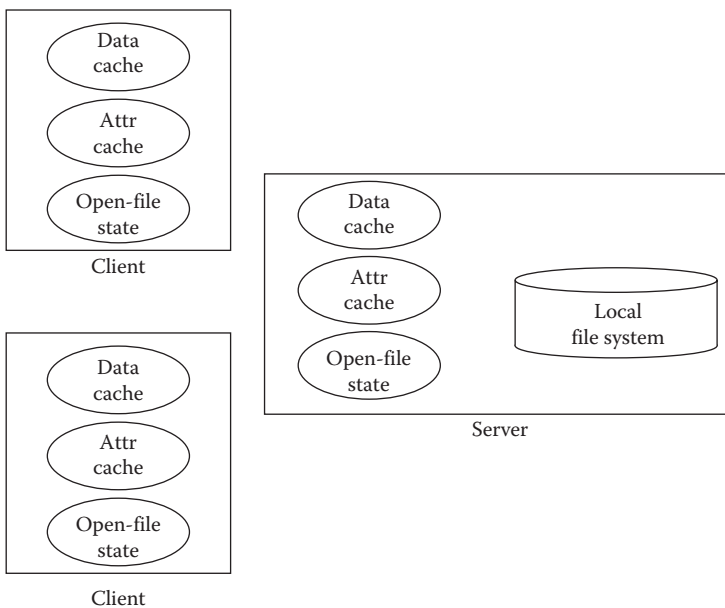

FIGURE 60.2 Possible locations for caches and open-file state in a distributed file system.

Though the factors affecting access speed are straightforward, those affecting consistency and recovery are not. So, before discussing the trade-offs among these concerns, we first spend some time discussing consistency and recovery, giving a quick overview of what is relevant to DFSs and focusing on data consistency.

Suppose a single thread is performing operations on files. We want the order in which these operations occur on the files to be the same as was executed by the thread; that is, we want the operations to be *time-ordered*. If things were otherwise, we would consider the file system broken and would not use it. If no operations are performed by other threads, any read of a particular location of a file by a thread retrieves the result of the thread's most recent write to the location. We call this property *single-thread consistency*.

It is not a big stretch to extend this form of consistency to an entire client computer: the operations on the file system by the computer are time-ordered, and thus, in the absence of operations by other computers, any read of a particular file location by a thread on the computer retrieves the result of the most recent write to the location by any thread of the computer. This we call *single-client consistency*.

It is a bigger step to extend consistency to the threads on all the client machines of a distributed system. But if all operations on a file system are time-ordered, and thus any read of a particular file location by any thread on any computer retrieves the result of the most recent write to that location by any thread on any computer, the file system is said to have *strict consistency*.

It may be difficult if not impossible to time-order the operations coming from many client computers. If operations are executed on different client computers, how do we know which happened first? In general, if this cannot be determined, it probably does not matter. What is important is that all parties agree on whatever order is selected and that the selected order be one that could have happened. Suppose Ted is updating a file on one computer and Alice is reading that file on another computer, if they do these operations at about the same time, and if the clocks on the various computers either are not synchronized well enough or do not have enough resolution to order the two events, then it really is not clear which happened first and either order makes sense—neither Ted nor Alice will be surprised by either outcome. Assuming that the system remains single-client consistent, this weakening of strict consistency is known as *sequential consistency* (Lamport 1979).

But suppose Ted's and Alice's computers are a foot apart and Alice reads the file immediately after Ted tells her he's modified it, both Ted and Alice will be unpleasantly surprised if Alice gets the old version of the file. To rule out such surprises, we might insist that our system be strictly consistent.

On the other hand, if Ted and Alice are savvy computer users, they would realize that expecting deterministic results from concurrent operations on remote files without some form of synchronization might not be realistic. So Ted might apply a write lock to the file before modifying it, and Alice might apply a read lock before reading it. Though this file system is not strictly consistent, it is said to have *entry consistency* (Bershad and Zekauskas 1991) if some *acquire* operation (such as taking a lock) can guarantee the client that the most recent contents of file locations are protected by the lock, and if some *release* operation can make the client's changes available to others.

What sorts of consistency do DFSs provide for data? NFS, as discussed in Sections 60.2 and 60.5 in the subsequent sections, provides single-client consistency but not strict consistency. If applications lock the files they are using, they get entry consistency, but this is strictly up to the applications. Common internet file system (CIFS), as discussed in Section 60.3, provides strict consistency. DFS, as discussed in Section 60.4, also provides strict consistency.

All systems must provide strict consistency for the lock-state portion of open-file state—locks make no sense otherwise. But, as described in Section 60.2, NFS versions 2 and 3 get away with not even sharing the reference state of files, let alone doing so consistently. Most systems keep the attribute state strictly consistent, but NFS provides at best entry consistency.

What happens if there is a failure? In a non-distributed system, a failure takes down the application and everything else. In a distributed system, failure of a client computer takes down its application. But if the server or other clients fail, the application is not necessarily affected at all. Another way of putting

this is that for non-distributed systems, either the entire system is up or the entire system is down. When the system comes back up after a crash, people do not expect the cache and the open-file state to be as they were before the crash—all application processes must be restarted anyway.

But with a DFS, partial crashes can happen and must be dealt with. One or more clients might crash, the server might crash, and there might be times during which certain computers cannot communicate with one another due to network problems. In some cases, complete recovery is possible. In others, for instance when a client crashes, problems are restricted to the crashed computer—no other computer is adversely affected. In still other cases, problems can occur that would not have happened if a local file system were being used.

For example, an application that has locked a file might discover that, because of a combination of server crashes and network problems, not only has it lost its lock on the file but also the file has been locked by another application. Ideally, of course, such “surprises” will not happen. But, as explained in the following sections, these surprises, though rare, are unavoidable. The best we can ask for is that applications are notified when they occur.

In the subsequent sections, we look at a few representative DFSs, discussing the trade-offs taken among speed, consistency, and recoverability. We start with NFS version 2, a relatively simple yet successful system. As already noted, it has a fairly relaxed approach to consistency but handles failures well. Next, we cover CIFS, which provides strict consistency but is essentially intolerant of server failures and network problems. We then discuss DFS, which provides strict consistency and is tolerant of server failures and network problems, but requires the cooperation of applications in coping, and finally NFS version 4, which does as good a job with failures as is probably possible.

A final concern, independent of the others, is the file-system name space. If all parties are on one computer, there is probably just a single directory hierarchy and thus one name space. But for the distributed case, the one-name-space approach does not necessarily make sense. Both NFS and CIFS allow each client to set up its own name space, and both also provide a means for all clients to share the same name space. DFS uses a model in which one global name space is shared by all in the distributed system.

60.2 NFS Version 2

NFS was developed by Sun Microsystems in the mid-1980s. Its design is simple,* yet successful; it and its descendants have been widely used ever since, uniquely among DFSs of its time. In this section, we focus on NFS version 2. Version 1 was used strictly within Sun. At the time of this writing, version 3 is in common use, while version 4 (discussed in Section 60.5) is beginning to be adopted.

NFSv2 servers are passive parties that give their clients a simple file store. They respond to client requests, but take no actions on their own. NFS clients actively maintain caches of information obtained from servers, performing read-aheads and write-behinds as necessary. The approach to consistency is rather relaxed but works well in practice. Here is how things work. An NFS server gives its clients access to one or more of its local file systems, providing them with opaque identifiers called *file handles* to refer to files and directories. Clients use a separate protocol, the *mount protocol*, to get a file handle for the root of a server file system. They then use the *NFS file protocol* to follow paths within the file system and to access its files, placing simple remote procedure calls to read them and write them. A third protocol added later, the *network lock manager protocol* (NLM), can be used to synchronize access to files. All communication between client and server is with a remote procedure call (RPC) protocol known as open network computing (ONC) RPC (see Chapter 9 of Doeppner (2011)).

Here, we call the combination of the mount protocol and the NFS file protocol *basic NFS*; basic NFS plus NLM we call *extended NFS*. We begin by discussing basic NFS.

* This characterization applies only to version 2 of NFS!

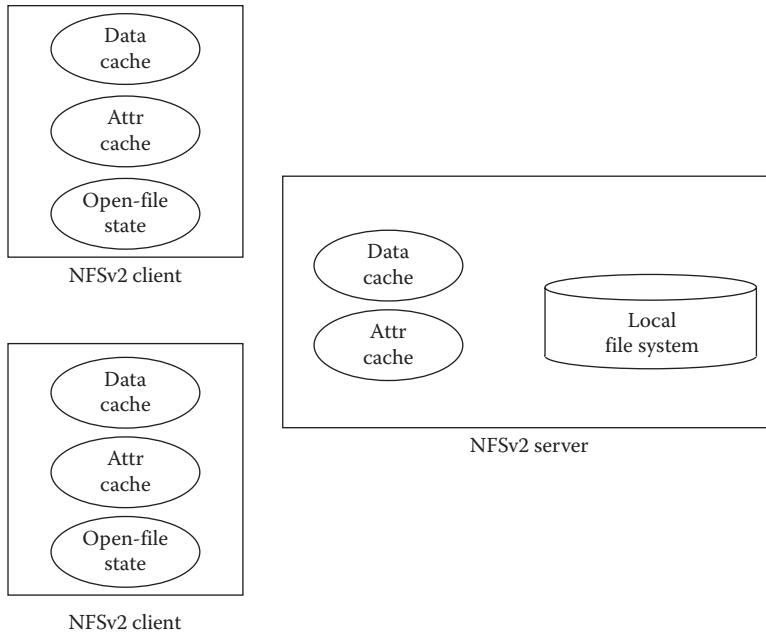

FIGURE 60.3 Distribution of components in NFSv2.

All open-file state information resides on the clients. Servers are thus called *stateless* since they are essentially unaware of what files clients have open, though they necessarily do hold data and communications state.

Figure 60.3 summarizes the information maintained on clients and servers. Clients maintain caches of file data and attributes as well as hold all open-file information (except for locks, which are maintained on the server via the NLM protocol). No other open-file information is held on the server.

To see how NFSv2 operates, let us work through an example. Suppose a Unix thread executes the following instructions, accessing a file system on an NFSv2 server:

```
char buffer[100];
int fd = open("/home/twd/dir/fileX", O_RDWR);
read(fd, buffer, 100);
...
lseek(fd, 0, SEEK_SET);
write(fd, buffer, 100);
```

Our thread opens a file, reads the first 100 bytes, then writes 100 bytes at the beginning of the file, replacing the previous data there. The kernel data structures representing the open file are just what they would be if the file were local. The only difference from the client operating system's point of view is that the actual operations on the file are handled by the NFSv2 client code rather than by a local file system such as FFS.

The NFSv2 server has its own directory hierarchy and exports a number of subtrees of this hierarchy to its clients. The client's operating system has mounted one of them on the local directory `/home/twd`. It did this by first placing a remote procedure call, using the mount protocol, to the server, and obtaining a file handle for the root of this subtree. As Figure 60.4 shows, any attempt to access the directory `/home/twd` is now interpreted as an attempt to access the remote directory represented by the file handle.

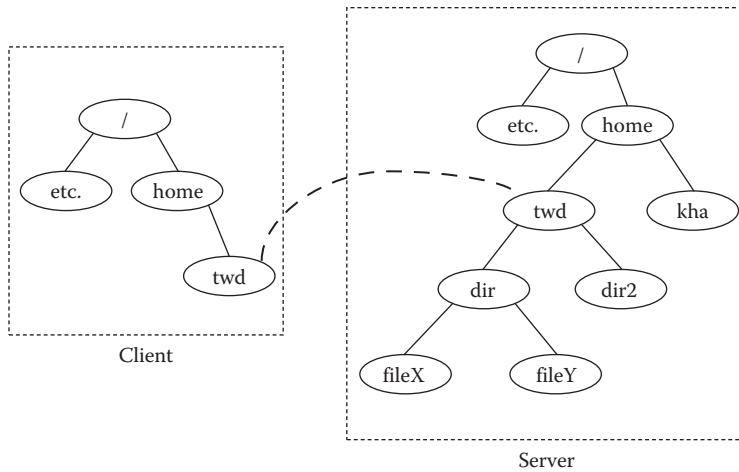

FIGURE 60.4 The client has mounted the server's /home/twd on its own /home/twd.

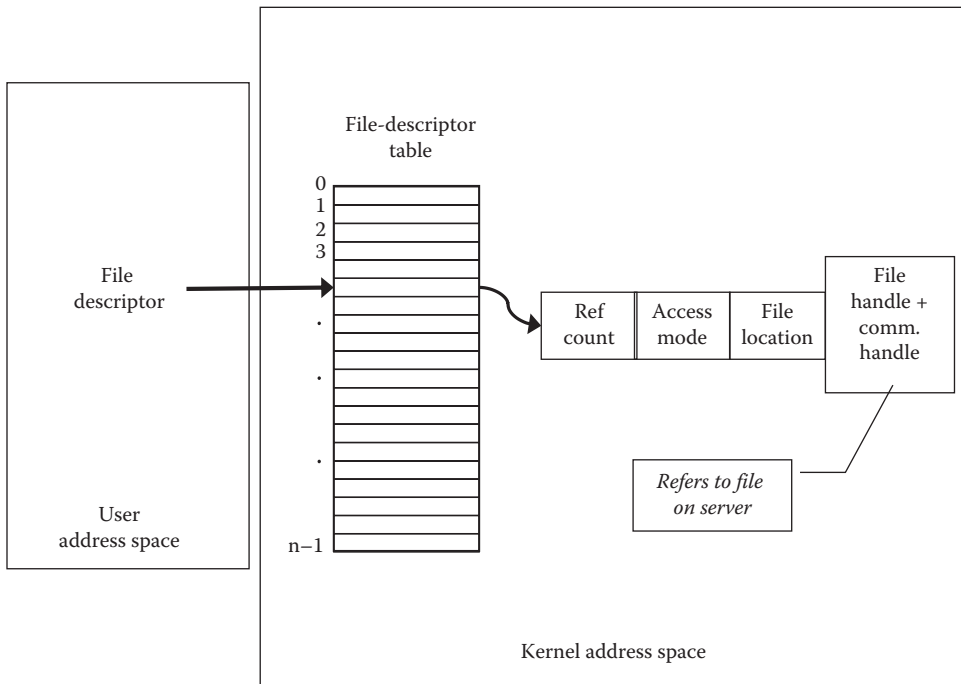

FIGURE 60.5 Open-file data structures on client.

Thus to follow the path /home/twd/dir/fileX, our thread, executing in the client operating system, goes as far as /home/twd and discovers that a remote file system is mounted there. It places a remote procedure call to the NFSv2 server's *lookup* routine, passing it the file handle for the remote file system's root as well as the pathname /dir/fileX. The server returns a file handle for fileX.

The client operating system records the fact that fileX is open, just as it would for a local file. However, rather than representing the file with an inode or equivalent, it uses the file handle together with a communication handle representing the remote server (see Figure 60.5).

When the thread performs the *read*, it first checks its local cache within the client operating system. If the data are not there, it places a remote procedure call to the server's read routine, passing the file handle, the offset within the file (0) and the length (100). The server returns the 100 bytes from that location.

The *lseek* call sets the local file offset to 0, but does not cause a request to be sent to the server. When the thread calls *write*, the data are first copied to the local cache. Sometime later, a kernel thread places a remote procedure call containing the file handle, the current offset (0), the data, and the length to the server's *write* routine. The server returns an indication of successful completion of the operation.

This is remarkably simple and straightforward, though we have omitted a few details (to be covered in Section 60.2.3). But let us look at the ramifications of this simplicity. We have already noted that the server maintains no open-file state: the client obtains a file handle for the file, but the server has no record that some client is using the file.

Consider the following code fragment:

```
int fd = creat("/home/twd/dir/tempfile", 0600);
char buf[1024];
unlink("/home/twd/dir/tempfile");
...
write(fd, buf, 1024);
...
lseek(fd, 0, SEEK_SET);
read(fd, buf, 1024);
close(fd);
```

The file `/home/twd/dir/tempfile` is created, then its directory entry is immediately removed. If this were done on a local file system, the file itself would continue to exist, even though there no longer is a directory entry referring to it—that the file is open makes it continue to exist. This code sequence is rather common in Unix programs, since it is a standard technique for creating a temporary file, one guaranteed to disappear once the process terminates: as soon as the file is closed, there is no longer a reference to it and the operating system deletes it.

Since NFSv2 servers do not keep track of whether files are open, the unlink request in the code above removes the last link to the file and leaves it with no other references—the file is then deleted, much to the client's surprise.

NFSv2 relies on the client to keep track of such state information and to modify its requests to the server accordingly. In our example, the client would realize that asking the server to *unlink* an open file is not in its best interests. So, rather than doing that, it sends it a *rename* request, changing the file's name to a special name that does not show up in normal directory lookups (in Unix, this is accomplished by using "." as its first character). Thus, the file no longer exists under its original name, yet the client's file handle still refers to it. When the client process closes the file, it sends an unlink request to the server, removing the file's special name from the directory and thus finally deleting the file.

This solution is clearly not perfect: it works only if the file is open on the same machine as the one doing the unlink. In practice, this is the only case that matters, so it does well enough. But what happens if the client renames a file, but crashes before the file is closed? Then the renamed file is not deleted and remains on the server. The server must periodically check for such orphaned files and delete them.

The NFS Mount Protocol, described in Section 60.2.2, lets clients access subtrees of server directory hierarchies. Clients may place these subtrees in their own directory hierarchies wherever they please, but it is usually more convenient to handle this automatically so that all clients have the same file-system name space. Most organizations using NFS define such a name space in an organization-wide database. Each client, using software known as the *automounter*, consults this database and mounts server-provided subtrees into its own directory hierarchy as necessary.

60.2.1 RPC Semantics

The NFSv2 protocols are layered on top of ONC RPC and depend on it for reliable communication between client and server. RPC extends the procedure-call abstraction across different computers. Ideally, when a client calls a remote procedure, it is assured that the procedure is invoked exactly one time, and the results are returned to the client. This assurance is made difficult because of the possibility of network and server failures. For example, if a client invokes a procedure on the server, but does not get a response, is it because of a network failure, a server failure, or both? Perhaps, the remote procedure was actually executed on the server, but due to a network failure, the response did not arrive at the client.

If the effect of executing a remote procedure multiple times is the same as executing it once, that is, the procedure is *idempotent*, then it is safe for the client to repeat a request if it does not get a response. Most of the procedures provided by NFSv2 servers for their clients are idempotent. For example, to modify a file, a client invokes a WRITE procedure providing the file's identity, the data to be written, and the file location that is to be modified. If the procedure is executed twice, the same data are re-written to the same location, but the effect is as if it has been written only once.

However, some NFSv2 procedures are not idempotent. For example, consider the procedure to unlink a file from a directory (which deletes the file if its only directory link is being removed). If the procedure is executed once, the link is removed. If it is executed again, the request fails, because the link cannot be removed (since it no longer exists). There is no harm done on the server from executing the procedure twice, but the result can harm a client application that inexplicably has a request fail that should have succeeded.

ONC RPC copes with this problem through the use of duplicate request caches (DRCs) on servers, which maintain lists of recently received RPC requests and their responses. Whenever a request is received, the server checks its DRC to determine if the request is a duplicate of one already received (clients assign unique identifiers to their requests; a retransmission of a request carries the same ID as the original transmission). If the request is a duplicate, then, rather than re-execute it, the server simply sends back the original response. This approach works perfectly if items are not removed from the cache unless they will never be received again. NFSv2 and v3 servers remove items from their DRCs after they've been there for a certain amount of time. This works well if clients and servers reside in "reasonably well behaved" networks, but, if the network is not-so-well-behaved, servers may re-execute a duplicate request. NFSv4's DRC does a much better job, as described in the subsequent sections.

ONC RPC handles requests as follows. If user datagram protocol (UDP), an unreliable protocol, is the transport protocol, the client RPC layer repeatedly retransmits each request (with suitable delays in between) until it gets a response. If transmission control protocol (TCP), a reliable protocol, is the transport protocol, the client RPC layer does not retransmit unless there is a loss of connection, in which case, a new connection is made and the client retransmits over it. With both transports, the effect is that requests are received by the server's RPC layer at least once. Most requests are for idempotent procedures, and thus can be safely executed many times in a row. The server uses its DRC to handle duplicate non-idempotent requests.

What is particularly nice about this approach is that client applications need not be aware that they are using a DFS and need do nothing special to cope with crashes or network problems. The client RPC layer eventually makes the desired result happen: if the server crashes while an application is attempting to read from a file, the read system call simply appears to be slow, but it eventually returns with the desired data (assuming the server recovers from the crash).

As an option, a client can set things up so that system calls on files of a particular remote file system eventually time out if the server has crashed or there is a network problem. In practice, this is done only rarely, because few applications do anything intelligent in response to such timeouts.

60.2.2 Mount Protocol

This is by far the simplest of the NFSv2 protocols. Its primary job is to provide clients with file handles for roots of exported file systems. It also provides limited security by giving these file handles only to certain specified clients.

What are file handles? Servers give them to clients to identify files on the server. From the client's point of view, they are completely opaque: their contents have no meaning other than as interpreted on the server.

From the server's point of view, however, file handles play a role similar to that of Unix inodes: they uniquely identify files. While a file might have multiple pathnames, it has only one file handle. A file handle must identify a file even if the file has been renamed; it must continue to be valid until the file is deleted. After a file has been deleted, its file handle must be invalid, so that clients can reliably determine that a file no longer exists.

So, what does a file handle contain? For a Unix server that actually identifies files by their inodes, the file handle contains an identifier for the file-system instance (the server might have many) as well as the inode number. Thus, it identifies a particular file within the file system.

But this is not enough: if a file is deleted, its file handle must become invalid. The problem with using the combination of inode number and file-system identifier as a handle is that, though this combination will be invalid immediately after the file is deleted, the inode number might be reused for a new file. Thus, the handle becomes valid again and refers to a different file from what the holder had intended.

To get around this problem, we need a way to distinguish between different uses of the same inode number (or similar identifiers). What is done is to tag each inode with a generation number, a 32-bit field that takes on a different value each time the inode is reused—a random value works well here. The file handle contains a copy of the value that is current when the handle is created. If the corresponding file is deleted and its inode reused, the generation number in the file handle no longer matches that of the inode, and the handle is rejected—the error message is “stale file handle.”

60.2.3 NFS File Protocol

The NFS File Protocol does most of NFS's work. It is responsible for communicating file data between client and server and for maintaining client caches and keeping them reasonably consistent. Its basic operation is remarkably simple. Client application processes make system calls on files. Forget-type operations—fetching data, file attributes, etc.—if the relevant information is in the cache, the call completes immediately. Otherwise, the NFS client code places a RPC to the server both to obtain the needed information for the cache and to return it to the application. For most put-type operations, such as file writes, the information is stored in the local cache, and sometime later NFS client code updates the server via a RPC.

Assuming the communications protocol is providing exactly once semantics for each client's RPC requests, the client caches are single-client consistent. But what happens if more than one client is using a file? The basic premise of NFSv2 is that file sharing takes place primarily for read-only files, such as binaries. Writable files are generally used by only one client at a time. So, with this premise as justification, NFSv2 uses an approximate approach to consistency. For cases in which the premise is unjustified, the separate NLM comes into play, as described in Section 60.2.4.

In the NFSv2, approximate approach to consistency, cached information is assumed to be valid for a certain period of time after it is put in the cache. NFS client code periodically checks with the server for changes to files that are at least partially cached on the client. If so, regardless of the extent of the changes, the cached information for the file is invalidated and subsequent get-type requests result in RPCs to the server.

To aid in doing this, clients maintain a separate cache of file attributes—information obtained from the server about the files they are accessing (see Figure 60.6). This information is essentially anything the server can provide, including access permissions, file size, creation time, access time, and modification time. This cached information is used to satisfy requests by processes for file attributes (via the *stat* and *fstat* system calls in Unix). It is also used in determining whether the cached data from a file is up to date. Cached attributes are valid only for a brief period of time, ranging from a few seconds to a minute, and cached file data are valid only while the file's attributes are valid. If an attempt is made

FIGURE 60.6 An NFSv2 client's data and attribute caches.

to access cached data beyond the attributes' validity period, a "GETATTR" RPC request is sent to the server asking for the file's current attributes. On return, the new attributes are cached; if they indicate that the file has not been modified since the previous attributes were cached, the cached data are still used. Otherwise, the file's cached data are flushed—this means that modified file blocks are sent to the server via WRITE RPC requests and unmodified blocks are removed from the cache.

This attribute caching helps keep caches "sort of" consistent but does not give any useful guarantees. Many NFS implementations go a step farther and provide "close-to-open" consistency: when a file is closed, all changes are sent to the server. When a file is opened, the remaining validity time for its cached blocks is ignored, and a GETATTR is sent to the server. The blocks are flushed if the new attributes indicate recent changes. This procedure helps prevent surprises: if a file is shared by multiple clients, but is open on at most one at a time, the clients' caches will be consistent.

Given the near lack of state information the NFS File Protocol keeps on the server, dealing with client and server crashes is straightforward—nothing needs to be done! However, care must be taken with certain operations so that crashes do not cause undue surprises. If a client application performs a synchronous request, such as writing to a file synchronously, the request really needs to be performed synchronously—the application should not be notified of its completion until after the server file system has been updated. Otherwise, in the event of a client or server crash, the user of the application may be under the false impression that the file has been modified.

In fact, all RPC calls that update the server must be synchronous: a client that receives a "successful-completion" response assumes its job is done—the server has been updated and the client can move on. So the modifications really must have been committed on the server. Otherwise, if the server crashes before the updates have been committed, they are lost forever.

This synchronous-update requirement slows file updates on NFSv2 systems, since, for example, all WRITE RPC requests must be synchronous. Some implementations handled this by providing a non-volatile cache into which updates could be committed on the server. The cache survived crashes, and its contents were written to the file system as part of crash recovery.

One of the major improvements in NFSv3 was to weaken the requirement for synchronous updates. Writes in NFSv3 may be asynchronous, meaning that the server may return a response even though the data has not been written to disk. But when the client sends a COMMIT RPC request, the server may not respond until the data from all previous writes to the file are safely on disk.

60.2.4 Network Lock Manager

The final component of NFSv2, forming extended NFS from basic NFS, is its network lock manager (NLM) protocol, which enables clients to lock files. While in the rest of NFSv2, the open-file state

resides in the clients, NLM maintains lock state on the servers, as well as on the clients. Its operation is simple: clients place RPC calls to the server requesting locks on files, and the server grants or refuses these requests on the basis of state information it maintains locally. But this shared lock state adds a new wrinkle to NFS: significant work must be done to recover from both client and server crashes.

NLM supports the standard Unix notion of file locks: locks are *advisory*, meaning that applications are free to ignore them, and are *byte-range*, meaning that they are applied to a range of locations within a file. They come in two forms, *shared locks* and *exclusive locks*. The latter are essentially write locks: no two may have overlapping ranges on the same file at the same time. The former are essentially read locks: they may overlap with each other, but not with exclusive locks.

The lock state is shared consistently by keeping most of it on the server, which keeps track of the locks applied to all its files. An application process applies locks to remote files just as it does to local ones—it issues a system call and is notified whether or not it was successful. The local (client) operating system places a LOCK RPC request to the server, which locks the file if possible, updating its own lock-state information, and sends back a success/failure response. If successful, the open-file state on the client is updated to indicate that a portion of the file has a lock applied to it.

The hard part of maintaining lock state is coping with crashes. NLM avoids much of the potential complexity of crash recovery by simply ignoring the difficult cases. In practice, this has worked reasonably well, primarily because NFSv2 is used in well behaved environments that lack Byzantine routers and other networking problems.

The first issue in crash recovery is determining that there has been a crash. This is fraught with difficulty since a false determination causes big problems. NLM avoids these problems by being extremely conservative. A computer is deemed to have crashed only when it comes back up and announces it is restarting. Otherwise, it is assumed to be running fine (despite, say, being unresponsive for the past hour).

Thus, NLM clients keep on disk a list of which servers they are holding locks from, and servers keep on disk a list of which clients are holding locks on their files. When a client restarts, it notifies the servers in its list that it is restarting, and the servers release all the client's locks.

Recovering from a server crash involves recovering the lock state of all the clients. This would be trivial if the state had been stored on disk along with the client list, but for performance reasons, it is not. Instead, the lock state is kept in volatile memory and thus disappears with a server crash. To recover it, servers rely on their clients.

As when clients restart, when a server restarts, it notifies all the clients in its list of lock holders. These clients then have a certain period of time, the *grace period* (typically 45 s), to reclaim the locks they held before the server crashed. During this period, the server accepts no new lock requests.

NLM's approach to recovery is not perfect. We take this up again in Section 60.5.2, when we discuss NFSv4.

60.3 Common Internet File System

CIFS is Microsoft's DFS. Its long history goes back to the mid-1980s, when it was developed by IBM and was known as the server message block (SMB) protocol, running on top of Network Basic Input/Output System (NetBIOS). Microsoft took over further development of SMB and renamed it CIFS in the late 1990s. Though it still can run on top of NetBIOS, NetBIOS is often layered on top of TCP and, with some simple extensions, SMB can run directly on top of TCP (without NetBIOS). The term SMB is still used to refer to the RPC-like communications protocol on which CIFS is layered.

The CIFS approach is to provide strict consistency among clients and servers, allowing client-side caching for efficient handling of the two most common file usages—when a number of clients are sharing a file read-only and when a file is being used exclusively by one client. One way to characterize the differences between CIFS and NFSv2 is that CIFS is always strictly consistent and usually

fast, while NFSv2 is always fast and usually strictly consistent. Though keep in mind that by “fast,” we mean only that client-side caching is used.

Unlike basic NFS (see Section 60.2), CIFS servers hold open-file state from their clients. Thus if a client crashes, this state must be cleaned up. On the other hand, if a server crashes, clients make no attempt to recover their state when it comes back up: operations on files that were open at the time of a crash will fail.

CIFS requires the transport protocol to be reliable and regards the transport connection as the sole indication of the health of the computer at the other end. So if the connection is lost, perhaps because of a network timeout, CIFS considers the other computer to have crashed.

This approach to failure allows CIFS to be simpler than NFSv2 and other DFSs. A request is not retried if the connection is lost: the application must assume the worst, that the server has crashed and there is no hope of recovery. Whether or not the remote procedure is idempotent does not matter.

The organization of the CIFS namespace is similar to that of NFS. Servers export “shares,” subtrees of their own hierarchies. Clients may place them in their local namespaces as desired—Windows clients typically assign drive letters to them (creating a local “forest”). Alternatively, much as NFS defines a namespace shared by all clients by using the automounter and a distributed database, Windows uses a distributed database called “active directory” to define a namespace shared by all clients.

To get a better idea of how CIFS works, consider the code in the following text, which is similar to the code we examined in Section 60.2 when looking at NFSv2:

```
char buffer[100];
HANDLE h = CreateFile(
    "Z:\\dir\\file",           // name
    GENERIC_READ|GENERIC_WRITE, // desired access
    0,                        // share mode
    NULL,                     // security attributes
    OPEN_EXISTING,           // creation disposition
    0,                        // flags and attributes
    NULL                       // template file
);
ReadFile(h, buffer, 100, NULL, NULL);
...
SetFilePointer(h, 0, NULL, FILE_BEGIN);
WriteFile(h, buffer, 100, NULL, NULL);
CloseHandle(h);
```

In this code, a thread opens an existing file (despite the name of the system call!), requesting both read-write access and that the file not be shared with others until the returned handle is closed (it does this by supplying a “share mode” parameter of 0—we discuss share modes later in this section). It reads 100 bytes from the beginning of the file, then, after resetting the file pointer, writes 100 bytes to the beginning of the file. Finally, it closes the handle, allowing others to open the file.

Here, in outline form, is what takes place for all this to happen. At some point before this code is executed, the client must have created a transport connection with the server. Then, so that the server can do access checking, the client identifies itself to the server (and proves its identity). Next, the client identifies to the server the “disk share” it wants to access. This is a subtree of the server’s file system that the server is willing to export. If the client is allowed access to the share, the server returns a “tree ID” (TID) identifying the share. Our client associates this exported file system with the drive letter “Z.” Note that this is much as in the NFSv2 mount protocol, via which the client obtains a file handle for the root of a server file system (see Section 60.2.2).

At this point, our client thread can issue the *CreateFile* system call to open the file it wants. It passes to the server the *UID*, identifying the user, the *TID*, identifying the share, and the path (in this case *dir\file*) to follow in that share. In addition, it passes the *desired access*, which the server checks to make certain it is allowed, the *share mode*, which the server must honor, and the other parameters (except for the template file, which is ignored when opening an existing file, but may be used as a source for the attributes if creating a new file). If successful, the server returns a “file ID” (FID), which the client subsequently uses to identify the file.

As in NFS, read and write system calls by client threads do not necessarily send requests to the server immediately; they might instead be satisfied by a local cache. But when the client operating system fetches data from the server or sends modified data back to it, it sends read and write requests that identify the file by the FID. The file pointer, used by the application thread to identify file position, is maintained on the client side; read and write requests sent to the server contain an explicit file location.

Unlike NFSv2 servers, CIFS servers must be aware of what their clients are doing. In general, they keep track of not only the reference counts on files, but also the *share modes*. These indicate in what ways a file may have concurrent opens. The default, a share mode of 0, is that concurrent opens are not allowed. But a thread can specify, for example, that others can open the file for reading or that others may open the file for writing, or perhaps for both. Thus, when a thread tries to open a file, the open succeeds only if the desired access does not conflict with the share mode of all the other current opens of that file.

CIFS supports “byte-range” locks that are similar to those supported by NFSv2 in that application threads can lock portions of a file. However, CIFS’s locks are mandatory—they must be honored by all threads on all clients, unlike the locks supported by NFSv2 (and NFSv3). From the client application’s perspective, locks are associated with the combination of the file handle and the process: all threads of one process using the same file handle share the lock on a byte range of a file. Even if this file handle is shared with threads of a different process, these latter threads do not share the lock. If another handle for the file is created in the original process (by opening the file again), threads using that second handle do not share the lock. Thus, the server must keep track of not only which file handle a lock is associated with but also with which process on which client machine.

60.3.1 SMB Protocol

The SMB protocol plays the role of RPC for CIFS. Like RPC, it is a request-response protocol: clients (and sometime servers) send requests; servers (and sometimes clients) send responses. However, unlike a true RPC protocol, it is not extensible. It consists of a predefined set of requests and responses, all in a fixed format. Nevertheless, it suffices for CIFS (after all, it was designed for CIFS!).*

As the name SMB implies, requests and responses are sent as message blocks, each containing a standard header along with some arguments and data. A client first sets up a session with a server that has already established the client user’s identity. The client and server must first negotiate, which version of the SMB protocol they are using and then, via a log-on procedure, establish the user’s identity (thus setting the UID) and prove it to the server. After the session is established, the client may request access to one or more server “shares,” obtaining a TID for each. With such a TID, the client may open a file, thus obtaining a FID.

Each client operating system must identify which user process is sending a request by supplying a process ID (PID) unique to the client. PIDs are necessary for correctly implementing locks but are also used to match responses to requests. The idea is that a process has only one outstanding request at a time—which made sense before processes were multithreaded, but not since. To allow the client operating

* Microsoft RPC is actually layered on top of SMB, primarily so that it can exploit the authentication and resource (share) identification provided by SMB. However, CIFS does not use Microsoft RPC.

TABLE 60.1 SMB Message Exchange in CIFS

Message	Meaning
SMB_COM_NEGOTIATE -> server client <- SMB_COM_NEGOTIATE	Client gives server list of SMB versions it is willing to use. Server chooses one and informs client. It also sends the client a security challenge.
SMB_COM_SESSION_SETUP_ANDX -> server client <- SMB_COM_SESSION_SETUP_ANDX	Client sends encrypted challenge to server, along with user's identity. Server verifies identity and fills in UID field.
SMB_COM_TREE_CONNECT_ANDX -> server client <- SMB_COM_TREE_CONNECT_ANDX	Client identifies the share it wants to use. Server fills in security fields and TID field.
SMB_COM_OPEN_ANDX -> server client <- SMB_COM_OPEN_ANDX	Client sends path name of file. Server performs access checks (based on UID) and, if OK, responds by filling in FID field.
SMB_COM_READ -> server client <- SMB_COM_READ	Client requests data from file. Server returns data.
SMB_COM_CLOSE -> server client <- SMB_COM_CLOSE	Client closes file. Server returns success.
SMB_COM_TREE_DISCONNECT -> server client <- SMB_COM_TREE_DISCONNECT	Client disconnects from share. Server returns success.

system (OS) to sort out responses to multithreaded processes, yet another ID is used: a multiplex ID, which, along with the PID, performs the function of ONC RPC's XID.

The set of IDs form the context for a request and are included in special field in the header, as needed. For many of the details of SMB see Storage Networking Industry Association (2002).

Table 60.1 (adapted from Storage Networking Industry Association (2002)) shows a typical exchange of messages.

A fair number of messages must be exchanged before the client can get any data from a file, and most of these messages simply add one more ID to the context. So, rather than require these messages in sequence, SMB lets them be batched: a client sends a sequence of requests in a single message, and the server responds to all of them in a single response message. This batching ability is given the ungainly name of "andX." Thus in the sample exchange, in Table 60.1, the requests starting with the session setup request through the read request can all be sent in one message. If they all succeed, the server sends back a single response containing all the IDs that have been established and the data requested by the read. If any of the requests fails, the server handles no further requests from the message and returns the cumulative result of all requests up through the failing one. Any request (or response) may be at the end of a batch; only those requests (or responses) whose names end with "_ANDX" may come before other requests (or responses) in a batch.

60.3.2 Opportunistic Locks

One way to achieve strict consistency is to perform all operations at the server without caching data at clients. This is CIFS's default approach, but definitely not the only one possible. Local caching of a file's data at a client is safe, with respect to consistency, either if the client is the only one using the file or if all clients using the file are doing so read-only. The hard part is limiting such caching to just those two cases.

CIFS relies on the server's knowledge of clients' open-file states to determine when it is safe for a client to do local caching. If a client opens a file for reading and writing that is not otherwise open, the server may notify the client that caching is safe. If another client wants to open the file (assuming the share mode permits it), the server must notify the first client that caching is no longer safe and that the client must send all changes it is made to the file back to the server. Then both clients may use the file, but no local caching is permitted on either.

When a client opens a file, as part of the open SMB request, it may ask for an *opportunistic lock* (or *oplock*). There are two categories of such locks: level I and level II. The former allow exclusive access; the latter allow shared access. The server may or may not grant the request depending on whether and how the file is open by others. If the client obtains a level-I oplock, then it is assured that no other client has the file open and thus it can safely cache file data (and metadata) locally. If it obtains a level-II oplock, then it is assured that no other client has the file open in a mode that allows changes, and thus it can safely cache blocks from the file, but any changes it makes must be sent directly to the server, and the server will then revoke all level-II oplocks on the file. Thus, if a file is being used for both reading and writing, a level-I oplock is needed, but if it is being used just for reading, level II suffices. Note that the client application is oblivious of oplocks—it simply opens files and performs operations on them. It is the client’s operating system that is responsible for local caching and thus must request oplocks.

To revoke an oplock, the server sends the client an oplock-break SMB request. If a level-I oplock is being revoked, the server will give it a level-II oplock if possible. The client must send back all changes to the server, then signify it is done so by sending a response to the oplock-break request. Since there is nothing to send back when a level-II oplock is being revoked, no response is required.

The CIFS protocol does not allow a client to request a level-II oplock. Instead, it must request a level-I oplock, but it might, at the server’s discretion, get a level-II one instead. This might seem a bit strange; the rationale is that though files are often used read-only, rarely are they opened that way. Thus, most opens are read-write, even though writing may well not be done. So, if one client has a file open read-write but does not write, and another client opens the same file read-write but does not write either, then if both clients request level-I oplocks, they will end up with level-II oplocks.

If a client closes a file for which it has an oplock, will its cache still be useful if it opens the file again a short time later? The SMB close request releases all oplocks associated with the file, so there’s no guarantee that cached data are valid if the file is reopened—since the client no longer has an oplock, the server is not obliged to notify the client if any other client opens the file. However, the client might cheat a bit: rather than sending an SMB close request to the server when its user application closes the file, it can keep quiet in hopes that some local application opens the file again. If this indeed happens and the client still holds the oplock, then the client is guaranteed that its cache is still valid. On the other hand, if another client opens the file, the server will revoke the original client’s oplock, thus telling it that its cache is no longer valid. At this point the client might tell the server that the file is really closed.

For level-II oplocks, such a delayed-close strategy might seem easy: the client holds a level-II oplock when the application closes the file. Shortly thereafter, an application opens the file again. Since the client already has a level-II oplock, not only is the cache still valid but no sort of request needs to be sent to the server. However, as we just mentioned, few applications open files read-only. Thus the second open will probably be for read-write use (even though the file might never be written to). Since the only opportunity the client has to request an oplock is when the file is opened, the client must request a level-I oplock on the off chance that the application might actually write to the file. Thus, an SMB open request must be sent to the server, and the server might grant the level-I oplock or might simply let the client keep the level-II oplock. But the cached file blocks at the client are still valid, so despite the need to send a request to the server, the delayed-close strategy is a win.

The delayed-close strategy for level-I oplocks works a bit differently. If an application closes a file and then it or some other client application opens it again, a level-I oplock need not be requested of the server, since the client already has one. Thus, until the level-I oplock is revoked, there is no need for the client to notify the server of any changes to the open state of the file, nor any need to write back modified file blocks (other than to reduce loss in the event of a client crash). However, if the server does revoke the level-I oplock, the client must not only send back to the server all modified file blocks but also update it to the file’s current open state by sending it whatever SMB open and close requests will get it there.

Not all clients are capable of doing this sort of batching, so there are actually two kinds of level-I oplocks—*exclusive* and *batch*. If a client holds an exclusive oplock, it must send the server an SMB close request along with all modified blocks when the application closes the file. It must then obtain a new

oplock if the file is reopened, at which time it may not use any previously cached blocks from the file. If a client holds a batch oplock, then it uses the delayed-close strategy mentioned earlier. Only on older systems do clients still use exclusive locks.

60.4 DFS

DFS, the DFS of distributed computing environment (DCE), is no longer in common use but is interesting because of its approach to caching and failure recovery. It is derived from an earlier DFS, Andrew File System (AFS).^{*} Both systems addressed the need for client caching of files in a day when primary storage was expensive: they use client disks to cache files from the server. AFS caches files in their entirety; DFS caches data from files in 64 KB blocks.

Like CIFS, DFS provides strictly consistent sharing of files. However, unlike CIFS, clients always use their caches, even if multiple clients are making changes to the same file. Further unlike CIFS, DFS attempts to recover from server crashes.

The DFS server coordinates its clients' use of their caches by passing out "tokens," each of which grants the client permission to perform a certain operation (such as read or write) on a range of bytes within a file. Since all operations are done in the client's cache, the tokens control the use of the cache.

Suppose an application on client A opens a file for reading and writing, client A's DFS cache manager (running as part of the operating system) sends an open request to the DFS server (using DCE RPC) asking for OPEN_READ and OPEN_WRITE tokens for the file (see Figures 60.7 through 60.12). The server sends back a response containing the tokens, keeping as part of its token state that such tokens are at client A. In response to the application's first read of the file, client A's cache manager requests data from the server, along with a DATA_READ token giving it permission to use this data in its cache. It fetches not just the data needed but 64 kB data blocks, thus performing aggressive read-ahead. If the client application performs a write system call, the client's cache manager first obtains a DATA_WRITE token from the server, granting the client permission to modify a range of bytes in its cache.

Suppose an application on client B opens the same file for reading and writing. Client B's cache manager obtains OPEN_READ and OPEN_WRITE tokens, as did client A's. The application now

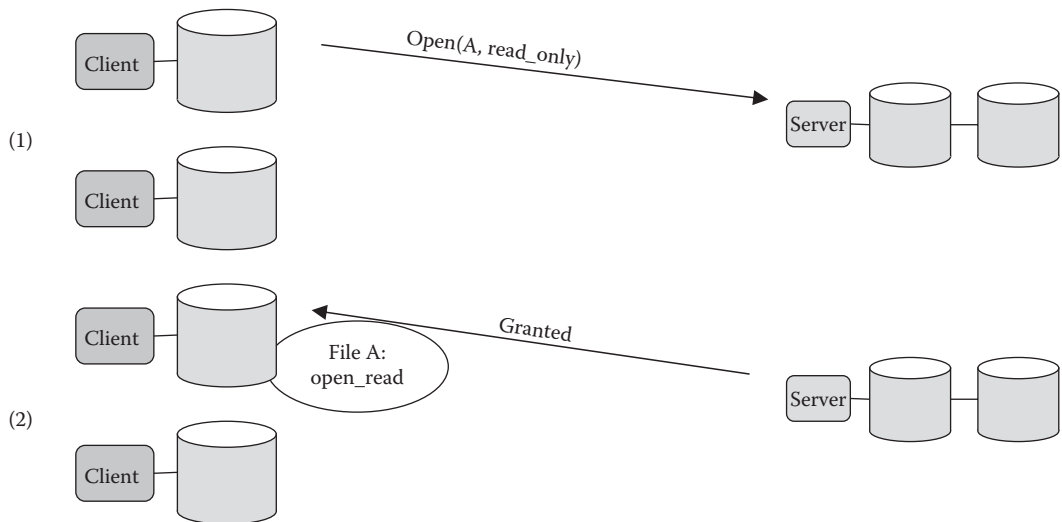

FIGURE 60.7 A DFS client opens a file read-only.

^{*} AFS stands for Andrew File System, so called because it was developed at Carnegie Mellon University: both Mr. Carnegie and Mr. Mellon had the first name Andrew.

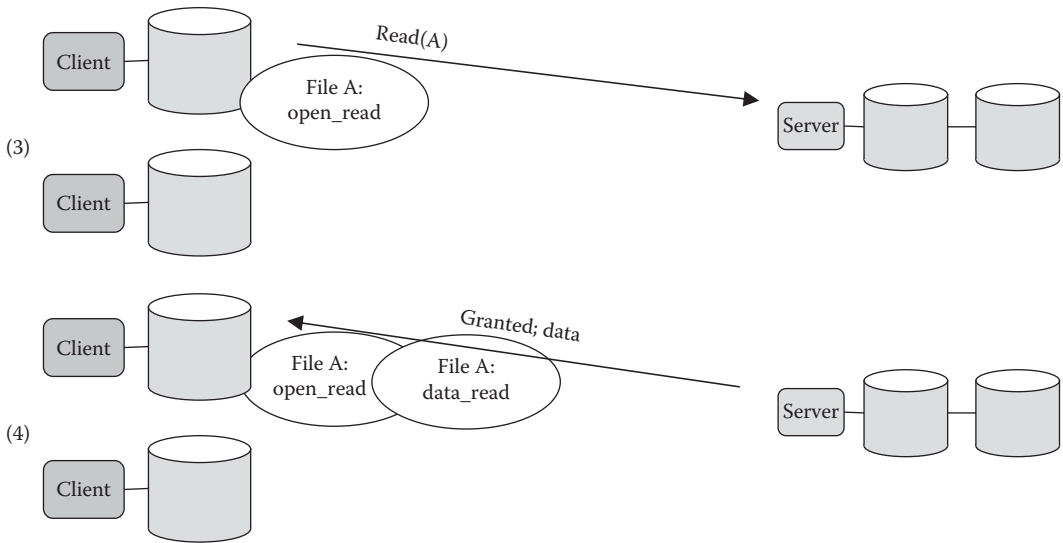

FIGURE 60.8 The DFS client reads data from the file.

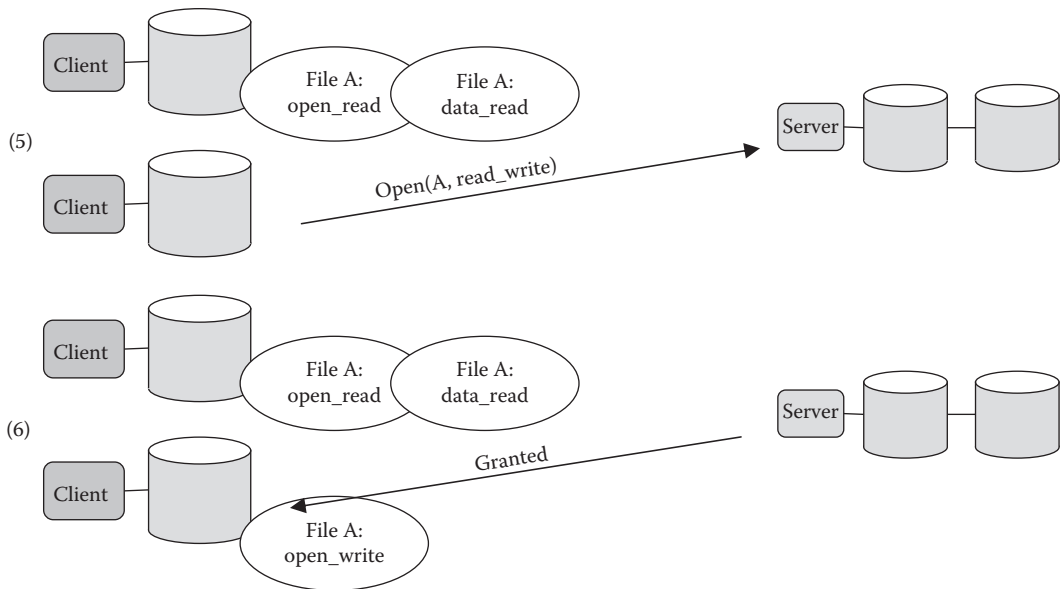

FIGURE 60.9 Another DFS client opens the file for both reading and writing.

performs a read system call for a portion of the file for which client A has a DATA_READ token (but not a DATA_WRITE token). This is not a problem, so the DFS server sends client B the data along with a DATA_READ token.

Now the application performs a read system call for a portion of the file for which client A has a DATA_WRITE token. Before the DFS server can grant B a DATA_READ token, it sends a revoke request to client A revoking its DATA_WRITE token. Client A responds by both giving up the token and sending back the modified file data from its cache. The server now sends client B both a DATA_READ token and the data.

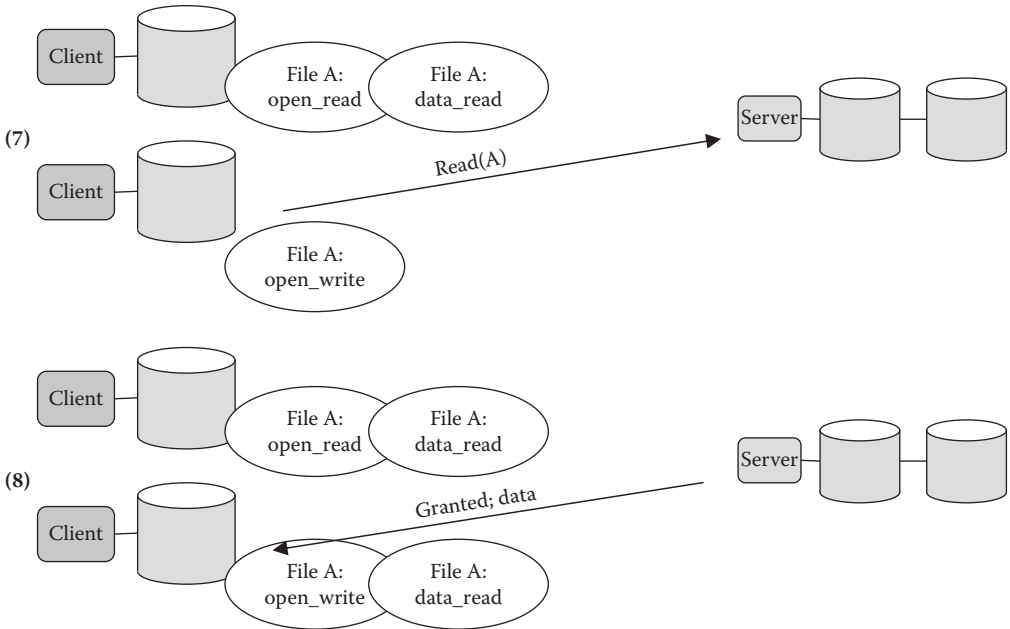

FIGURE 60.10 The second DFS client reads from the file.

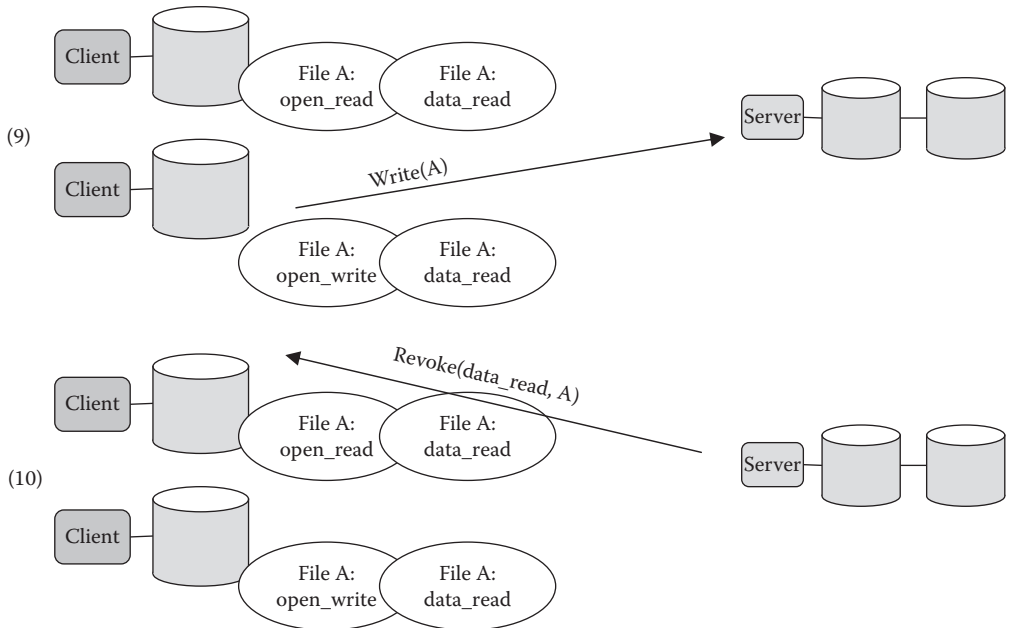

FIGURE 60.11 The server revokes the first client's data_read token.

This is all straightforward, though perhaps laborious. Like both NFSv2 and CIFS, DFS handles the common cases efficiently: if only one client is modifying a file and no clients are reading it, or if a number of clients are reading a file but none are modifying it, all file data resides in client caches and just a minimal number of messages are exchanged. Unlike NFSv2 but like CIFS, all client caches are strictly consistent with the server.

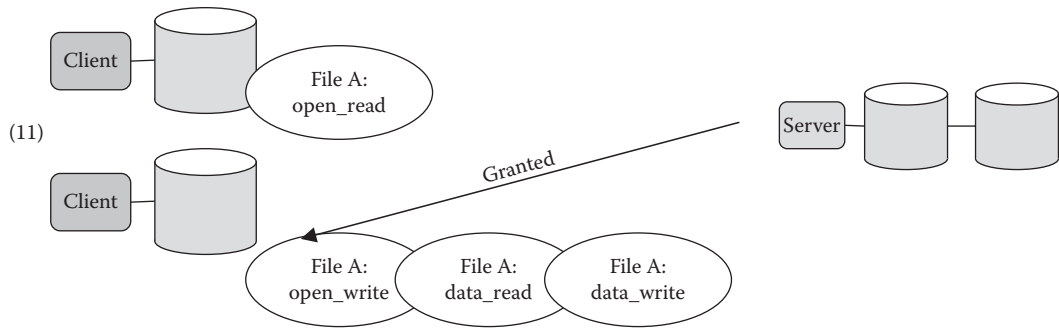

FIGURE 60.12 The DFS client gains permission to write to the file.

The DFS server, like the CIFS server, maintains a fair amount of state information about its clients. In DFS, this information consists of all the tokens held by each of the clients. If a client crashes, the DFS server simply removes the client's tokens from its state information. If the server crashes, then a procedure almost identical to that used by NFSv2's network lock manager recovers the server state from the clients.

Providing strict consistency is relatively easy when, as in CIFS, no attempt is made to recover from server crashes. Recovering from server crashes is relatively easy when, as in NFSv2, no attempt is made to provide strict consistency. DFS tries to do both and has to make some compromises.

The primary issue is client behavior while the server is not responding. If the server is actually down and the client's tokens will not have timed out by the time the server comes back up, then it would be reasonable to let client applications continue to function, where possible, using their local caches. But it could be that the server is not down, just unreachable because of network problems. If so, it is possible that the server, not being able to contact our client, has assumed it to have crashed; our client's tokens might then be unilaterally superseded by the actions of another client, one that can communicate with the server.

Because of this uncertainty, DFS forces system calls on open files to fail once the client determines that the server is not responding. When the server does respond, perhaps having just recovered from a crash, then if the client's tokens are still valid, system calls on open files succeed again.

This approach has the advantage of adhering to POSIX file semantics as long as system calls succeed. However, unlike NFSv2, where client applications can be oblivious to periods of server unresponsiveness, DFS requires the client to be prepared for system calls to fail while the server is unreachable and to retry them explicitly. Furthermore, contact with the server might be lost after an application has performed its last write to a file but before it has closed the file and before the data has been transferred to the server. Thus the only system call left that can fail, and thus tell the application that something is wrong, is the close. It is therefore important that applications check for errors from close when using files from a DFS server. However, few applications do this, since with other file systems it seems inconceivable that close could actually fail.

60.5 NFS Version 4

NFSv4 is a major revision of NFS. Its designers' goals were to provide better performance, stronger consistency, and stronger security than in prior versions, to support not only Unix clients but also Windows clients, and to work well on the modern Internet, particularly where clients and servers may be behind firewalls. A side effect of all this is that the three separate protocols of prior NFS versions (mount protocol, file protocol, and network lock manager) are all combined into a single protocol.

NFSv4 dispenses with the mount protocol by having servers combine their exported file systems into a single "pseudo file system" and supplying a RPC request to obtain the root of that file system. Figure 60.13 shows the file system of a server that exports a few of its subtrees to clients; Figure 60.14 shows the pseudo file system that is made available to clients—note that anything not exported by the server is not seen by clients.

FIGURE 60.13 The directory hierarchy of an NFSv4 server that exports three subtrees.

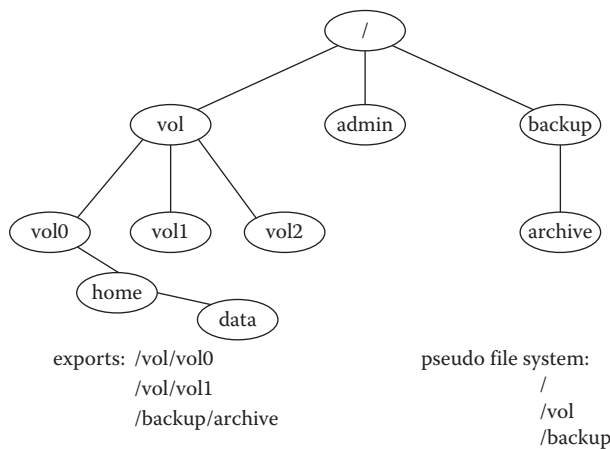

FIGURE 60.14 The pseudo file system that clients of the server of Figures 60.10 through 60.13. (see /admin and /vol/vol2 are not seen.)

NFSv4 reduces network traffic by using *compound RPC*, which allows a number of RPC requests to be encoded in a single message and their responses to be returned in a single message, much as is the case with CIFS's and X facility.

We focus here on consistency and failure handling. Of particular interest is NFSv4's support for *mandatory locks* (it supports advisory locks as well) and *share reservations*—the same thing as share modes in Windows. The network lock manager of prior NFS versions supported only advisory locks. Mandatory locks are expected by Windows applications and supported by some versions of Unix. Share reservations are not really usable by Unix applications—there is no standard API for them—but they are required by Windows applications.

NFSv4's consistency model essentially combines the rather weak consistency of prior NFS versions and the strict consistency of CIFS. If clients use locks or share reservations appropriately when accessing files, NFSv4 guarantees entry consistency. If locks are not used, consistency is the same as that in prior NFS versions. As a performance optimization, NFSv4 uses a technique similar to CIFS' *oplocks* called *open delegation*. It allows a server to delegate to a client the chores of managing opens, locks, and caching for a file, while no other clients are performing conflicting operations.

The big difference between NFSv4 and CIFS is NFSv4's tolerance for failures. Prior versions of NFS were failure-tolerant as well, but NFSv4 is a step more so, since its servers hold much more state information than those of prior versions.

CIFS depends on the transport protocol to insure that requests are properly ordered, without duplicates. NFS, on the other hand, effectively has the notion of a session layer above the transport, and it is this session layer that insures proper ordering of requests.* Thus if the transport connection is lost, CIFS has no additional information to insure proper request ordering and must delete all client state on the server, causing any current and subsequent client requests to fail. NFS does not depend on the transport protocol for proper ordering and thus can recover from a loss of transport connection (and can run on unreliable, connectionless transports such as UDP).

In prior versions of NFS, this connection layer does not require any state information on the server other than the DRC, and thus clients do nothing explicit to set up the session or take it down. But NFSv4, as we discuss in Section 60.5.1, requires more substantial session-oriented state information. Though clients explicitly establish sessions, there is no explicit action to take them down. Instead, as explained in the subsequent sections, servers remove session state when the client appears to be no longer active, but clients can recover it.

60.5.1 Managing State

NFSv4 servers maintain a hierarchy of state. At the top is the inventory of active clients. Each client identifies itself to the server, providing a unique *client ID*. In response, the server puts together client-ID state, which includes a *lease period*: if the server does not hear from the client during this period, it concludes that it has crashed or has otherwise lost interest, and thus the server can rid itself of the client-ID state and all subordinate state. A client renews its lease by making any sort of NFSv4 request to the server. If it has nothing else to say, it can send a special *renew* request that does nothing but renew the lease.

When a client does open a file, there are additional concerns. To support share reservations, each time some client opens a file the server must put together an *open-state* record containing the access modes and the share reservation. The server returns the client a *state ID* to refer to it, which, along with the NFS file handle, plays the role of a Unix file descriptor or a Windows file handle and is included with subsequent file operations to identify the caller's open state.

The open-state records and state IDs form the elaborate data structure shown in Figure 60.15 in which the client has a number of files open, each with its own open-state record. We explain this figure more fully in the subsequent sections, where we explore the notion of an "open owner."

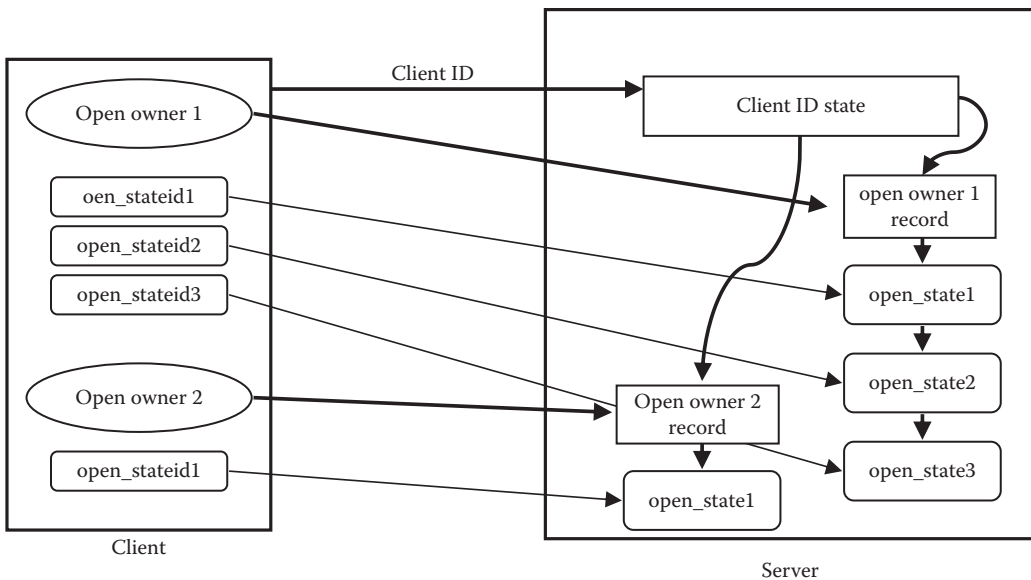

FIGURE 60.15 Open state in NFSv4.

* The session layer is implicit in NFS through version 4.0 and is made explicit starting in version 4.1.

60.5.1.1 Mandatory Locks

NFSv4 supports not only advisory byte-range locks but mandatory ones as well. The latter are a rarely used feature of Unix, partly because it has not been supported by NFS in the past, partly because using it is somewhat obscure (it is enabled by turning on a file's set-group-ID access-permission bit and turning off its group-execute permission bit. On Linux, one must additionally turn on this facility for an entire file system by setting a mount flag). Adding to the confusion is the fact that Windows' semantics for mandatory byte-range locks (it does not support advisory locks) are different from Unix's. In both systems, byte-range locks belong to a process. Thus, for example, in Unix, suppose a process P1 opens file F, producing file descriptor FD1, and then forks a child process P2. If P2 places a mandatory exclusive byte-range lock on byte 0 of the file via FD1, then only P2 may access that byte—not P1, even though they share the same open-file-table entry for the file. Now suppose P2 opens the same file again, this time producing file descriptor FD2. Even though P2 had locked byte 0 via FD1, it can still access that byte via FD2—what matters is that the process has the file locked; it does not matter which file descriptor is used.* However, things are different in Windows, where the lock is associated not just with the process but also with the Windows file handle. Thus in a Windows version of this example, the process is not allowed to access byte 0 via FD2 until the lock placed via FD1 is removed.

When a server receives a read or write request from a client, it needs to know which locks held by the client actually apply to this particular request. For a Unix client, the answer would be all locks held by the client process for the file in question, but for a Windows client, it would be just those locks held by the client process that were placed using the same Windows file handle as was used for the read or write request. But the server does not necessarily know, which requests came from which processes or which requests were made through which Windows file handles.

Rather than give the server this information (which would have to include whether Unix, Windows, or some other lock semantics are being used), the NFSv4 client instead assigns “owners” to locks. When it issues a read or write request, it lets the server know which locks apply by telling it who the owner is. So, for Unix clients, all locks taken by a particular process might be given the same owner, or perhaps all locks taken by a particular process on a particular file might be given the same owner (it does not matter which, since the read or write request identifies the file). For Windows clients, all locks taken by a particular process via a particular Windows file handle are given the same owner. The server does not need to know what the client's lock semantics are; it just needs to keep track of lock owners.

A *lock owner* on a client is simply a unique (to the client) integer. When the client requests a lock requiring a new lock owner, it passes the corresponding integer to the server. In response, the server establishes *lock state* to represent this lock owner and returns to the client a *lock-state ID* referring to the state. Henceforth, the client uses this lock-state ID rather than the lock-owner integer. When the client requests additional locks for the same lock owner, it passes the corresponding lock-state ID to the server. When, for example, the client sends a write request to the server, it includes a lock-state ID to tell the server which locks should apply (a special lock-state ID is sent if no locks apply). Thus the server's lock state represents all the locks held by a particular client lock owner. See Figure 60.16.

60.5.1.2 Maintaining Order

NFSv4's state hierarchy of client ID, open state, and lock state presents challenges. Client crashes must be detected and no-longer-useful state removed from the server. Not only must server crashes be detected, but clients must reestablish their state on the servers. And finally, everything must function correctly in spite of Byzantine routers.

Establishing the client-ID state is far from immune to problems with late-arriving duplicates. If the server receives a request to establish a client ID that already exists, it might decide that the client has

* Another property is that all byte-range locks of a file are removed if any of the process's file descriptors for the file are closed. So suppose P2 in our example was not aware that FD1 and FD2 refer to the same file. If it then locks the file via FD2 and closes FD1, it might be surprised to discover that the file referred to by FD2 no longer has a lock.

FIGURE 60.16 Lock state in NFSv4.

crashed and has restarted. Even a request to establish a client ID that does not exist might be a long-delayed duplicate from a client that is no longer active. Setting up the state again might tie up resources needlessly.

Open requests (with share reservations) and mandatory lock requests are particularly sensitive to Byzantine routers. Suppose, for example, a portion of a file is locked, then unlocked, and then a much-delayed duplicate of the lock request arrives at the server. If the server does not realize it is a duplicate and locks the file again, then, since the client does not know the file is locked, the file might stay locked for an arbitrarily long period of time.

An explicit session layer, introduced in NFSv4.1, simplifies matters tremendously. Recall that a problem with the DRC of prior NFS versions was determining how long a request must remain in the DRC—the intent is that a late-arriving duplicate request will be recognized as a duplicate, no matter how late it is. Earlier versions of NFS used a simple time-based mechanism for removing requests from the DRC. In NFSv4, clients identify concurrent streams of NFS requests; requests within each stream are assigned sequence numbers, and the streams themselves are assigned slot numbers. The DRC is divided into corresponding slots. When a request is received, it is cached in the associated DRC slot. When a request with a larger sequence number is received, it replaces the previous entry in the DRC slot. If a request with a sequence number equal to the one in the DRC slot is received, the previous response is returned. If a request with a smaller sequence number is received, it must be a very late-arriving duplicate and is discarded (see Chapter 9 of Doeppner (2011) for details). With this approach, *in the absence of server crashes*, open requests, lock requests, data-transfer requests (reads and writes), etc. have exactly once semantics—there are no problems with Byzantine routers and duplicates that cross transport-connection boundaries.

60.5.2 Dealing with Failure

NFSv4 deals with failure issues not handled by its predecessors. Though it uses basically the same strategy for recovery from server failures as the network lock manager of v2 and v3, there is more state to recover and there are more operations that depend on this state. Not only locks but also all open state must be recovered. Because locks may be mandatory and share reservations definitely are mandatory, it is particularly important that crashed clients be detected quickly and restarted servers recover their state quickly. But in addition, there is a new problem: when a server restarts, the client with the most recent lock state might be temporarily unreachable, but a client with older, superseded lock state might try to reclaim that state on the server.

Leases provide the basic defense against client crashes. Clients are expected to renew their leases; if a client ID's lease time expires, the server assumes it has crashed and may dispose of all its state, thus closing all files and breaking all locks. This might be considered pretty drastic if the client has not really crashed but there is merely a temporary network problem. It is also very different behavior from that experienced by NFSv2 and v3 clients: they never had to worry about the server's closing their files, since the server never knew they were open in the first place. However, such behavior is unavoidable when unresponding clients hold lock state or share reservations.

A client might crash, reboot, and recontact the server well before its original lease has expired. The fact that the client is reestablishing its client ID might be a clue to the server that it has restarted, but there are reasons other than crashing that a client might do this. So included with the client-ID state on the server is a 64-bit *verifier* that is supplied by the client when it establishes its client ID and is different each time the client reboots. Thus, if the server receives a set-up-client-ID request from a client for which it still has state, if the verifier supplied with the request is different from what's included with the saved state, then the server knows the client has restarted and the saved state should be discarded. But if the verifiers are the same, then the saved state is still valid.

Clients find out about server crashes when RPC requests that depend on open and lock state return error codes indicating that the state no longer exists. For a period before then (while the server was down), such calls might have timed out, but the only way for a client to distinguish a server problem from a temporary communications problem is for the server to give a positive indication that it has no record of the client. The problem might turn out to be not that the server crashed, but that the client's lease expired; but from the client's point of view, lease expiration is just as bad, if not worse.

As with the network lock manager in v2 and v3, when a server restarts, it establishes a grace period during which clients may recover their states. How long should the grace period be? A client would not discover that the server has crashed until it sends it a request. But the client is not required to send the server a request until just before its lease expires. So, in case a client renewed its lease just before the server crashed, the server's grace period should be at least as long as the lease period.

Suppose a client discovers that its server state has disappeared, its first response is to reestablish its client-ID state, along with a new verifier. Then, as with the network lock manager, it tries to reclaim its previous state.

Now the server has decisions to make. If it is not in its grace period following a restart, then the reason the client's state no longer exists is probably that it was discarded after the client's lease expired. This could be due to incompetence on the client's part, but is most likely the result of a network problem. If the server can determine that no conflicting opens or locks have been given to other clients since the lease expired, then it may allow the client to reclaim its state. But, in general, the server probably cannot determine this, so it must refuse the reclaim request and the client must report an error back to the application (and thus the application must be prepared to cope with the bad news).

If the server is within its grace period, then the reclaim request is probably for state held when the server crashed, and thus it should be granted. However, the client might have been disconnected from the server because of a network problem. In the meantime, the client's lease expired, the server granted a conflicting lock to another client, and then the server crashed. Finally, the network problems experienced by the first client have been solved, and it is now trying to reclaim its (ancient) state. But it really should be the second client whose state is reclaimed.

The general problem for the server when it receives a reclaim request is to make sure that the state being reclaimed has not been superseded by more recent operations by other clients. The NFSv4 specification (RFC 3530*) requires servers to err on the side of safety: if they are not sure, they must refuse the reclaim request.

The only way for a server to be absolutely sure is to record all share reservations and locks in stable storage, so that they can be recovered after a crash. This is probably too time-consuming for most servers.

* <http://www.faqs.org/rfcs/rfc3530.html>.

At the other extreme, a server could simply refuse to accept reclaims on the grounds that it does not have enough information to determine if any of them are for the most recent state.

A reasonable compromise is for the server to keep enough information on stable storage to determine which client IDs hold state. Then, during the grace period, it can refuse all reclaim requests from clients who did not hold state at the time of the most recent crash.

RFC 3530 suggests servers record the following information on stable storage for each client ID:

- Client ID.
- The time of the client's first acquisition of a share reservation or lock after a server reboot or client lease expiration.
- A flag indicating whether the client's most recent state was revoked because of a lease expiration.

In addition, the server stores on stable storage the times of its two most recent restarts. Doing this requires minimal server overhead, yet allows it to determine whether a client definitely held valid server state at the time of the last server crash. We take this up in Exercise 9.

60.6 Conclusions

DFSs are normally made as transparent as possible to users and their applications; as we have seen, much has been done to make accessing remote files indistinguishable from accessing local files. The major problem is coping with failure, both of communication and of machines. NFS has been successful because of its compromises. Prior to version 4, it provided semantics that were “pretty close” to local Unix file semantics, with a response to failure that “pretty well” insulated the client from server and network problems. CIFS, and to a certain extent DFS, were based on the premise that providing semantics that are exactly the same as local semantics is more important than insulating the client from server and network problems. NFSv4 is attempting to come as close as possible to achieving local-file-system semantics while still insulating clients from server problems (and vice versa).

61.1 Introduction

A *mobile operating system*, or *mobile OS*, is an operating system that is designed to run on a mobile device, such as a mobile phone, personal digital assistant (PDA), or a tablet computer. Like traditional operating systems, a mobile OS is the software layer that sits between the device's hardware and its application layers. As such, a mobile OS is an abstraction built in software that hides the details of the hardware layer from the applications that sit atop it.

Its primary role is to manage the device's hardware resources—the processor, memory, input/output (I/O) devices, network, etc.—and to provide a variety of services and easy-to-use software interfaces to support the device's various uses. This would include providing a user interface (UI) as well as providing programming interfaces that allow developers to create applications to extend the device's basic functions.

Although many of the issues and challenges that characterize operating systems research and development are present also in mobile OS development, the field is characterized by distinctive computational issues made important by the size limitations of mobile devices, their reliance on battery power, and by their mobility.

61.1.1 Historical Overview

A *mobile phone* (or cellular phone) can send and receive telephone calls over a radio link. The calls are transmitted over a *cellular network* that is operated by a service provider. The very first mobile telephone call was made in 1946 from a car using Bell Laboratory's Mobile Telephone Service (MTS). MTS became a commercial service provided by AT&T in St. Louis and other metropolitan areas. The system had very few radio channels and relied on a human operator to connect calls. Ten years later, a Swedish company developed the first automatic car phone system, which used vacuum tube technology and

weighed 88 pounds [Wikipedia: History of the mobile phone 2012]. Named mobile telephone system A, it allowed calls to be made and received in the car using a rotary dial. The car phone could also be paged.

The first handheld mobile device was developed in 1973 by Motorola. It weighed 2.5 lb and offered a talk time of 30 min and took 10 h to recharge [Wikipedia: History of the mobile phone 2012]. The world's first public cellular call was made in the New York City to a landline by Dr. Martin Cooper, a general manager for the communications systems division at Motorola. "As I walked down the street while talking on the phone," Cooper once told an interviewer, "sophisticated New Yorkers gaped at the sight of someone actually moving around while making a phone call" [Greene 2011].

In 1983, Motorola commercially released the DynaTAC phone—seen sported by Michael Douglas in the 1987 movie *Wall Street*—which is considered one of the world's first mobile phones. Based on the prototype developed in 1973, the DynaTAC weighed almost two pounds, provided 1 h of battery life, and stored 30 phone numbers in its phonebook.

In 1987, Nokia launched the Mobira Cityman 900—the first handheld mobile phone for Nordic Mobile Telephony (NMT) networks. The Mobira Cityman 900 became an iconic device when Soviet leader Mikhail Gorbachev was photographed using a Cityman to make a call from Helsinki to Moscow [Ross Catanzariti n.d.]. In 1989 Motorola MicroTAC 9800X was released, which was one of the first truly portable phones, with its ability to be slipped into a jacket pocket. The Motorola International 3200 followed in 1992 as the first digital hand-sized telephone.

Early mobile phones did not have operating systems in the full sense of the term. Rather, they were controlled by *embedded systems*—that is, a system that is specifically designed to control the device's particular hardware components, such as its battery and radio transmitter, and software. Unlike a true operating system, an embedded operating system does not load and execute applications and is not designed for general purpose computing system.

61.1.2 Cellular Networks

With the advent of the mobile telephony devices, there was a need for cellular network technology that could provide broader coverage and faster and more reliable data transmission capabilities. The introduction of cellular technology made possible the re-use of frequencies by multiple users in small adjacent areas covered by relatively low-powered transmitters, making widespread adoption of mobile telephones economically feasible.

AT&T's MTS, introduced in 1947, now considered zero-generation service, was a precursor to modern day cellular networks. The service relied on an operator to connect both incoming and outgoing calls [Massa 2006]. In the 1970s, AT&T introduced the first-generation (1G) analog mobile phone services, one of the first automatic mobile networks to get Federal Communications Commission approval in the United States [AT&T 2012].

These systems were referred to as *cellular*, due to the method by which the signals were handed off between towers. A *cell* can be visualized as a geographic area with a single *transceiver* known as a base station or cell tower. In order to avoid interference, adjacent cells use different sets of frequencies [Marshall Brain 2011]. Contemporary cellular networks use a system whereby towers are situated at three corners of a hexagonal shaped cell. As shown in Figure 61.1, each tower broadcasts three directional signals, each of a different frequency. The frequencies within a given cell differ from the frequencies in all six adjacent cells. As a device travels through a geographical area, it switches from one frequency to another in a process known as a *handoff* [Wikipedia: Cellular network 2012]. Typically, the base station chooses a frequency as the device enters its area and the device automatically switches to the new frequency. To the cell phone user, the switch is usually imperceptible and, ideally, communication is not interrupted.

In terms of global systems, the Japanese telecommunications company, NTT, built its own network in 1979. Five years later, it was the first 1G network to cover an entire country. The NMT network operated in Denmark, Sweden, Finland, and Norway followed in 1981, becoming the first system to feature international roaming.

FIGURE 61.1 Cellular network. (http://en.wikipedia.org/wiki/Cellular_network)

The 1990s saw the emergence of two digital networking standards: the European global system for mobile communications (GSM) standard and the North American code division multiple access (CDMA) standard [Wikipedia: 2G 2012]. GSM-based phones use subscriber identity modules—SIM cards—to store user data and are not linked to a particular device. In the United States, CDMA carriers use network-based white lists to verify their subscribers. That means, you can only switch phones with your carrier’s permission, and a carrier does not have to accept any particular phone onto its network. Both CDMA and GSM are *multiple access* technologies—that is, they enable users to combine multiple phone calls or Internet connections into one radio channel.

GSM is a *time division* system. Voice signals are transformed into digital data and then given a channel and a time slot. On the other end, the receiver listens only to the assigned time slot and pieces the call back together. CDMA is a *code division* system. A call’s data are encoded with a unique key and combined with other calls and all are transmitted in the same time slot. Receivers use the key to divide the combined signals into its individual calls [Segan 2012]. In addition to sound, CDMA and GSM networks are also capable of transmitting small amounts of data, making possible such features as the short message system (SMS), or text messaging, caller ID, and voicemail.

FIGURE 61.2 Nokia 1011. (http://www.reghardware.com/2007/11/09/ft_nokia_1011/)

Nokia's 1011 was the world's first commercially produced GSM mobile phone, becoming the model for the "candy-bar" design found in many of today's low-cost mobile phones. The 1011 had a monochrome display (see Figure 61.2), an extendable antenna, and a phonebook that stored up to 99 phone numbers.

In the late 1990s, the general packet radio service (GPRS) standard emerged. This added packet-switched data capabilities to existing GSM networks, which initially used a circuit-switched telephony system. Informally, GPRS is also called 2.5G. It allows users to send graphics-rich data as packets and to transmit IP packets to external networks such as the Internet [GSM World 2012]. GSM/GPRS accounts for over 80% of all 2G subscribers [Wikipedia: 2G 2012].

The introduction of the third-generation (3G) networks allowed mobile telephone customers to use audio, graphics, and video applications, enabling widespread mobile Internet services. NTT DoCoMo launched the first commercial 3G network in 2001, using the wideband CDMA (W-CDMA) wireless standard. W-CDMA, also known as universal mobile telephone system, offers greater spectral efficiency and bandwidth for more data capacity and is a refinement of the 2G CDMA system [Wikipedia: History of the mobile phone 2012].

In 2009, the fourth-generation (4G) network standard emerged, which includes such communication technologies as long-term evolution, worldwide interoperability for microwave access, and evolved high-speed packet access. These 4G standards are shepherded by the 3G partnership project, a standards governing body for GSM technologies that is responsible for the technical specifications [3rd Generation Partnership Project 2012]. The 4G networks use an IP-based architecture where everything (including voice) is handled as data, similar to the Internet. These data-optimized networks are geared toward an ever expanding demand for bandwidth and mobile capacity.

By the end of 2011, there were 6 billion mobile subscriptions, according to estimates by the International Telecommunication Union, the United Nations Agency responsible for information and communication technologies [International Telecommunication Union 2011]. With each progressive generation of cellular technology, we see improvements in data transfer capabilities, range, and reliability of the cellular networks, as summarized in Table 61.1. The increasing capabilities of services from 1G to 4G has led to the increasing popularity of smartphones.

61.1.3 Smartphone

A *smartphone* is a mobile phone with computer-like features, including a larger screen and an operating system capable of supporting third-party applications and running on different hardware architectures [Oxford University Press 2010]. Phones that typically have smaller screens and the ability to support some advanced functionality, such as web browsing or music and videos, are known as *feature phones*.

TABLE 61.1 Network Generations

Generation	Commercially Available	Dominant Technology	Applications	Speed
1G	Japan, 1979	Analog—AMPS	Voice only and no data services	14.4–28.8 kbps
2G	Finland, 1991	Digital circuit switch—GSM and CDMA	Short messaging service (SMS) and digital encryption	56–115 kbps
3G	Japan, 2001	Digital Packet Switched—W-CDMA (UMTS)	Mobile TV, video on demand, video conferencing, and location-based (GPS) services	2+ to 56 Mbps
4G	South Korea, 2006	IP-based network—LTE and WiMax (3GPP)	Broadband services and HD video streaming	100 Mbps–1 Gbps
5G ^a	Anticipated in 2020	Still in R&D phase	Improved service quality and intelligent networks and devices	1 Gbps +

^a At present, 5G is not a term officially used for any particular specification.

They usually have a limited operating system and, in general, do not support third-party software. If they do, they usually run on Java or binary runtime environment for wireless and are often standalone items that do not integrate with other features of the phone [Lee 2010].

Smartphones have revolutionized the way people interact with each other and with digital media. The first smartphone can be traced to Bell South's and IBM's Simon, released in 1993, which was a phone, personal data assistant (PDA), and fax machine, built into a single mobile device about the size of brick [Reed 2010]. It included a stylus-operated touchscreen and let you send and receive fax messages. It also included a built-in notepad, an e-mail client, contact list, and a calendar (Table 61.2).

Ericsson was the first brand to coin the term “smartphone” with the release of its GS88 in 1997, which contained a built-in keyboard and touchscreen and personal data assistant application suite [Wikipedia: Smartphone 2012]. Nokia released the Nokia 9000 Communicator in 1996 with a flip open keyboard design. In 2000, the touchscreen-based Ericsson R380 smartphone was the first device to use an open operating system called Symbian OS developed by Nokia. Microsoft released its first operating system targeted at the mobile device market, the Pocket PC, in 2000. This represented the first major push by a software company (as opposed to a phone company) into the mobile space. In 2001, we see Palm OS, BlackBerry OS, and Windows CE coming onto the scene. In 2002, Research in Motion (RIM) entered the mobile phone market with its BlackBerry 5810 device, the first mobile device optimized for e-mail and web browsing. During the 2000s, the Symbian system was the market leader for smartphone operating systems until it was surpassed by the Android operating system in 2011.

In 2007, the introduction of the Apple iPhone's iOS Operating System, the first major mobile OS to come out since the early 2000s, made a notable impact on the mobile OS marketplace. During most of the 2000s, the design of mobile OS, for the most part, did not undergo major change [Brookes 2012]. At the same time, however, hardware devices were making substantial technical leaps in terms of the capabilities and performance. iOS changed the perception of smartphones from that of a device targeted largely toward the business community to that of a commodity that all consumers could use. With this change came an increased emphasis on enhancing and enriching the *user experience*. Consequently, iOS focused more attention on the UI, including high resolution screens with spectacular graphics and such features as *multi-touch*, all of which were designed to appeal to the everyday consumer.

Apple also introduced a software developer kit to enable third-party application developers to write their own programs and distribute them to the end users through a common marketplace. This created a large community of developers writing applications (“apps”) that extended the functionality of the devices.

TABLE 61.2 Advanced Devices

Device	Capabilities	Device	Capabilities
Basic mobile phone	Network services, including: Voice telephony and voicemail SMS (short message service) USSD (unstructured supplementary service data)	Smartphone	As featurephone plus: Video camera Web browser GPS (global positioning system) 3G+ internet access Mobile operating systems (such as iOS, android, and blackberry) Ability to download and manage applications VoIP (voice over internet protocol) Mobile TV Removable memory card
Feature phone	As basic mobile phone plus: MMS (multimedia messaging service) Still picture camera MP3 music player 2G+ data access	Tablet	As smartphone plus: Front and rear facing cameras Larger screen and memory capabilities Faster processors External device connectivity ports.

Source: World Bank. Information and Communication for Development 2012: Maximizing Mobile. Case Study, Washington, DC: World Bank, 2012.

Note: The list of capabilities is not exhaustive and not all devices have all features.

In 2008, HTC released the HTC Dream, based on the Android operating system. Android was developed by Google in conjunction with the Open Handset Alliance (OHA), a consortium of 84 technology and mobile companies committed to developing open standards for mobile devices [Open Handset Alliance 2012]. OHA members include mobile operators, handset manufacturers, semiconductor companies, software companies, and commercialization companies. Google also released the Android market place (known today as Google play) for third-party application developers to develop and distribute applications. Unlike Apple’s iOS, which is proprietary and not licensed to third parties, Google’s Android operating system was released under the Apache open source license and was adopted by many mobile device manufactures. As a result, perhaps of its open licensing approach, Android has become the market leader for mobile OS, capturing over 50% of the market share in 2011 [Gartner Inc. 2012].

61.1.4 Commercial Development

As the preceding discussion highlights, the field of mobile OS is a rapidly growing area of research and development, most of which has been driven by the mobile phone and mobile technology industries. During the first few years of smartphone technology, the market was dominated by one or the other major phone manufacturers such as Nokia and RIM. Since 2007, however, the mobile OS market has come to be dominated by companies known for their software products, mainly Apple and Google as shown in the worldwide smartphone sales in the subsequent sections (Figure 61.3). Similar to the browser wars of the 1990s between Microsoft’s Internet Explorer and Mozilla’s Firefox and the earlier battles between Macs and IBM PCs, the mobile OS ecosystem has come to be dominated by a couple of players.

The current market leader is the Android operating system with over 56% of the global market as of February 2012, followed by Apple’s iOS operating system. The other systems, including RIM’s Blackberry, Microsoft’s Windows Mobile, and the Symbian OS, trail far behind the two leaders (Figure 61.4).

FIGURE 61.3 Smartphone sales. (Smartphone. Wikipedia. 2012. <http://en.wikipedia.org/wiki/Smartphone> [accessed October 3, 2012].)

FIGURE 61.4 Mobile operating systems global leaders. (Gartner Inc. “Android Extended Lead While Apple iOS Market Share Growth Paused.” Gartner Newsroom. August 12, 2012. <http://www.gartner.com/it/page.jsp?id=2120015> [accessed October 3, 2012].)

61.2 Underlying Principles

What distinguishes mobile OS from traditional operating systems are three main characteristics: (1) the relatively small size of the devices, (2) their mobility, and (3) their inclusion of hardware that is not typically found on laptop and desktop computer systems.

The relatively small size of mobile devices and the competitive drive to pack as much functionality as possible into a small space leads to important design considerations regarding power, memory

management, and processor utilization. Mobile OS are tasked with functioning within these resource-starved environments, while being accessible at a moment's notice.

As is true of desktop computers, a phone's ability to run multiple applications simultaneously depends on the amount of RAM it contains and the clock speed of the processor [Ginny Mies 2010]. Current generation smart phones typically have a 1Ghz, single-core processor and 512 MB of RAM with about 8–16 GB of storage built in. By comparison, a typical desktop computer is equipped with a 3+ Ghz multi-core processor, 2–4 GB of RAM, and 500 GB+ of external storage. Older and lower-end smartphones usually have around 256 MB of RAM—enough to run a handful of applications with little or no decrease in performance. Such a phone is capable of supporting texting, making calls, browsing the Web, and playing a few app games. High-end phones, such as the iPhone 4 and the Samsung Nexus S, have 512 MB of RAM and can run more applications without slowing the phone's performance.

Battery life is a key consideration for a mobile OS, as the majority of the time the device is not directly plugged into a power source and needs to be on or in-standby mode in order to respond to incoming calls and messages. A battery's up time will vary depending on the amount of time spent making phone calls, running apps, whether the apps are using such features as Wi-Fi or global positioning system (GPS), and other factors.

Most smartphones and regular cell phones today use liquid crystal display technology, range in size from 3 to 4.3 in., and are capable of displaying high definition video. Smartphones generally have a touchscreen interface and allow the user to interact directly with the phone's features and operating system. Some models have physical keyboards. The limited screen size is a consideration for both the mobile OS and application developers.

The phone's mobility poses special challenges for a mobile OS. Perhaps, the primary challenge at the OS level is optimizing battery usage. Another unique challenge is maintaining connectivity with cell phone towers though the device's radio hardware. The mobile OS must take into account the type and nature of a connection available to it and seamlessly transition for the user without interrupting ongoing activities such as making calls or receiving and sending text messages and other data transmissions. Mobile applications need to be able to function in an environment where the network connectivity is intermittent and can be interrupted. For instance, when a user is downloading a file or playing a video, the phone must still be able to respond to an incoming phone call or message. Obviously, phone functionality and communication ability are high priorities for mobile devices.

Although mobile devices contain some of the same features as desktop and laptop computers—for example, cameras, Bluetooth—supporting these features poses unique challenges for the mobile OS because of the relatively small size and power constraints of mobile devices. However, mobile devices also contain features not typically found in laptop and desktop computers. One of the prime examples, perhaps, is the inclusion of GPS hardware and gyroscope and accelerometer sensors. Such features place unique demands on the system to provide services that permit the easy development of location aware applications. Similarly, because of their small size and power needs, touchscreen interfaces place unique demands on the operating system.

Finally, because of the constant connectivity of mobile devices and the increasing consumer demand for sharing all types of information—images, messages, locations—data protection and information security are important considerations for mobile OS designers and app developers alike.

61.2.1 Mobile OS

There are a wide range of mobile OS and releases, far too many to provide a detailed description of each one. In this section, we will provide a brief summary of some of the most influential systems that have emerged, focusing on systems that have played some kind of unique role in the history or development

TABLE 61.3 Worldwide Mobile Device Sales to End Users by Operating System in 2012 (Thousands of Units)

Operating System	2012 Units	2012 Market Share (%)	2011 Units	2011 Market Share (%)
Android	98,529.3	64.1	46,775.9	43.4
iOS	28,935.0	18.8	19,628.8	18.2
Symbian	9,071.5	5.9	23,853.2	22.1
Research in Motion	7,991.2	5.2	12,652.3	11.7
Bada	4,208.8	2.7	2,055.8	1.9
Microsoft	4,087.0	2.7	1,723.8	1.6
Others	863.3	0.6	1,050.6	1.0
Total	153,686.1	100.0	107,740.4	100.0

Source: Gartner Inc. “Android Extended Lead While Apple iOS Market Share Growth Paused.” Gartner Newsroom. August 12, 2012. <http://www.gartner.com/it/page.jsp?id=2120015> (accessed October 3, 2012).

of this field. According to a 2012 Gartner report, the top mobile OS are Android, Symbian, Apple iOS, RIM BlackBerry, MeeGo, Windows Phone, and Bada [Gartner Inc. 2012] (Table 61.3).

- *Android (Google Inc.):* Initially released in 2005, programmed in C/C++ and Java and based on the Linux platform, Android has become the dominant operating system for smartphones and tablet devices. As an open source platform, it has been readily adopted and modified by multiple manufacturers and mobile operators and as such there is a proliferation of versions and variants in use today. Android’s App Inventor programming language developed by MIT allows users with limited programming ability to write their own apps using their web browser and a block-based development environment [Massachusetts Institute of Technology 2012].
- *Bada (Samsung Electronics):* A proprietary platform initially released in 2010, programmed in C++. Samsung is using its own Bada operating system, in parallel with Android OS and Windows Phone, for smartphones they develop (Samsung 2012).
- *BlackBerry OS (RIM):* A proprietary platform initially released in 1999, programmed in Java, the BlackBerry platform is best known for its native support for corporate e-mail services including Microsoft Exchange, Lotus Domino, and Novell GroupWise. BlackBerry used to make up 52.4% of the smartphone market in 2008. According to Q2 2012, the present mobile market share held by BlackBerry is 5.2% [Gartner Inc. 2012].
- *iPhone OS/iOS (Apple):* A proprietary platform initially released in 2007, programmed in C/C++ and Objective-C, the iOS mobile OS is available only on Apple manufactured devices and has not been licensed for third-party hardware. Apple iOS is derived from Apple’s Mac OS X Debian Linux-based operating system [Apple Inc: Start Developing iOS Apps Today 2012].
- *Symbian (Accenture):* Initially released in 1997, programmed in C++ and Qt, Symbian originally developed by Nokia, was transferred to Accenture in 2011 (Accenture 2011). Symbian is one of the oldest and the most successful mobile OS until 2010, when it dramatically lost market share to Android and iOS.
- *Windows Phone (Microsoft):* Initially released in 2010, the Windows Phone OS is programmed in C/C++ and NET built on the Windows CE platform. With Windows Phone, Microsoft features its design language called Metro, also found in Windows 8. The Windows Phone OS replaces the previous Windows Mobile OS developed in 2000 by Microsoft. Windows Mobile was discontinued in 2011 (Microsoft: Channel 9 2010).

We now provide a more detailed description and discussion of the two most dominant systems at the current time—Google’s Android OS and Apple’s iOS. We will focus on three main roles that the mobile OS

plays: (1) the abstraction it presents in hiding hardware details from the application layer, (2) the approaches it takes to managing the systems resources, and (3) the interface it presents to users and developers.

61.2.2 Android OS

61.2.2.1 Linux Kernel

As shown in Figure 61.5, the Android OS is built on the Linux Kernel. Initial versions of the OS were based on the Linux 2.6 kernel. Version 4.0 and above are based on Linux 3.3 kernel. Although Android runs on Linux, it would be misleading to consider it a Linux distribution, or *distro*, because it leaves so much out of the Linux system, including many standard libraries, shells, editors, and programming frameworks [Bray 2010].

61.2.2.2 System Libraries

On top of the Kernel sits a collection of C/C++ libraries, including, among others, the following [Android: App Framework 2012]:

- Libc—a Berkeley Software Distribution (BSD)-based version of the standard C system library.
- SGL—a 2D graphics library.
- OpenGL—a 3D graphics library.
- SQLite—a lightweight relational database system.
- WebKit—a web browser engine that allows apps to include an embedded Web view.

FIGURE 61.5 Android architecture.

61.2.2.3 Dalvik Virtual Machine

Android runs primarily on hardware platforms based on the Advanced RISC Machine (ARM) architecture, a 32 bit reduced instruction set architecture that is widely used in mobile devices [Wikipedia: ARM Architecture 2012]. ARM’s dominance among mobile phone architectures—according to Stephen Furber, one of the original designers of the ARM architecture, there are more ARMs than people on the planet [Fitzpatrick 2012]—is due primarily to its power efficiency. It reportedly consumes one-tenth the amount of electricity as other 32 bit processors. Android has also been ported to the x86 platform [Shah 2011].

Android’s runtime environment is based on the open source Dalvik Virtual Machine (VM), originally designed and written by Daniel Boorstein in cooperation with Google [Dalvik Virtual Machine 2008]. The Dalvik VM is designed for machines with memory and speed constraints and is therefore well suited for mobile devices. Unlike the Java VM, which uses a stack-based architecture, the Dalvik VM is register based. It is optimized for low memory requirements and it allows multiple VM instances to run at the same time. It relies on the underlying Android OS to handle process isolation, memory management, threading support, and other system functions, as shown in Figure 61.6.

Android applications are written in Java and compiled first into Java byte code (.class) files. These are then compiled into Dalvik byte code (.dex) files before loading onto the Android device. In early Android versions, the Dalvik VM ran interpreted. The Froyo (2.2) release of Android contains a just-in-time compiler for Dalvik. Although this improves the run-time performance over previous releases, there is still considerable discussion and debate about Android’s choice of the Dalvik over the Java VM. For example, one recent comparison of the two systems, by an Oracle engineer, claims that Dalvik runs two to three times more slowly than Oracle’s Java SE Embedded Hotspot VM [Vandette 2010]. Of course, this sort of comparison between the Java VM and Dalvik does not take into account other factors that may make Dalvik a more suitable choice for Android,

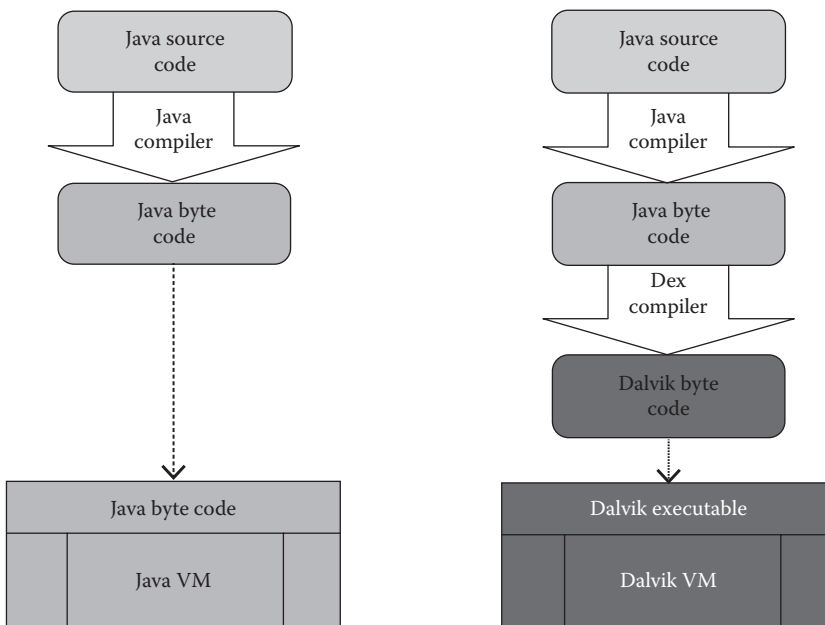

FIGURE 61.6 Dalvik virtual machines. (<http://stackoverflow.com/questions/7541281/what-is-dalvik-and-dalvik-cache>)

including its open source license and the fact that it can run multiple instances simultaneously. The picture is also clouded by the fact that Google is currently being sued by Oracle over its use of Java in the Android OS [Lowe 2012].

61.2.2.4 Resource Managers

Atop the system libraries sits collection of *managers* that comprise the *application framework*. The framework provides abstractions for controlling and managing the various functions that make up system's operations. Some of the main managers are as follows:

- *Activity manager*: An Android application is comprised of a collection of *activities*, which represent the different tasks or actions that users can do—for example, make a phone call, send an e-mail message, and take a picture. Activities are designed to interact with the user [Android: Activity 2012]. The activity manager interacts with the activities currently running in the system. We discuss the activity life cycle in more detail in the subsequent section.
- *Content providers*: Content providers manage access to structured data. They encapsulate various kinds of data and provide a unified interface (abstraction) for storing, retrieving, and securing data of various kinds. They also provide a mechanism through which data are shared among different processes and applications. Content resolver objects are used as clients that communicate with content providers through a client/server like interface. The provider object receives data requests from clients, performs the requested action, and returns the results. Android provides built-in content providers for audio, video, images, and personal contact information [Android: Content Providers 2012].
- *Package manager*: The package manager installs, removes, and manages all of the application packages that are installed on the system. Among other tasks, the package manager oversees the systems security, granting, and authenticating the various permissions needed by applications to manage systems resources. Android applications run in a sandbox and need explicit permission to perform specific tasks such as making telephone calls, taking pictures, and accessing the Internet (Android: Package Manager 2012).
- *Telephony manager*: The telephony manager provides access to information about the telephony services on the device and manages access to the various services needed to make and receive calls, provided the application has the necessary permissions (Android: Telephony 2012).
- *Location manager*: The location manager provides access to information about the device's location services. Applications can use the methods in this class to determine the availability and type of services to register listeners to receive notification of location changes (Android: Location Manager 2012).

61.2.2.5 Applications

Android applications are bundled into *packages* or archives that have an *.apk* suffix [Android Open Source Project 2012]. The package contains all of the application's code, data, and resource files (Android: Permissions 2012). Android uses a *sandbox* model based on the *principle of least privilege* for managing applications and maintaining security during runtime. Under this model, an application has access only to those components required to do its work. An application can access only those parts of the system for which it is given explicit permission.

Applications are isolated from one another in terms of both their identities and runtime contexts:

- Applications are considered Linux users, and each application has a unique user ID. Permissions to access the application's files are controlled through the user ID. An application is only able to access its own files.
- Each application runs in its own process on its own VM. Thus, the application's code is completely isolated from that of other applications and from the system.

In terms of sharing data among applications, although it is possible for two applications to share the same user ID and inhabit the same process, applications share data or resources primarily through a *permissions* system. For example, access to a user's contacts or SMS messages must be requested. Permissions for such accesses are granted (or not) when the application is installed.

Applications are made up of four basic types of *components* [Android: App Framework 2012]:

1. *Activities*: An *activity* is the basic computational unit that interacts with the user. It consists of a single screen, or *view*, which contains the UI. An application typically consists of several activities that work together. For example, an e-mail application might have an activity for composing e-mail messages and an activity for listing the user's messages.
2. *Services*: A *service* is a component that runs in the background to perform some long-running task. For example, a service might be used to download data from the Internet. Services do not have an UI.
3. *Content providers*: A *content provider* manages a collection of persistent data that can be stored in a database, on a website, in the file system, or in some other form. Applications with the appropriate permissions can query content providers to access or modify data. An example would be saving and retrieving photos in an image gallery.
4. *Broadcast receiver*: A *broadcast receiver* responds to system-wide broadcasts, for example, the announcement that an e-mail or SMS message has been received or that the system's battery is low. Broadcasts may come from the system or from another application. Broadcast receivers do not have a UI, but they can use *notifiers* to display messages on the phone's status bar.

61.2.2.6 Activities and User Interaction

Activities are the basic computational units that interact with users. The *Activity* class takes care of creating a window and defining *the UI* [Android: Activity 2012].

The activity architecture is designed around the principle of *responsiveness*—that is, providing a crisp, responsive UI, with user interactions taking priority over other system operations [Android: Designing for Responsiveness 2012]. The activity manager and the window manager guard against applications that are insufficiently responsive, posting an *Application Not Responding (ANR)* dialog if the application cannot respond to user input or does not respond within a certain time limit. This could happen if the application blocks while waiting for an I/O operation to complete or takes too much time to build a complex data structure in memory. The ANR dialog permits the user to kill the app or to continue waiting, but its presence is usually a sign that something is wrong with the app's design or performance.

Android activities are managed with an *activity stack*. When a new activity is started, it is placed on top of the stack and becomes the *running activity*. The activities below it are, typically, kept in memory, but would not come to the foreground until all the activities above them are popped off the stack. Thus, the user is always interacting with the top activity on the stack.

Activities can be in one of four states [Android: Activity 2012]:

1. *Active or running*—it is on the top of the stack and visible in the foreground.
2. *Paused*—it has lost focus but is still visible. It retains its state but the user cannot interact with it. For example, a paused activity may be one that has displayed an interactive dialog that is prompting the user for some action. The system can kill a paused activity if its memory is needed.
3. *Stopped*—it is completely obscured by another activity. Stopped activities retain their state but they can be killed by the system if their memory is needed.
4. *Killed*—if an activity is killed by the system, it is dropped from memory either by asking it to finish or by simply killing its process. When it is displayed again, it must be restarted from scratch.

Figure 61.7 provides an overview of the activity lifecycle. The ovals represent the activity's state, and the rectangles represent callback methods available to the program as the activity progresses through its lifecycle.

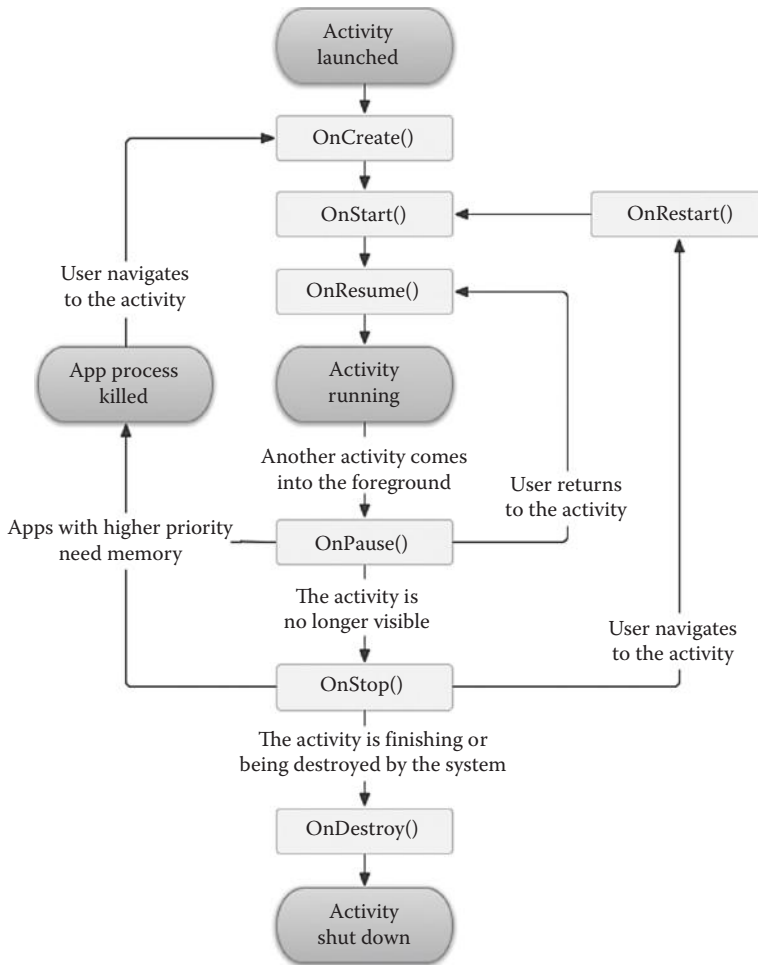

FIGURE 61.7 Activities life cycle. (Android: Activity. “Public Class–Activity.” Android Reference. 2012. <http://developer.android.com/reference/android/app/Activity.htm> [accessed October 9, 2012].)

For the applications programmer, the following interface provides access to all the main points of activity’s lifecycle:

```

public class Activity extends ApplicationContext {
    protected void onCreate(Bundle savedInstanceState);
    protected void onStart();
    protected void onRestart();
    protected void onResume();
    protected void onPause();
    protected void onStop();
    protected void onDestroy();
}
  
```

As the names of these methods suggest, the entire life cycle is *event driven*. When the system finds it necessary to interrupt an activity—for example, because of an incoming phone call—it dispatches an event that can be handled by one or the other of these methods. Because applications can be interrupted at any time, it is important that they be designed for such possibilities. For example, an app that is accepting

input from the user—for example, composing an e-mail message—must be able to save the application’s state if interrupted so that it can be restored when the application is restarted. Persistent data can be saved in the *onPause()* method and restored in the *onResume()* method. In terms of saving dynamic parts of the application’s state, Android provides the *onSaveInstanceState(Bundle)* method, which is invoked just before the activity is placed in the background, and *onRestoreInstanceState(Bundle)*, which is invoked just before the activity is placed in the foreground. Note that the *onCreate()* method can restore such state even if the activity is killed by the OS.

The design of the Activity lifecycle promotes a response UI and the ability of the OS to interrupt an activity at any time in response to incoming phone calls, battery failures, lack of memory, and other events.

61.2.2.7 Intents and Intent Filters

Communication within and among applications and activities take place through messaging objects known as Intents [Android: Intent 2012]. An *Intent* is a passive data structure that represents an operation or task to be performed. Intents can be used to start activities and applications or to communicate with background services. They provide a mechanism for late runtime binding between the code different applications.

The Android system provides both explicit and implicit intents. An *explicit intent* specifies a particular component or activity by its name—for example, an e-mail component or list activity—and is primarily used to communicate among the activities and services that make up a single application. The intent is used to instantiate the component or start the activity and pass information to it—working in a similar fashion to a non-blocking *remote procedure call*. An *implicit intent* does not identify a particular object or activity. Instead, it describes a particular task—such as the “send email” task. The OS then takes responsibility for identifying objects that are available in the system to perform that task. For example, the built-in *ACTION_SENDTO* action expresses a request to send some type of message (e-mail or SMS). The type of message, the destination phone number or e-mail address, and the message itself would be specified in a uniform resource identifier identifying the target of the intent. The system then searches among registered entities for an e-mail or messaging application that handles that type of action and sends a broadcast to all entities that satisfy the target criteria.

Components use *intent filters* to identify to the system which intents they can handle. For example, a broadcast receiver would use an intent filter to identify those applications it will accept text messages from—that is, Google Voice, Android Messaging, or some other application. For system-wide intents, this would typically be done in the *Android manifest*, a static document that describes the application’s activities and permissions and informs the system about its various intent filters.

61.2.2.8 User Interface

Android provides a variety of pre-build UI components such as structured layout objects and UI controls that allow you to build the graphical UI for your app. Android also provides other UI modules for special interfaces such as dialogs, notifications, and menus [Android: User Interface 2012].

All UI elements in an Android app are built using *View* and *ViewGroup* objects [Android: User Interface 2012]. A *View* is an object that draws something on the screen that the user can interact with. A *ViewGroup* is an object that holds other *View* (and *ViewGroup*) objects in order to define the layout of the interface. Android provides a collection of both *View* and *ViewGroup* subclasses that offer common input controls (such as buttons and text fields) and various layout models (such as a linear or relative layout).

A typical Android app consists of action bars and the app content area [Android: Design 2012].

1. Main action bar is the command and control center for an app. The main action bar includes elements for navigating the app’s hierarchy and views and also surfaces the most important actions.
2. View control allows users to switch between the different views that the app provides. Views typically consist of different arrangements of data or different functional aspects of the app.

3. Content area is the space where the content of the app is displayed.
4. Split action bars provide a way to distribute actions across additional bars located below the main action bar or at the bottom of the screen.

61.2.3 Apple iOS

61.2.3.1 Overview

The mobile OS that runs on the Apple iPhone, iPod touch, and iPad devices is iOS. Unlike Android, an open source system running on many hardware platforms, iOS is a proprietary system that is not licensed to third parties and runs exclusively on Apple products.

iOS is derived from Apple's OS X system, with which it shares the Darwin system. Darwin is Apple's open source, POSIX-compliant OS first released in 2000.* Darwin currently includes support for the 64 bit Intel x86 processors as well as for the 32 bit ARM processors used in the iPhone, iPod touch, and iPad [Wikipedia 2012]. Darwin does not include many of the defining elements of Mac OS X and iOS, in particular the Cocoa API and thus, Darwin by itself cannot run Mac or iOS applications.

The Cocoa and Cocoa Touch APIs are what give Mac and iOS applications their distinctive look and feel. Cocoa contains several API kits—for example, the *Foundation Kit*, the *Application Kit*, and the *Core Data Frameworks*—and the libraries and frameworks to support those kits. It also includes the Objective-C runtime library [Wikipedia: Cocoa API 2012]. Cocoa applications are typically written in Objective-C using Apple's proprietary development environment, which consists primarily of the Xcode integrated development environment (IDE) and its built-in *Interface Builder*, an application for building UIs (Apple Inc: Cocoa 2012).

Cocoa Touch is an API for building UIs for the iOS (Apple Inc: Cocoa 2012). It includes features and technologies to support multitasking, gesture recognition, and animation and includes several kits and frameworks that extend the functionality of Cocoa. The UI kit, which extends Cocoa's Application Kit, provides the API for supporting graphical user interfaces. The Game Kit framework provides an API for game developers. The *iAd* and *Map Kit* frameworks provide API support for Apple's mobile advertisement platform and its newly unveiled mapping platform. The layer architecture for iOS is depicted in Figure 61.8.

The iOS system interfaces are organized into frameworks. A *framework* is a *directory* that contains a dynamic shared library and the resources (such as header files, images, helper apps, and so on) needed to support that library. Frameworks are linked to the application project.

FIGURE 61.8 Layer architecture of iOS.

* POSIX, which stands for portable operating system interface, is a set of IEEE standards for Unix operating systems that define the programming interface (API) and command shells.

61.2.3.2 Core OS

iOS is a Unix system based on the Mach kernel. *Mach* is the operating system kernel developed at Carnegie Mellon University in the mid 1980s. Although sometimes mentioned as one of the first *microkernels*, the version of Mach used in iOS is not a microkernel.*

Darwin, the Mac OS X kernel, is based in turn on the XNU (X is not Unix) kernel, a hybrid kernel that combines features of the Mach kernel with components from BSD, and Driver Kit, an object-oriented API for writing device drivers. The Mach kernel, which was developed at Carnegie Mellon University in the mid 1980s, is a simple kernel that runs core OS functions as separate processes. Darwin incorporates certain features from BSD (Wikipedia 2012)—specifically from the FreeBSD kernel—including the following:

- POSIX API (BSD system calls)
- Unix process model atop Mach tasks
- Basic security policies
- User and group IDs
- Permissions
- The network stack
- Virtual file system code
- Local file systems, including hierarchical file system and network file system
- Cryptographic framework
- Inter-process communication system

From the perspective of the application developer, the core OS layer contains the following low-level system features and frameworks [Apple Inc: The iOS Environment 2012].

- The *accelerator* framework (introduced in iOS 4.0) contains digital signal processing, linear algebra, and image-processing libraries.
- The *core Bluetooth* framework contains libraries for interacting with *Low Energy Bluetooth* accessories.
- The *external accessory framework* provides libraries for communicating with devices that can be connected to an iOS device through its 30 pin dock connector or through its wireless Bluetooth interface.
- The *generic security services* framework based on the IETF RFC 2743 and RFC 4401 standards. In addition to offering the standard interfaces, iOS includes some additions for managing credentials that are not specified by the standard but that are required by many applications.
- The security framework provides interfaces for managing certificates, public and private keys, and trust policies. It supports the generation of cryptographically secure pseudorandom numbers. It also supports the storage of certificates and cryptographic keys in the keychain, which is a secure repository for sensitive user data.

61.2.3.3 Runtime Environment

The iOS system is based on the same technologies used by Mac OS X, namely, the Mach kernel and BSD interfaces. Thus, iOS apps run in a Unix-based system and have full support for threads, sockets, and many of the other technologies typically available at that level. However, there are places where the behavior of iOS differs from that of Mac OS X [Apple Inc: The iOS Environment 2012].

- *The virtual memory system*: In iOS, each program still has its own virtual address space, but unlike Mac OS X, the amount of usable virtual memory is constrained by the amount of physical memory available. iOS does not support paging to disk when memory gets full. Instead, the virtual

* A *microkernel* is the bare minimum of mechanisms needed to implement an operating system. It typically consists of low-level address space management, thread control, and interprocess communication (IPC) functions. These are the software elements that run at the most privileged level (e.g., in kernel mode or supervisor mode). By contrast, a *monolithic kernel*, would include other traditional operating system functions, such as device drivers, schedulers, virtual memory, and file systems.

memory system simply releases read-only memory pages, such as code pages, when it needs more space. If memory continues to be constrained, the system may send notifications to any running applications, asking them to free up additional memory.

- *The automatic sleep timer:* When the system does not detect touch events for an extended period of time, it dims the screen initially and eventually turns it off altogether. For applications that do not use touch inputs, such as a game that relies on the accelerometer, the automatic sleep timer can be disabled to prevent the screen from dimming.
- *Multitasking support:* In iOS 4 and later, *multitasking* allows apps to run in the background even when they are not visible on the screen. Most background apps reside in memory but do not actually execute any code. These apps are suspended by the system shortly after entering the background to preserve battery life.

At install time, iOS places each app (including its preferences and data) in a *sandbox*—that is, a set of fine-grained controls that limit the app’s access to files, preferences, network resources, and hardware. As part of the sandboxing process, the system installs each app in its own sandbox directory, which acts as the home for the app and its data. User sensitive data can be stored in a *keychain*, an encrypted container for passwords and other secrets specific to an app. Keychain data for an app are stored outside of the app’s sandbox.

61.2.3.4 Programming Model

iOS application development depends on the iOS software development kit (SDK) and Xcode, Apple’s IDE. Xcode employs a single window, called the *workspace window* that presents most of the tools needed to develop apps (Apple Inc: Xcode 2012). The iOS SDK extends the Xcode toolset to include the tools, compilers, and frameworks you need specifically for iOS.

iOS apps are written in objective-C, an object-oriented language, that extends the standard ANSI C programming language with syntax for defining classes and methods [Apple Inc: Start Developing iOS Apps Today 2012]. It also promotes dynamic extension of classes and interfaces that any class can adopt.

Figure 61.9 shows the key objects that are most commonly found in an iOS app. iOS apps are organized around the model-view-controller design pattern (Apple Inc: Cocoa 2012). This pattern separates the data objects in the model from the views used to present that data. Models encapsulate application data, views display and edit that data, and controllers mediate the logic between the two. This separation promotes code reuse by making it possible to swap out your views as needed.

61.2.3.5 User Interface

Apple’s iOS devices are known for their aesthetically pleasing and intuitive UI that has set Apple devices apart from other mobile OS. The *iOS Human Interface Guidelines* is a high level document that describes the guidelines and principles that developers follow for UI and user experience design. It does not describe how to implement designs in code.

An iOS app has a single window, unless it supports an external display; the user sees one screen at a time. An app’s window fills the device’s main screen and provides an empty surface that hosts one or more views that present the app’s content. An iOS *window* differs in important respects from a window in a typical computer app. For example, an iOS window has no visible components (such as a title bar or a close button) and it cannot be moved to a new location on the device display. Instead, the window simply represents a container for visual content that is mapped to the device’s screen. Users experience an iOS app as a sequence of screens through which they navigate. From this perspective, a screen generally corresponds to a distinct visual state or mode in an app.

In iOS, the UIKit framework provides the infrastructure for building graphical applications, managing the event loop, and performing other interface-related tasks [Apple Inc: Start Developing iOS Apps Today 2012].

For a more in-depth look at the iOS programming guidelines and documentation visit the iOS Developer Library (<http://developer.apple.com/library/ios>).

FIGURE 61.9 Key objects found in iOS apps. (http://developer.apple.com/library/ios/#documentation/iPhone/Conceptual/iPhoneOSProgrammingGuide/AppArchitecture/AppArchitecture.html#apple_ref/doc/uid/TP40007072-CH3-SW1)

61.3 Impact on Practice

In 2012, 75% of the world’s population currently has access to a mobile subscription [World Bank 2012]. A total of 13.2% of the world’s 6.1 billion cell phones are smartphones, but the rate exceeds 30% in larger markets like the United States, Germany, and Britain [O’Brian 2012]. Mobile computing devices bring computing to the masses in a way not seen since the introduction of the personal computer in the 1980s.

A new wave of “apps,” or smartphone applications, and services, driven by high speed networks, social networking, and online crowd sourcing, is helping mobile phones transform the lives of people around the globe. Nearly 40 billion apps for iPhones and Android devices have been downloaded worldwide by mid 2012 [Lunden 2012]. Research reports forecast the worldwide smartphone application market, which it estimates will grow from \$1.94 billion in 2009 to \$15.65 billion by 2013 [Wauters 2012] (Figure 61.10).

As the mobile landscape develops and smartphones gain market share, content providers are finding new ways to reshape and broadcast information to the public. Regular websites can be reformatted to meet mobile capabilities. Mobile phones are becoming the “third” screen (after television and PCs) used to access content and are reshaping content delivery.

Given technological convergence, smartphones can now function as a digital equivalent of a Swiss army knife a wallet, camera, television, alarm clock, calculator, address book, calendar, newspaper, navigational device, and gaming console combined. The latest smartphones are not just invading the computer space; they are reinventing it by offering so much more in both voice and non-voice services.

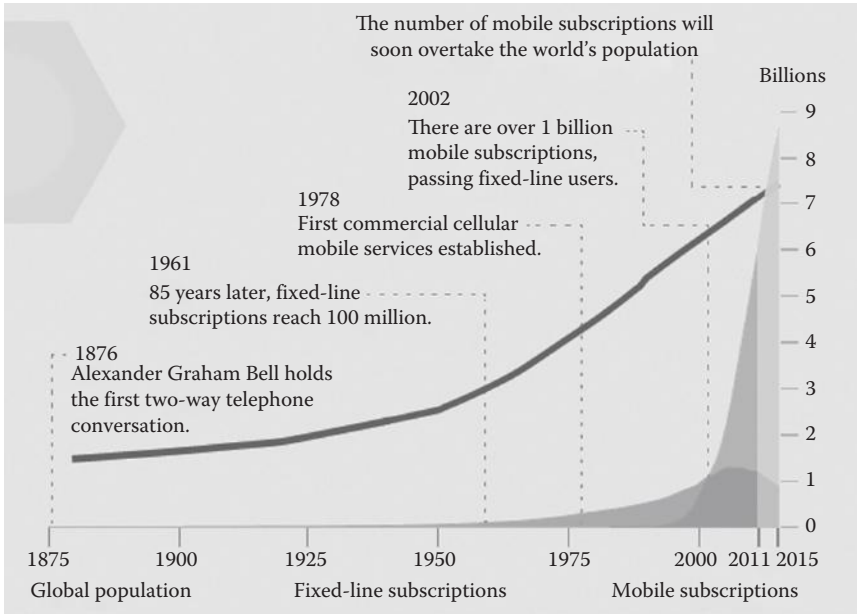

FIGURE 61.10 Global population, mobile subscribers, and fixed-line subscriptions. (World Bank. Information and Communication for Development 2012: Maximizing Mobile. Case Study, Washington, DC: World Bank, 2012.)

61.3.1 In Healthcare

According to research conducted by Manhattan Research in 2009 on the professional use of smartphones by physicians, about 64% of the physicians in the United States used smartphones in 2009 compared to only 30% in 2001. This report found a noticeable increase in smartphone adoption and predicted that 81% of physicians would use smartphone in the United States by 2012 [Cooper 2009].

Mobile OS platforms are capable of running third-party applications specifically developed for the healthcare field. For instance, John Hopkins antibiotics guide “Johns Hopkins ABX Guide,” which is available for the Android, iOS, Blackberry, and Windows platforms, provides information on the treatment of infectious diseases to help make decisions at the point of care. The guide breaks down details of diagnosis; drug indications, dosing, pharmacokinetics, side effects, and interactions; pathogens; management; and vaccines into easily accessible, frequently-updated, quick-read entries on the mobile device [Unbound Medicine Inc. 2012].

Market research firm Juniper Research believes that some 3 million smartphone users will be using their devices for remote health monitoring by 2016 [Thomas 2012]. Patients and doctor alike can access electronic health records (EHR) through smartphone applications such as MEDITECH EMR, which using a web browser to access clinical data including laboratory results, vital signs, intake and output, allergies, active medications, and documents (reports and notes) (MEDITECH 2012).

There are many health education-based applications available on the App stores that range from teaching children healthy eating habits, blood glucose calculators, telemedicine applications to a fall detector that uses the built-in accelerometer to work out if a person has fallen. Smartphones are poised to change the way we interact with our medical professionals.

The challenges of smartphone-based healthcare include limited battery life, small screen size, potentially erroneous data input, computer viruses including spyware, magnetic interference with medical devices, potentially inefficient patient–physician interactions, loss or theft, and breaches of data privacy and security [Mosa 2012].

61.3.2 In Agriculture

In addition to weather updates, facts and figures that were once the scribbled domain of old receipts and tattered pieces of paper at the farm are now organized on a smartphone [Gerke 2012]. From pasture grazing records to serial numbers and checkbook register, applications are available to help keep track of important information quickly and easily.

Mobile applications for agriculture and rural development have generally been designed locally and for specific target markets, with localized content specific to the languages, crop types, and farming methods in the region.

61.3.3 In Banking

As the adoption of smartphones continues and speed of access improves, customers across every age group are becoming increasingly comfortable with conducting more and increasingly complex transactions through their mobile phones. eBay Inc.'s PayPal division handled \$4 billion in mobile payments in 2011 [Kucera 2012]. Banks now offer customers extended mobile services, which allow them to deposit a check (using a picture of the check), check their balances, transfer money, and locate cash points.

Japan's Jibun Bank, for example, was created in 2008 as a joint venture between the country's largest bank, BTMU and KDDI, a telecommunications operator. Designed from the outset as a mobile-only bank—that is, without being based on a network of physical branch offices—within 2 years, it had more than one million accounts and US \$1.7 bn in deposits [KPMG 2011].

61.3.4 Privacy and Security

With the proliferation of mobile apps that provide electronic monetary transactions to accessing medical records on a smartphone, one has to take into consideration the security and privacy of the underlying data. In addition to the obvious risk of losing one's mobile device, smart phones can be vulnerable to third-party information-stealing applications and other malware. Security is intimately bound to the design of the platform for which the mobile application is built.

Smartphone operating systems have both advantages and disadvantages with respect to offered security. On the one hand, they use application sandboxing to contain exploits and limit privileges given to malware. On the other hand, they collect and organize many forms of security and privacy sensitive information—such as location information and phone status—simply as a matter of operation, and make that information easily accessible to downloaded third-party applications [SPSM workshop 2012]. Users and application developers are restricted from accessing and modifying core elements of the OS such as the kernel and system daemons through software and policy controls. These controls are implemented by mobile OS developers, cellular carriers, and smartphone manufactures. But given the fact that consumers can choose, wittingly or unwittingly, to allow third-party applications to have access to that data, such controls can only go so far in protecting sensitive personal data.

For example, when an Android application is downloaded from the market, the user is presented with a list of permissions that the application requires—for example, access to the Internet, to their Google or Twitter accounts, to the phone's camera, etc. But the details and implications of granting such permission is not totally transparent and may lead to unanticipated data sharing.

61.4 Research Issues

The advent of mobile computing has introduced new challenges for the designers of mobile devices and mobile OS. One such challenge is to reduce power consumption in ways that minimize the adverse effect on usage. Savings in power consumption can be “spent” by extending battery life and (or) by reducing the physical size of batteries, thus reducing the physical size of mobile computing devices [Welch 1995].

For software developers, the availability of multiple platforms and the lack of standardization make it difficult to decide what mobile OS to develop on. Processing power, storage, and functionality differ wildly from device to device. It is virtually impossible to build and maintain one application that will run on Blackberry, Symbian, Android, iOS, and other mobile platforms. Supporting multiple operating systems requires one to rewrite the application in each of the different native environments. Needing to build and maintain two or more versions of a smartphone app raises the difficulty level of many development projects significantly.

Indeed, even confining one's focus to the Android platform presents considerable challenges given the large number of manufacturers and phone companies providing Android products and competing with each other for market share. Already, there are significant differences among the various Android versions and among the features promoted by the different vendors. So far, this variability among systems has not proved to be an impediment in Android's adoptability as some had predicted. The situation is somewhat better for iOS developers because of Apple's tight and proprietary control of the platform. But even on the iOS platform, or any single platform, given the rapid development and advancement of device features, an application developed for one version of iOS may quickly become incompatible with newer devices, which require new releases of the OS.

In an attempt to address this challenge, cross-platform development tools for mobile systems are beginning to emerge. Among these tools are Appcelerator Titanium, Phonegap, QuickConnect, Rhomobile, and WidgitPad (Warren 2012). Most use a mix of HTML, CSS, and JavaScript, plus some native "wrapper" code for accessing hardware features like GPS, a camera, or an accelerometer [Dern 2010]. Considerable "tweaking" is required to get applications to function at all across multiple-platforms. One limitation of cross-platform tools is that they may not support particular functionality specific to one operating system or the other. However, in some cases, they do help reduce application development time and costs, while exposing an application to a larger smartphone market segment.

Among the numerous areas of research and development are the following:

- *Haptic technology*, or *haptics*, is a tactile feedback technology that takes advantage of the sense of touch by applying forces, vibrations, or motions to the user [Shubha 2012]. An example would be the use of vibration to confirm that a touchscreen button has been pressed. Haptic devices may incorporate tactile sensors that can measure the force exerted by the user on the interface. These would then be interpreted by the operating system to provide input to the application or feedback to the user. The interface acts as both an input and output mechanism to enhance the user experience. Immersion, a developer of touch feedback technology, announced a new Developer Kit that allows a form of adaptive feedback. For instance, while swiping through Facebook pictures, the force feedback will change from light clicks to longer rumbles according to how many comments it had.
- The emergence of voice activated, *intelligent personal assistants* is an area of applications research. Apple's iPhone has "Siri," the voice-activated virtual assistant that it introduced in October 2011 with the iPhone 4S (Dolcourt and Bennett 2012). The feature has the potential to change how consumers retrieve information and interact with their mobile devices, giving them the ability to find information on the Web with natural voice commands and to perform other tasks. "Google Now" for the Android 4.1 Operating System introduced a similar voice search service for Android-based devices shortly after.
- Google and its mobile partners introduced an alternative to the credit card with a technology called *near-field communications (NFC)* that lets users make payments wirelessly at cash registers [Wingfield 2012]. NFC is a set of standards for smartphones and similar devices to establish radio communication with each other by touching them together or bringing them into close proximity, usually no more than a few centimeters.
- Project Glass is a research and development program by Google to develop an *augmented reality head-mounted display* [Goldman 2012]. The intended purpose of Project Glass products would be

the hands-free displaying of information currently available to most smartphone users. Virtual objects and information could be overlaid on the real world and displayed to the wearer.

- As mobile connectivity and smartphone devices become ubiquitous, we are seeing a shift in the perception and expectations of end users, with access to media rich content virtually anywhere. *Unified communications* (UC) is the integration of real-time communication services with non real-time communication services into a single platform [Vodafone 2010]. As such, UC is not a single product but a portfolio of products that provide a consistent UI and user experience across multiple devices, platforms, and media types. In many cases, these solutions can be hosted remotely, effectively providing a scalable Cloud Service for mobile devices.
- In 2010, Apple filed a patent application for a small *fuel-cell* power supply that could potentially give the iPhone and iPad enough power to last for weeks without the need to plug them in [Wingfield 2012]. Fuel cells use hydrogen and oxygen to produce electricity with no pollution.

61.5 Summary

Mobile devices are arguably the most ubiquitous modern technology: in some developing countries, more people have access to a mobile phone than to a bank account, electricity, or even clean water. Mobile communications now offer major opportunities to advance human development—from providing basic access to education or health information to making cash payments to stimulating citizen involvement in democratic processes [World Bank 2012].

As we have seen in this chapter, the smartphone has evolved over a short period of time and is still at the start of its growth curve. Devices and operating systems are becoming more powerful and less expensive to operate. The App development market has rapidly grown and continues to evolve. Today, mobile development is a multi-disciplinary endeavor requiring familiarity with a host of other areas, including wireless networking, location-based systems and distributed application development [Finkel 2004]. The mobile OS share the common goals to: (1) to hide details of hardware by creating abstractions, (2) to allocate resources to processes, and (3) to provide an effective UI, similar to desktop operating system, while operating within the parameters of a mobile environment with limited connectivity, small footprint, power, and hardware resources.

This chapter has attempted to condense a rich and in-depth field of mobile OS to provide a brief historical overview of the field and the evolution of the present day smartphone and mobile OS. It provided a summary look into the architecture of two of the most popular OS: Google's Android OS and Apple's iOS. For an in-depth study, the reader should refer to the corresponding developer guides.

Key Terms

1G: 1G is short for first-generation wireless telephone technology. This generation of phones and networks is represented by the brick-sized analog phones introduced in the 1980s.

2G: 2G is a second-generation digital mobile phone network allowing for the introduction of digital data services, such as SMS and e-mail.

3G: 3G is a third-generation mobile phone network that supports higher data capacities, enabling features such as mobile Internet access. A 3G network is also capable of video calling.

4G: 4G is like the other generations in that its advantage lies in increased speeds in data transmission. There is currently no formal definition for 4G, but there are objectives. One of these objectives is for 4G to become a fully IP-based system, much like modern computer networks. The supposed speeds for 4G will be between 100 Mbit/s and 1 Gbit/s.

BREW: Binary runtime environment for wireless is an application development platform created by Qualcomm, originally for code division multiple access (CDMA) mobile phones, featuring third-party applications such as mobile games. It is offered in some feature phones but not in smartphones.

- GSM:** Global system for mobile communications. GSM is the most popular standard for mobile phones in the world.
- HSDPA:** High-speed downlink packet access. HSDPA is a 3G mobile protocol that offers higher data capacity and transfer speeds. This means that more information—such as video—can be transferred wirelessly to your phone at faster speeds.
- Infrared:** Infrared (IrDa) is a short-range wireless technology that provides a way to connect and exchange data between mobile phones. It has largely been succeeded by Bluetooth.
- MMS:** Multimedia messaging service. MMS is the sending of messages that include multimedia such as images, audio, video, and text.
- Pre-paid:** Pre-paid is a mobile phone account where credit for phone calls is paid up front and not billed by the month.
- Push e-mail:** When new e-mail is sent to you, it is instantly transferred (or “pushed”) to a mobile phone handset.
- SIM card:** Subscriber identity module card. A SIM card is a removable “smartcard” that is inserted into a mobile phone. SIM cards store the service provider details and identify the customer to the mobile network. You need a SIM to connect to a mobile phone network and make calls.
- SMS:** Short message service. SMS is the sending of short (160 characters or less) text messages, to and from mobile phones. Receiving SMS messages is free of charge but sending them costs 25 cents across all networks in Australia. Some networks may offer discounted rates for SMS messages sent across their own network.
- WAP:** Wireless application protocol. WAP is an Internet-like service for a mobile phone. WAP is not the same as using a browser on a computer.
- Wi-Fi:** Wi-Fi stands for Wireless Fidelity and is a wireless technology that allows connection to the Internet when in range of an “access point.” It is normally associated with accessing the Internet from a computer, but many mobile phones—particularly business smartphones—have Wi-Fi as a feature.

62.1 Background

The original motivation to introduce a layer between the user application and the underlying hardware was based on the assumption that certain tasks are common across certain applications and the application developer needs an abstraction layer from the underlying hardware. Early operating systems had not been much more than a hardware abstraction layer offering basic interfaces to interact with external input and output devices and essential intrinsics of the processing units for computing, graphics, sound, or other special purpose processors.

Over the years operating systems evolved significantly in complexity accordingly with the new hardware functionalities available and the introduction of graphical user interfaces as an essential part of the abstraction layer. However, for performance hungry applications, the layer introduced by the operating system and the libraries on top of it aimed at achieving maximum portability was not appropriate. Using the new features of the most recent graphics cards has been essential for high-end games and key to differentiating them from their competitors. As a result, environments offering a more direct access to the capabilities of their underlying hardware, such as DirectX or OpenGL, offer in principle an alternative operating environment to *normal* applications. As the complexity of the operating system is dependent on the variety of the hardware platforms where it may run, some operating systems have limited such platforms (e.g., Mac OS X has a significantly reduced number of platforms compared to Microsoft Windows or Linux). An extreme case are gaming consoles with a clearly defined hardware profile as well as a significantly reduced footprint.

In this chapter, we argue that with the current trend of exploding complexity of the hardware layer within a computing system, and across computing systems, traditional operating system approaches

are not only a threat for the application developers that need to program around their limitations, but prevent the developers from taking advantage of the opportunities of a connected world.

The core part of this chapter is the discussion of a new approach called service-oriented operating system. We conclude the chapter with the application of the model to three scenarios, one from the high-performance computing domain, another one inspired by an ambient intelligence setting, and a third one from intelligent manufacturing systems.

62.1.1 Current and Future Hardware Evolution

While many innovations are integrated into every new generation of computing hardware, systems have appeared quite stable for many years from an application developer viewpoint. Most computers have been using the x86 architecture based microprocessor with increasing frequency and transistor count. Most application developers focus their designs and implementations on a sequential platform considering communication and computing as separate functions. Better performance could be achieved by investing regularly in new hardware with only moderately increasing power costs. The motivation to spent effort in software optimization was limited to special application domains. Legacy applications, even if developed many years ago, would run faster by simply porting them to new architectures.

Recently the situation has dramatically changed, driven by the need to improve the power efficiency. Even low-end computing systems and smartphones include multicore processors. These devices have integrated graphic capabilities which are also used for computing. However, they run into performance bottlenecks when accessing data stored in the memory or communicating with other computing subsystems. The general availability of *parallel* computing capabilities comes with increased heterogeneity of the computing platform and, at the same time, increased demand for optimization. Nowadays a typical computing system is equipped with one or more multicore CPUs with different types of connectivity between each other and to the peripherals (e.g., the core closer to the communication bus can send and receive data over the network faster), and accelerating components such as general purpose graphic processing units. Hierarchical memory approaches with fast and large memory areas and fused processor architectures bringing together CPUs, graphic processors, and communication capabilities on one single chip will soon be available. Moreover, within the family of x86-based CPUs more and more differences between vendors in specific instruction sets and cache architectures are emerging. Competing architectures, such as ARM-based processors, are moving from the embedded systems domain into mainstream computing.

The energy efficiency of applications is now a major concern. An application that is using only five percent of the theoretical peak performance, for example, because it has bad cache hit rates, is wasting much more energy than the one saved through hardware optimization. Consequently, the application developer is facing two major challenges at the same time. On the one hand, the underlying platform is becoming increasingly complex and heterogeneous, and innovation cycles for new hardware is shorter than ever. At the same time, there is a need to handle parallelism and save energy by designing algorithms that exploit data locality and use efficiently the available computing capabilities. Application developers are finding it extremely difficult to cope with these new realities.

62.1.2 Programming Models

Parallel programming is not a new topic, and a couple of programming models have been used on high-performance computing (HPC) systems for over a decade. Besides simple multithread programming approaches, applications are very often parallelized using specific programming models such as OpenMP and/or the Message Passing Interface (MPI). These programming models have been designed for scientific/technical computing intensive applications and are only partially suited for other kinds of applications. In particular, if used in conjunction to realize node parallelism (across the cores of

a single server) with OpenMP and using MPI for the communication across nodes, the correct usage is very complex and demanding for programmers.

Partitioned global address space (PGAS) approaches, such as Co-Array Fortran (CAF) or Unified Parallel C (UPC), bring parallelism as a basic element into the programming language to deliver an abstraction layer for distributed data. This approach is more suited to reach the application developer community at large. However, achieving high performance and scalability is complex as it is with other parallelization methods.

For addressing the heterogeneity of the computing platforms, approaches to deliver a higher level of abstraction to the application developer are available. Models, such as OpenAcc or Task-based approaches as StarSs and OpenMP 4.0, are competing with more hardware-oriented models such as OpenCL and CUDA. These models, while conceptually supporting different architectures, are often limited to a few platforms.

62.1.3 Communication Models

With the increasing amount of computing capability in a single node/server, very often applications need to be spread across several computing systems to overcome limitations on memory size or to achieve strong scaling (delivering a solution of fixed size in shorter time, in contrast to weak scaling solving a larger problem in similar time). Consider an extreme case where an application could be distributed across as many nodes as the number of its subproblems, where the subproblems fit in each node's cache. While this would clearly speed up the calculation on each node (as access to the cache is much faster than accessing to the main memory) for most problems, the synchronization across the nodes sharing intermediate results might become the dominating factor in the execution time. While in this scenario the latency will be dominating, in other cases the bandwidth limitations and the time needed to transfer data from main memory to the network and back into the main memory of the receiving server might be the limiting factor.

Consequently, communication and computing cannot be considered to be orthogonal elements of an application, but their balance have to be integral part of the design and implementation.

62.2 Analysis

The trends in hardware development discussed in the previous section have increased, and will continue to increase, the complexity of programming. The fundamental assumption of the authors is that current models will lead to a significant and increasingly, growing gap between the capabilities of the hardware and the ability of the *averagely skilled* application developer to exploit these capabilities. This “parallel divide,” where an increasing number of application developers is no longer able to efficiently exploit new hardware capabilities, demands for a new software development model. Such a model has to be able to make use of the wide variety of available computing resource types, taking advantage of its specific characteristics while at the same time reducing the complexity of programming.

Although advanced or specialized application developers will still be able to efficiently use the complex machine's computing resources, it is necessary to provide a solution for the average programmers. The approach must be more abstract, reduce noticeably the development time, and ease portability while having only an acceptable performance penalty compared to handmade optimizations.

The current situation resembles the dilemma between writing code in assembler or in a higher-level language. An experienced programmer with in-depth knowledge of the underlying hardware might extract more performance, but using a high-level language will reduce development time, facilitate debugging, and allow easier portability among different hardware architectures.

62.2.1 Need for a New Programming Model

Existing programming models are not able to deliver this abstraction level as they are typically too tightly coupled with the hardware system and rely on lower layers to control the communication and execution of the program.

Extending or combining existing programming models, for example, to reflect specific user needs or individual application domains (such as OpenMP for parallelization in a cache-coherent common address space machine and MPI for parallelization in a non cache-coherent or noncommon address space machine), will further increase programming complexity. In the current programming models, optimizations have to be done manually by the developer by adapting the source code to the destination platform or by the compiler performing static analysis and specific optimizations for the destination infrastructure. But to obtain an efficient utilization of the infrastructure, the developer must take into consideration as many details as possible of the destination infrastructure. For example, performance is negatively affected by cache misses; organizing and partitioning the data structures according to the processor's cache size to minimize this impact will greatly improve performance. The main problem is that different processors have different cache sizes, access patterns, and hierarchies. Consequently optimizing a program for one platform can lead to performance degradation on another system or even limit program portability if specific instructions are used.

On the other hand, one cannot expect compilers to generate completely optimized code by just using static analysis of the program for different platforms. Typically this leads to parallel branches for different architectures for the same program to overcome limitations of the hardware, the specific compiler capabilities, or even conceptual limitations of the programming language.

A new programming model has to consequently rely on the user knowledge to express optimization hints coming from the problem domain, perform run-time code analysis, and realize a segmentation and distribution across the infrastructure that can change and adapt over time. Language extensions and optimization hints might range from low-level ones (to unroll loops over communication patterns) to data layout assertions to express domain-specific elements.

62.2.2 OS Support

Many of the issues previously exposed could be solved by constant recompilation of an annotated source code or by making the operating system aware of its environment, enabling it to predict memory usage and code dependencies in order to adapt the program to the running environment characteristics. The source code or the programming model, when the application is not written for an specific machine, do not know about the level of parallelism and concurrency of the machine and the infrastructure specifics, while the processor architecture has no view of the overall program and its possible threads. The operating system, being the middle tier between the two perspectives, is hence the ideal place to address this; the only execution "layer" having access to all the information required to resolve these issues is the operating system. The operating system is the interface between the hardware, usually unknown to the software developer, and the program.

Current operating systems cater for threads and processes—its distribution and scheduling—, and to memory management; they control the machine and program interaction with the hardware. But this is one of the main limitations under the current hardware evolution. The execution environment itself should cater for the right functionalities, reflecting the infrastructure specifics to the current deployment. In other words, the developer should have a common interface for all segments/processes for communication, message exchange etc., without having to restrict to the specifics of the current deployment. This would mean, for example, that threads just specify the data they use and access it in a common fashion, regardless whether the underlying platform is a shared-memory, cache-consistent, or nonunified memory access architecture.

Even though the execution environment will know the details of the hardware infrastructure, it is obviously not sufficient to just leave the matching of the access operations to the environment, as it will not know the details about which data is required where and when. In a straight-forward approach, all data access would be matched to the necessary messaging and routing, thereby creating a central memory instance. This in turn would create an immense overhead in communication on the network, downgrading the performance even more than for an implementation that does not match the infrastructure details but takes into account segmentation, distribution, and prefetching of the data.

In fact, information from both sides, that is, the hardware layout and the work/data layout of the program have to be aligned with each other by the operating system. This implies however that our way of specifying the work and data layout of code has to change into a way that allows for the best mapping to different environments. For example, the coder should identify which part of the data is manipulated by which part of the code, so that a compiler or intermediary analyzer can identify how to distribute data and when consistency needs to be maintained. This information can then be used by the execution environment dynamically depending on the destination platform layout, respectively, of the specific architecture of that platform.

Each thread or code instance would therefore need a different way of realizing the same logical functionality, depending on the real data dependencies and access requirements, as well as on the destination platform specifics. With traditional architectures, the operating system would effectively have to cater for all the related functionalities itself and “outsource” the intelligence to finding the right mapping to the developer.

As mentioned earlier, the application developer should not have to worry about the code distribution to nodes, as this depends on the specifics of the destination platform, that is, memory architecture, I/O, available devices, etc. But the developer must provide enough information for the operating system’s code analyzer so that it can identify the cross-segment exchange of data, without having to restrict itself to a specific deployment or segmentation.

Even though monolithic operating systems still scale well, they are tightly coupled to a specific resource type, making the integration diverse resource types difficult to manage. Furthermore, monolithic OS assume that the infrastructure is comparatively static and thus cannot provide simple means to cater for fault tolerance response as the corresponding supervision would produce additional management overhead. Monolithic approaches also tend to lose efficiency when cross-process communication reaches a certain threshold as there are too many synchronization steps have to be managed.

62.3 Derived Operating System Model

A primary concern for the efficient execution of distributed programs in future infrastructures consists in providing an execution environment that does not control the process(es) from a central point and that is capable of providing and exploiting the capabilities of each individual resource. A major concern is the degree of messaging overhead created by centralized control and cache misses. To reduce the amount of messaging, it must be ensured that each part of the code can effectively run as a completely independent (i.e., concurrent) process. This means that data exchanges have to be reduced to a minimum, with other processes or even the operating system. The degree of “independence” is thereby not so much defined by the total number of shared data but by the amount of messaging relative to the underlying connectivity speed. If timing is correctly exploited, messaging has no impact on performance since no process has to wait for another due to lack of data (i.e., locking).

As has been noted, most “processes” or segments forming an application require minimal operating system requirements toward the environment they are running on, if they are carefully restructured. Often enough, developers completely depend on integrated frameworks (such as .NET) that are so tightly integrated with the operating system that even simple process calls will lead to system interrupts and therefore to unnecessary overhead.

In principle, any program can be written so that it does not require any operating system support—this implies however that effectively the developer writes his own operating system as part of his intended application logic, which is neither realistic nor helpful. Instead, we require an execution environment (operating system) that can itself be distributed and adjusted in a fashion that it only provides essential capabilities to each executing thread/process, and still maintains consistency with as minimal impact on execution and communication overhead as possible.

62.3.1 Modular OS Architectures

Effectively the architecture should provide minimal OS environments per executing segment that nonetheless still caters for all the additional capabilities and requirements to maintain a distributed execution and therefore all the dependencies between the executing segments. For example, a regular multi-threaded application with one main thread and a hundred worker threads that all read data from a central main memory should implement the functionalities for accessing this memory location, but requiring hardly any other OS support. What is more though, this functionality differs strongly between platforms and their organization, that is, whether memory is shared, whether remote memory access is supported, etc.

This means implicitly that even though only limited functionality is required, the different requirements originating from the environment impose that no single implementation can provide the necessary capabilities. The current approach consists in the operating system providing a variety of strongly related functionalities that can be exploited for a wide set of tasks.

This is where the strength of modular approaches comes in: from the programmer's perspective, only specific functionalities are required that can be exposed in a common way, leaving it to the execution environment to decide on the actual implementation of the respective functionalities. This is not unlike dynamically shared libraries where the right implementation of the library can be chosen on basis of the hardware specifics. Shared libraries thereby are essentially nothing more than programming extensions, built up on the operating system.

With the modular approach the functionalities are tightly integrated with the rest of the execution environment. Effectively, the whole operating system makes use of the same operations, though with different flavors, according to the execution circumstances. This can increase performance drastically and allows for better alignment between execution and platform.

One very essential consequence of this approach is the fact that applications and the operating system are equally structured in a modular/segmented fashion. In other words, the operating system invokes its functionalities in the same way as the applications, putting the applications essentially on the level of control of the operating system.

Modules forming the essential operating system behavior and contributing to the application execution can therefore be deployed in any fashion across the infrastructure. To this end, however, a strong messaging mechanism must be in place that can realize the communication between modules across the deployment—this implicitly puts messaging in a special position compared to all other modules (see section on OS capabilities).

As opposed to classical operating system architectures, this implies that there is not one, common deployment and instance of the whole operating system within the infrastructure, but instead there are different modules instantiated all across the environment that communicate with one another to fulfill the respective functionality. The operating system is effectively spread all over the environment.

In order to allow for coordinated execution, the individual modules need to be carefully controlled and configured so as to compensate and supplement each other, rather than competing against each other as it is currently the case when multiple OS instances run within the same environment.

The modules are not so much higher order extensions, comparable to libraries, but can be compared better to service instances in a distributed environment such as web services. What is more though, the “service” or module does not have to reside at a designated, static location, but can be freely relocated,

instantiated, and replicated according to the current requirements, therefore comparing it more with the classical ideas behind grid computing or cloud computing.

62.3.2 Execution Lifecycle and Background Support

Before we take a look at the actual architecture of such a modular, distributed operating system, it is worth examining how the system behaves principally as a whole, if a new application is executed within such an environment. We can thereby identify the following major steps:

1. Analysis
2. Preparation
3. Deployment
4. Execution and maintenance

During *analysis* the code to be executed is analyzed with respect to its specific preconditions and requirements toward the infrastructure and its potential to be executed in parallel/concurrent segments. This means in particular that the indicators provided by the developer with respect to the code–data relationship and the degree of parallelism, and respectively the concurrent code segments, are identified. There are different means to support the automation of this step, such as dependency identification, code segmentation, automated parallelization, etc. For the operating system to work properly, the actual mechanisms to identify these possibilities are secondary. What is of main relevance is how this information relates to the distributed execution of the code.

The main information required for enabling distributed execution consists in bringing out all aspects that create any form of dependency beyond the local code. This implies the following:

1. Remote memory access: Any access to nonlocal memory space, whereby “local” means local to the executing segment (thread, process), which does not necessarily mean local to the function/class/object in the source code.
2. Explicit communication: Any explicit invocation or messaging with nonlocal (see earlier text) code instances, segments, or even devices. Again the actual scope depends more on the executed segmentation than on the source code structure.
3. Work segmentation: Similar to communication and memory access, code execution may jump between threads/processes/segments in order to perform the actual distributed execution—this equally covers intended jumps (invocations, branches), as well as unintended ones (created by segmentation) and ones to exploit concurrency (executing multiple segments at once).

Principally, the developer needs to indicate the data and code segment dependencies and relationships in a form that is understandable by the compiler, analyzer, or interpreter that converts the information into an executable form that the operating system can handle. The most promising approach is a graph representation of the code structure whereby the different types of dependencies are denoted as weighed edges. The weighs can convey different information with respect to amount of data communicated, frequency of communication, etc. Edge direction can represent direct access types (read, write). This graph not only allows for easy identification of concurrent code segments but also of communication points, data dependencies, etc.

In [6], we elaborate about mechanisms that allow for automated characteristics extraction and matching. New models are thereby required to specify the capabilities of hardware in an abstract form.

Preparation of the application code and the computing environments involves conversion of the code to accommodate for the requirements arising from the segmentation and deployment, as well as the selection, instantiation and configuration of the required operating system modules, i.e., enabling provisions with the right functionalities.

Code preparation may include replacing the dependencies with explicit system calls to cater for the distributed execution, that is, in particular, to inject messaging points where according to the original

code only foresee memory access and where the dependency graph identifies a cross-segment relationship. Nonetheless, the preparation phase can be regarded as part of the compilation step, if we consider dynamic re-arrangement as a form of re-compilation.

It must be noted that with the growing heterogeneity and principally dynamicity at execution time, the classical concept of completely isolated development, compilation, and execution steps can no longer take place as such—instead, the steps *must* become intertwined to fully exploit the potential of future hardware infrastructures.

Though developers will not and should not write code for a specific destination platform, they will have to give explicit hints that implicitly relate to the mapping of the code to the infrastructure, particularly regarding dependencies and concurrency. As the deployment may change depending on time-sharing and available resources, the operating system must be able to rearrange and re-distribute the code without having to go through an explicit compilation phase. Just-in-time compilers are a clear indicator of this trend.

At the *Deployment* phase, the *selected* segmentation of the code, including all its required operating system modules, will be deployed in the infrastructure according to the application's layout identified during the preceding stages. This step includes all configuration steps required in order to make distributed execution take place, such as registration of the communication endpoints, reservation and registration of the address spaces, etc.

If the analysis and preparation are considered outside the actual operating system lifecycle, the main OS operation starts with the deployment of the code, as well as the deployment of the operating system modules themselves.

Finally, during the *Execution* phase, the application will be executed across the deployment created in the preceding phase. It must be noted that not all code will necessarily be designated to a specific processing unit during the execution initialization. Instead, the application behaves more like a workflow, with individual segments (“services”) being deployed at run time upon invocation. This way, concurrency can be exploited even if the exact timing behavior can only be estimated, and thus allow for dynamic reaction to the arising time-sharing constraints.

The operating system must be able to dynamically create and relocate instances of both the application, and—more crucially—of itself; its own modules.

The major task for the operating system during distributed execution consists of ensuring state consistency and communication across the individual instances—both on the OS and the application level. Since the deployment is not fixed and may change dynamically at run time, the operating system *as a whole* has to ensure that all the relevant parts are always reachable from all communicating segments. In other words, the segments can always be executed as if the environment would adhere to the original specification, even as if the platform would be a single-core sequential processor.

In close relationship to the types of dependencies identified earlier, this means, in particular, that the operating system must provide mechanisms to

- Access memory and maintain state
- Access (I/O) devices
- Communication routing between instances/segments
- Event handling across instances

In general, the operating system will provide a dedicated (virtual and managed) address space for each application, allowing the memory manager of the processor to execute relative jumps and calls within the same local address space range and leaving it up to the operating system to handle the page swaps. In most cases (with the exception of applications dedicated to parallel execution), the address space will be continuous, that is, at least within the same physical location. This means that jumps and calls will not leave the machine, unless the developer has explicitly specified it.

In the more dynamic distributed case, this assumption does not generally hold true, as any jump or memory access may imply leaving the physical boundary of the executing entity, and therefore out of the locally assigned address space. The classical way of handling this via a page miss event may not suffice

anymore in this case, as the access may imply remote processing. Remote page swapping, that is, copying data from a remote location just into cache, without having another local replica, is generally not advisable, as it implies that every page swap would have to deal with all the communication overhead, even if the cache was not altered, that is, no update is required.

The key factor consists of good data segmentation and identification of the right points for the communication and update of data. Without loss of generality, we assume that the system calls are embedded by the compiler on basis of the annotations provided by the developer and the results from the analysis and matching phase prior to the execution of the code. Memory access in such a distributed environment turns from the explicit access to a specific memory space into requesting the operating system to make the corresponding data set available for accessing. The developer does not have to identify the origin of the corresponding data, nor for distributing it to all linked code segments.

All communications must be executed in the background in order to be nonblocking, and thus allow the execution of other operations before the actual memory access takes place. At the same time, the operating system must offer support to handle communication in different forms, wherever the developer explicitly requests it.

Considering the circumstances, in particular regarding the flexible, potentially dynamic distribution of processes across the infrastructure, a particular task for the operating system consists of maintaining the right communication endpoints. To realize this, such an operating system must support multiple mechanisms:

- Hierarchical lookup tables: Primarily serve the purpose of providing the right communication endpoints for specific address spaces.
- Routing: Due to the potential dynamicity, endpoints may move without all related instances being informed; the operating system must provide means to forward the communication from the old to the new endpoint.
- Fault handling mechanisms: Fault handling mechanisms must ensure that wrong lookups do not automatically lead to failure of the according application, but the study of this issue is beyond the scope of the current document.

62.3.3 Essential OS Capabilities

Based on the preceding discussion, we identify a set of essential functionalities that a distributed operating system must offer over a classical, monolithic and centralized OS architecture. We must thereby explicitly distinguish between exposed functionalities (as visible to the developer or user) and actions arising from the distributed usage of the available functions. As discussed at the beginning of this section, messaging mechanisms must be exposed to the user without adding any further burden to the endpoint. Messaging depends thereby very much on the processor architecture and thus differs between different deployments and execution cycles. Notably, the same level of distinction also applies to the operating system itself: due to its modular organization, many of its functionalities are implicit to the way execution is handled.

On the other hand, the individual functionalities should not hide capabilities and mechanisms that the user may potentially want to exploit for his own benefit that he may want to be able to control at least to a certain degree (such as specifying a security protocol, distinguishing different means for ensuring consistency, etc.).

It is of utmost relevance that the dependencies between functionalities is kept to an absolute minimum, so as to (a) allow easy replacement and adaptation, and (b) not generate management and communication overhead that would exceed the gains of a modular architecture again.

We can identify the following main base capability categories an operating system must provide in order to enable distributed execution:

- Communication: With a messaging-based approach, communication support is implicitly an inherently relevant capability, covering not only the message exchange between the execution segments (code blocks), but also the implicit and explicit communication between operating

system modules. Communication is a transparent underlying capability for routing invocations and messages to the necessary endpoint without the respective code having to identify it explicitly. Nonetheless, the developer must be able to explicitly use the communication capabilities to send messages to dedicated endpoints in a thread-/MPI-like fashion.

- **Memory management:** With the application and its data being distributed all across the infrastructure, memory access is not straight-forward from any executing code; in particular with multiple blocks being executed concurrently, the data space may either be replicated or centralized. In either case, the developer should not have to cater for the specific mechanisms. Instead, the operating system must provide means that grant managed access according to the deployment specifics. This means that memory management is tightly coupled to the communication capabilities in order to enable remote access and state maintenance.
- **Scheduling:** Multitasking was originally implemented by sharing the same resource between multiple processes and having the scheduler distribute the processing time between them. With large scale, distributed infrastructures, the primary goal of a scheduler is distribution and timely invocation of the blocks. From a single processing unit's point of view, execution ideally becomes a fairly sequential task, thus dedicating most of the unit's performance to the respective task. Nonetheless, some use cases will initiate more processes than resources are available to run them on, and individual processes may be stalled due to communication delays and interdependencies, so that the scheduler will still have to be able to execute classical context switches in order to maximize resource usage.
- **Deployment and process management:** Strongly related to scheduling, the operating system must be able to *remotely* deploy and trigger processes (or more correctly: code segments) in order to be able to distribute the application across the infrastructure in a way that reflects the parallelism and concurrency of the code. This implies that the designated destination resource provides the base means that allow reception, deployment, and linking of the code. This includes, in particular, communication and memory management functionalities.

In addition to these, we can identify lower-level functionalities that at first glance would have to be considered subsumed by the ones listed earlier. These however may be explicitly used by the application and must therefore be exposed in a way that the developer can invoke them according to his needs:

- **File management and I/O management:** Devices in a system are generally exposed via a common communication bus, classically denoted as I/O (input and output). Modern systems distinguish between different buses, depending on the type (and location) of the device in question. Most of these devices must be accessible to the user at least in some form, such as the disk drivers, printers, screens, etc. The OS must provide common means to reach the devices and interact with them without having to cater for the protocol details. The location of the according devices may thereby not be known to the user, so that similar routing mechanisms are needed as for memory management.
- **Interrupt handling:** Handling requests from devices and software instances is an essential feature of all operating systems to control the infrastructure. Some interrupt events are obviously handled by the operating system, but the developer may want to exploit, inspect, and react to such events by capturing them. The corresponding capability must be available to both the operating system itself (infrastructure management) and the developer through an extended forwarding mechanism.

Finally, to enhance the operating system behavior, additional, so-called “supporting” capabilities are required, which provide the essential information for the individual OS components to execute the code in the way described earlier:

- **Code analysis and segmentation:** The introduction of web services and the cloud gave rise to increased exploitation of remote procedure call like interactions, and thus to a workflow-like segmentation of the application in the first instance. The code analysis must identify external

dependencies, that is toward libraries, operating system calls, devices, etc., that effectively define the segmentation and mapping of the code on the infrastructure. Notably, the segmentation identified by the developer does not have to be the most suitable for the destination infrastructure and also the data structure plays an important role in the sensible distribution of code, as it may create dependencies that effectively counter any segmentation. This analysis results in a dependency graph of potential code and data segments, including any form of additional constraint information as given by the developer, that can be exploited for the purpose of distribution and mapping to the destination platform.

- **Resource management:** In the environment described earlier, resources are no longer treated as concrete processor models, micro-architectures, device types, etc., but instead as abstract entities that provide certain capabilities and impose specific constraints. As heterogeneity increases, devices must be characterized according to their capabilities and must be classified according to how code can make use of these characteristics. Along the same line, resources must be discoverable; changes in the resource setup must be communicated to all related nodes, so as to take potential recovery actions, respectively, to exploit the additional resources. This step is particularly relevant as a precedent to deploying the code.
- **Code transformation:** In order to match the code against the infrastructure and to exploit its characteristics, it is necessary to transform the code accordingly. This is an extension to the classical compilation step, which involves optimization steps. More important, due to the segmentation and re-arrangement of the memory layout, additional commands for maintaining communication and accessibility to the data have to be injected. Since the layout of the code and infrastructure may change at run time, the mapping and the code transformation should not be a static; it must be possible to adapt the code at run time according to the environmental conditions.

Effectively, the “vertical” supporting capabilities can be regarded as part of the code compilation process, as their main tasks consist in converting the code so as to meet the infrastructure and distribution requirements. It must be noted, however, that many of the steps may have to be executed again at run time. We can thus distinguish between preparational steps and steps to be performed at execution run time under dynamic conditions. This leads to a compilation structure that effectively incorporates the following four steps:

1. Analysis of the code
2. Conversion into a pre-executable code
3. Just-in-time adaptation to infrastructure
4. Just-in-time compilation to destination

62.3.4 OS Layout

The primary concern when building an operating system architecture that meets the capabilities listed earlier consists in identifying a minimal representation of these capabilities in terms of software components. In other words, in identifying the set of minimal components that are sufficient to provide the necessary functionalities, yet do not create performance issues simply because of communication overhead created by segmenting the functionalities into individual components. Essentially, this means that the dependencies between the given set of capabilities in different usage contexts need to be identified.

We can categorize the core functionalities into five major domains (cf. Figure 62.1), namely, capabilities related to executing the processes, handling memory and storage, handling the devices and hardware, supervising the infrastructure, and finally, the messaging support across all these domains.

The primary principle of a service-oriented operating system architecture consists of instantiating only the essential capabilities that are required for executing a specific functionality. Deployment

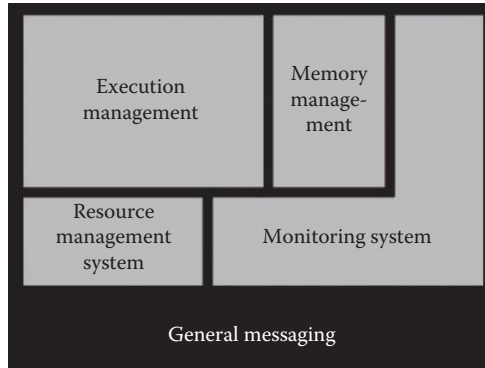

FIGURE 62.1 High-level architecture of the service-oriented OS architecture.

does not have to be co-located with the calling code/function, due to the message-based approach, but remote invocation implicitly leads to higher communication overhead that can stall the process. An optimal segmentation of components keeps the communication overhead and the load on memory (and therefore chances for cache misses) low.

This means that even though the components belonging to the functional groups identified earlier provide the same type of functionality, their individual instantiation can differ quite significantly. We can best exemplify this by a process load operation from a specific designated memory space, local to the full application. In other words, the data space is global to the application but not necessarily to the individual process trying to invoke it. Any memory access can therefore be regarded as a load operation from an unknown source that takes a specific amount of time. If the timing behavior can be predicted and if the usage logic is known, prefetching mechanisms can be enacted to improve processing performance [2].

The developer will not want to decide between server (remote) and client (local) invocations either, but instead the programming convention must follow traditional standards. The compiler or runtime handler must be able to replace the memory accesses with invocations to the memory management system.

A completely managed environment, where all data access is first routed through the operating system, on the other hand, will create additional system management overhead to memory accesses that could be handled directly in cache. The best approach in terms of performance is determined by the type and amount of data, as well as the degree of sharing. In general, the analysis must identify these dependencies and inject the right access means accordingly.

62.4 Applying Service-Oriented Operating Systems

As already discussed, future infrastructures will be characterized by a high degree of mobility, parallelism, and heterogeneity of resources while users expect more and more performance. This can only be achieved by exploiting parallelism and concurrency of the applications. This section will demonstrate how the architecture outlined in the preceding section behaves in the following scenarios.

62.4.1 High-Performance Computing Scenario

High-performance computing (HPC) is designated by a single application requiring a large amount of resources to achieve the necessary performance, with respect to precision, amount of data and/or speed. Performance is primarily defined by the degree of communication taking place during execution, as

data consumption/production is in general faster than communication allows. Reducing any form of communication is thereby the primary concern of any developer.

As can be shown, a centralistic operating system creates additional communication overhead that outweighs the overhead generated by a message-based system [1]. What is more, due to the monolithic organization of current operating systems, system invocations may cause a huge amount of cache misses [6]. Finally, the overhead for creating and handling threads ranges in the number of hundreds of thousands of cycles [3,4] as classical operating systems have not been designed for parallel applications, thereby hindering low workload threads in a large-scale programs, and thus optimal exploitation of the environment.

The actual system support required by each thread is comparatively low and relates in particular to handling memory and I/O. With the current structure of OS architectures, each thread is effectively lugging a whole management system with it that obstructs execution and leaves a major footprint on the local memory. The service-oriented approach generates stand-alone (barebone) applications out of each thread that can run without the full management environment of an operating system. As these threads effectively run directly on the chip/core without any intermediary layers, they can be instantiated and executed much faster, very similar to classical DOS applications. Any additional requirements relating to security, reliability, etc., can thereby be dynamically added at the cost of degrading performance.

62.4.2 Connected World Scenario

In the future, we must not expect the user to outsource specific tasks, for example, to a HPC platform anymore, but instead the user will expect to be *integrated* into the resource mesh, that is, that the underlying resources and infrastructure becomes seamlessly available to the running applications, thereby extending capabilities, usage (such as sharing of data), and performance.

In the classical approach for the connected world scenario, the user would own a global ID that enables him to be recognized in a variety of contexts and that allow the respective application to pull information (such as favorite songs) from a distributed or cloud-like data storage environment. This would however only partially address the requirements of the future mobile user, in particular where execution of interactive applications (such as a document editor with shared data) is required. In such cases, some part of the application has to reside locally with the user to provide the necessary interfaces, even if the interface itself is displayed in a browser-like application.

The user's applications may vary widely and will not be restricted to commonly known and deployed applications, such as Open Office, but also include less common applications, and even completely self-developed code. Applications in turn may be composed of a variety of other functionalities (services, applications, etc.) that each in turn has different requirements toward the executing infrastructure, ranging from high performance to shared or social connectivity. Identification of the identity of the user alone is thereby insufficient, for example, if the user wants to run complex simulations on (or from) his mobile device.

Whilst web service like approaches allow integration of remote services, they do not offer the flexibility or performance needed in most cases. For example, communicating the necessary data from the United States to France will lead to significant delays even with the future network developments and increase in performance. This requires a more flexible distribution of code and data than currently considered in any application code. Some global cloud infrastructures may already exhibit indicators of a development in this direction, yet this is far from providing users with the full flexibility of deployment and execution.

With a service-oriented operating system, this capability essentially comes for free with the structure of the OS itself. The principal organization scheme of the OS thereby allows realization of the old grid dream where any resource can be designated host of a dedicated service [5]. The approach goes even further by allowing partial integration of the resource for only limited capabilities and execution, much

like sharing cores for multiple tasks in a local desktop. In this case, it is not so much the other device getting access granted to the user data, but hosting temporarily a function on behalf of the user that in turn enables accessing the respective data. In other words, the user will not only be able to play his favorite playlists, but also can use his favorite application for doing so.

Future offices, hotels and conference centers can essentially offer pure resource power to their users who plug in any low power mobile device to run their own applications and perform their individual tasks with extended execution performance. The resources become effectively nothing else but extensions to the mobile device that dynamically move with and adapt to the user's behavior and requirements. The mesh of resources used for this purpose form an isolated environment of their own, with external interfaces only provided and used as specified by the user, respectively developer.

62.5 Conclusions

With the introduction of multicores, specialized infrastructures, Internet provided utility computing, etc., the IT environment is quickly building up to significant changes in our way of thinking of software and hardware. These changes are thereby not matched by our approach for dealing with them, in particular in terms of software development and execution. The average programmer still treats the system like a single core Turing machine with immediate data availability. As the heterogeneity and dynamicity grows, however, solving the problem cannot be put onto the developer alone, but must be matched by the infrastructure's capabilities to adjust itself *and* the code according to the current requirements.

This all builds up toward an environment where the individual resource can never satisfy all the user's requirements without incorporating additional devices and/or services. Already we have the notion of such global infrastructures through web services, social networks, and clouds, yet they are countered by the increasing demand for performance in complex applications.

Classical operating systems are simply not designed for such environments and they lead to increasing overhead both in terms of execution performance and development time/effort. Bringing service orientation not only to the application but also to the underlying execution management framework, that is, the operating system, enables the realization of such scenarios while reducing the inherent performance losses.

The service-oriented approach does not only match the requirements for minimal load on the individual processing unit and for distributed deployment and management of applications spanning multiple devices. It also allows for much easier adaptation toward and integration of new device types. Where classical operating systems effectively had to be rewritten completely even for minor changes (see, e.g., [1]), the service orientation allows for component-wise adaptation and instantiation according to the device properties.

For decades, the monolithic, centralized operating system architecture has prevailed. All the adjustments to meet a specific processor model have made the OS sluggish to adaptation. New infrastructures and usage demand for a much meaner and leaner architecture than monolithic approaches can offer. Service orientation needs to become a natural part of such architectures in order to meet these requirements.

63.1 Introduction

In the 1940s, John von Neumann pioneered the design of basic computer architecture by structuring computers into two major units: a central processing unit (CPU), responsible for computations, and a data storage unit, or memory. This architecture is demand driven, based on a command- and instruction-oriented computing model. The basic unit cycle of execution, typically composed of a single instruction, consists of four steps:

1. Obtain the addresses of the result and operands.
2. Obtain the operand data from the operand location(s).
3. Compute the result data from the operand data.
4. Store the result data in the result location.

Note here how separation of the execution unit from the memory unit has structured the sequence. Data must be located and piped from memory, operated on, and transferred back to memory to be available for the next operation. All operations in a von Neumann machine operate this way, in a stepwise, structured manner. The von Neumann model has been the basis of nearly every computer built since the 1940s.

Imperative programming languages are modeled after the von Neumann model of machine execution and were invented to provide the abstractions of machine components and actions in order to make it easier to program computers. Abstractions such as variables (which model memory cells), assignment statements (which model data transfer), and other language statements are all abstractions of the basic von Neumann approach.

In this chapter, we address the fundamental principles underlying imperative programming languages and examine the way the constructs of imperative languages are represented in several languages. We devote special attention to features of more modern imperative programming languages, among them support for abstract data types (ADTs) and newer control constructs such as iterators and exception handling. Examples in this chapter are given in a variety of imperative programming languages, including FORTRAN, Pascal, C, C++, MODULA-2, and Ada 83. In the Best Practices section, we explore in more detail the languages FORTRAN IV (chosen for historical reasons), C and C++ (its imperative parts), and Ada 83.

63.2 Data Bindings: Variables, Type, Scope, and Lifetime

In this section, we discuss some of the fundamental properties of imperative programming languages. In particular, we address issues related to binding time, the properties of variables, *types*, scope, and lifetime.

63.2.1 Binding Time

We will find it useful to classify many of the differences in programming languages based on the notion of binding time. A *binding* is the association of an attribute to a name. The time at which a binding takes place is an important consideration. There are many times when a binding can occur. Some of these are as follows:

- *Language definition*: when the language is designed. An example is the binding of the constant name `true` to the corresponding Boolean value.
- *Language implementation*: when a compiler or interpreter is written. An example is the binding of the representation of values of various types.
- *Compile time*: when a program is being translated into machine language. For example, the type of a variable in a statically typed language is bound at compile time. In statically typed languages, overloaded functions are bound at compile time.
- *Load time*: when the executable machine language image of the program is loaded into the memory for execution by the execution unit. The location of global variables is bound at load time.
- *Procedure or function invocation time*: the time a program is being executed. Actual parameters are bound to formal parameters and local variables are bound to locations at procedure invocation time.
- *Run time*: any time during the execution of a program. A new value can be bound to a variable at run time. In dynamically typed languages, overloaded functions are bound at run time.

As we examine fundamental issues in the definition of imperative programming languages, we will keep in mind the distinctions between languages based on differences in binding time.

63.2.2 Variables

Imperative languages support computation by executing commands whose purpose is to change the underlying state of the computer on which they are executed. The *state* of a computer encompasses the contents of memory and also includes both data that are about to be read from outside of the computer and data that have been output.

Variables are central to the definition of imperative languages as they are objects whose values are dependent on the contents of memory. A variable is characterized by its attributes, which generally include its name, location in memory, value, type, scope, and lifetime.

Depending on context, the meaning of a variable may be considered to be either its value or its location. For instance, in the assignment statement, $x := x + 1$, the meaning of the occurrence of the variable x to the left of the assignment symbol is its location (sometimes called the l-value of x), whereas the meaning of the occurrence on the right side is its value, that is, the value stored at the location corresponding

to x (sometimes called the r -value). The location of global variables is bound at load time, whereas the location of local variables and reference parameters is typically bound at procedure entry. The value of the variable can be changed at any point during execution of the program.

63.2.3 Types

Types in programming languages are abstractions that represent sets of values and the operations and relations that are applicable to them. Types can be used to hide the representation of the primitive values of a language, allow type checking at either compile time or run time, help disambiguate overloaded operators, and allow the specification of constraints on the accuracy of computations. Types also can play an important role in compiler optimization.

Types in a programming language include both simple and composite types. The use of *simple types* such as integer, real, Boolean, and character types allows the user to abstract away from the actual computer representation of these values, which may differ from computer to computer. The operations on simple types may or may not be supported directly by the underlying hardware. For instance, many early microprocessors supported only real or floating-point operations in software.

Some languages (e.g., those derived from Pascal) allow the programmer to define their own simple *enumerated* types by simply listing the values of the type. The ordering of elements in this enumeration is significant as these types typically support successor and predecessor functions as well as ordering relations. Later we will discuss mechanisms for supporting *ADTs*, another way of constructing types that can be used as though they were primitive to a language.

Many languages support the creation of *subrange* types, which allows a programmer to define a new type as a copy of a type with a subset of its values. The new type comes equipped with the same operators as its parent type and is usually compatible with the original type.

Composite or structured data types can be created from simple types using *type constructors*. Typical composite types include arrays, records (or structures), variant records (or unions), sets, subranges, pointer types, and, in a few languages, function or procedure types. For instance, arrays are typically constructed from two types: a subrange type that provides the set of indices of the array and another type representing the values stored in the array. Not all languages support all these type constructors. For instance, function and procedure types are provided by MODULA-2 but are not available in Ada 83. Many languages support strings as special types of composite types, for instance, as arrays of characters, but they may also be provided as built-in types.

Most imperative languages bind types to variables statically. These bindings are usually specified in declarations, but some languages, such as FORTRAN, allow implicit declaration of variables, with the type binding determined by the name of the identifier (e.g., in FORTRAN if the name starts with I through N , then the variable is an integer, otherwise real).

An important issue in type-checking programming languages is type equivalence. When do two terms have equivalent types? The two extremes in the definitions of *type equivalence* are structural and name equivalence:

- *Structural equivalence*: Two types are said to be *structurally (or domain) equivalent* if they have the same structure. That is, they are built from the same type constructors and built-in types in the same way.
- *Name equivalence*: Two types are *name equivalent* if they have the same name.

The language C uses structural equivalence, whereas Ada 83 uses name equivalence. There are also a range of possibilities between these two extremes. For instance, Pascal and MODULA-2 use *declaration equivalence*: two types are declaration equivalent if they are name equivalent or they lead back to the same structure declaration by a series of redeclarations.

Inequivalent types may be compatible in certain situations. For instance, two types are assignment compatible if an expression of one type may be assigned to a variable of another. For instance, in Pascal, a subrange of integer is assignment compatible with integer, even though the types are not equivalent.

An application of these ideas can be found in the rules for determining whether a particular actual parameter may be used in a procedure call for a particular formal parameter. In Pascal, if the formal parameter is a reference parameter, then the actual parameter must be a variable of equivalent type. If the formal parameter is a value parameter, then the actual parameter must be assignment compatible.

As mentioned earlier, some languages support the creation of subrange types. The new subrange type is usually assignment compatible with the original type. Because of this compatibility, the new type is called a *subtype* of the parent in Ada. Another mechanism available in Ada, called *derived typing*, defines a new type by constructing an exact copy of a type that already exists. However, the resulting new type is distinct and is not type equivalent or even assignment compatible with the existing type.

The type equivalence rules are the cause of one of the greatest limitations in the use of Pascal. If a formal parameter has an array type, then the actual parameter must have an equivalent type. In particular, the subscript ranges of the two arrays must be identical. Thus, it is impossible to write a procedure in Pascal that can be used to sort different-sized arrays of real numbers. (Actually, the current ANSI standard Pascal provides a special mechanism to allow exceptions to this rule.)

Ada escapes from this problem by designating some properties of types to be static, while others are dynamic. For example, in a type defined to be a subrange of integers, the underlying static type is integer while the subrange bounds are a dynamic property. Only the static properties of types are considered at compile time by the type checker, whereas restrictions due to dynamic properties are checked at run time.

Consider the following Ada declarations as an example of type bindings:

```
type COINS is (PENNY, NICKEL, DIME, QUARTER);
subtype SILVER is COINS range (NICKEL..QUARTER);
type CHANGE is new COINS;

C1, C2; COINS;
S: SILVER;
CH: CHANGE;
```

COINS is an enumerated type, defined by the programmer to allow assignments such as

```
C1 := DIME.
```

SILVER is a subrange of COINS, which includes only the values NICKEL, DIME, and QUARTER. CHANGE is a derived type taken from COINS.

Because Ada employs name equivalence, only C1 and C2 are equivalent, but S is assignment compatible with them. If Ada used structural equivalence, then variables C1, C2, and CH would be equivalent.

63.2.4 Scope

The scope of a binding is the area or section of a program in which that particular binding is effective. The method and extent of *scope rules* that define a binding scope will, to a large degree, affect the usefulness and applicability of a language. If, for instance, the rules allow the scope of a binding to be determined by the execution path of a program, the language might be more flexible, yet the code becomes harder to understand.

Scope rules are tied tightly to concepts of binding time. *Static scope rules* determine the scope of a binding at compile time and are based on the lexical structure of the program. *Dynamic scope rules* determine the scope of a binding at run time. Thus, an occurrence of a variable name in a procedure may refer to one variable the first time it is evaluated yet refer to an entirely different variable the next time, depending on the execution path at run time. Most imperative languages use static scope rules.

As an example of scope rules in Ada, consider the code in Figure 63.1. Static scope rules are determined by the program block structure, which does not change while the program runs. Therefore, the call to procedure P prints the variable J defined in the outer, main program, no matter where it is called from. Likewise, the assignment in block 1 at reference point A changes J from the block and not from

```

with TEXT_IO; use TEXT_IO;
procedure SCOPED is
  package INT_IO is new INTEGER_IO (integer); use INT_IO;
  I, J: integer;

  procedure P is begin put (J); new_line; end P;
begin
  J := 0;
  I := 10;
  declare -- Block 1
    J: integer;
  begin
    j := I; -- reference point A
    P;
  end;
  put (J); new_line;
  declare -- Block 2
    I: Integer
  begin
    I := 5
    J := I + 1; -- reference point B
    P;
  end;
  put (J); new_line;
end;

```

FIGURE 63.1 Scoping rules in Ada.

the main program. Dynamic scope rules, on the other hand, typically follow dynamic call paths to determine variable bindings. If Ada used dynamic scope rules, the first call to `P` from block 1 would print the value 10 corresponding to the `J` from block 1, whereas the second call to `P` would print the value 3 corresponding to the `J` from the main program.

63.2.5 Execution Units: Expressions, Statements, Blocks, and Programs

An *expression* is a program phrase that returns a value. Expressions are built up from constants and variables using operators. As described earlier, variables may represent two values, depending on context: their location and the value stored at that location. Operators may be built-in, like the arithmetic and comparison operators, or may be user-defined functions.

Reflecting the sequential order of von Neumann computation, an imperative language specifies the order in which operations are evaluated. Typically, evaluation order is determined by precedence rules. A typical precedence rule set for arithmetic expressions might be the following:

1. Subexpressions inside parentheses are evaluated first (according to the precedence rules).
2. Instances of unary negation are evaluated next.
3. Then, multiplication (`*`) and division (`/`) operators are evaluated in left to right order.
4. Finally, addition (`+`) and subtraction (`-`) are evaluated left to right.

Although procedure rules are commonly used by imperative languages, some languages use other conventions to avoid precedence rules. For example, PostScript uses postfix notation for expressions, while LISP uses prefix notation. APL evaluates all expressions from right to left without regard to precedence, using only parentheses to change the evaluation order.

The fundamental unit of execution in an imperative programming language is the *statement*. A statement is an abstraction of machine language instructions, grouped together to form a single logical activity.

The simplest and most fundamental statement in imperative programming languages is the assignment statement. This statement, typically written in the form `x := e` or `x = e` with `x` a variable

(or other expression representing a location) and e an expression, is usually interpreted by evaluating e and copying its value into the location represented by x . This is known as the *copy semantics* for assignment.

Less common are languages that use the sharing interpretation of assignment. In these languages, variables generally represent references to objects that contain the actual values. The assignment $x := y$ would then be interpreted as binding the object referred to by y to x rather than its value. Since both variables refer to the same object, they share the same value. If the value of one is changed, the value of the other will also change. This is the *sharing semantics* for assignment.

Declarations and statements may be grouped together to form a *block*. Procedure and function bodies are represented as blocks, whereas *control structures* (discussed subsequently) can also be understood as acting on blocks of statements (generally without declarations). The most general form of a block contains a *declarative* section, which contains the declarations that define the bindings that are effective in the block, and an *executable* section, which contains the statements over which the binding is to hold, that is, the scope of the declarations.

In the so-called block-structured languages (including most languages descended from ALGOL 60, e.g., Pascal, Ada, and C), blocks may be nested. Within any block, therefore, there can be two kinds of bindings in force: *local bindings*, which are specified by the declarative sections associated with the block, and *nonlocal bindings* (also known as *global bindings*), which are bindings defined by declarative sections of blocks within which the specific block is nested.

Consider again the code from Figure 63.1. The first two assignments of the main program assign J from the main program the value 0 and I from the main program the value 10. The next assignment assigns the value 10, derived from the global I , to the variable J from the first inner block. When the definition of the second inner block is encountered, the variable I is found in the local scope, while J is found in the *outer* scope, that of the main program. The value 6 will be printed for J at the end of the main program.

63.3 Control Structures

By adopting the semantics of the basic execution cycle of a von Neumann architecture, an imperative language adopts a strict sequential ordering for its statements. By default, the next statement to execute is the next physical statement in the program. Control structures in imperative languages provide ways to alter this strict sequential ordering. The most common control structures are *conditional structures* and *iterative structures*. *Unconstrained control structures* are also allowed in most languages through the use of goto statements.

63.3.1 Conditional Structures

Conditional control structures (also known as *selection statement*) determine whether or not a block of statements is executed based on the result of one or several tests. These structures fall into one of the two following classes:

63.3.1.1 If Statements

All imperative languages include some form of if statement. This control structure provides a text and a single statement or statement block to be executed if the test evaluates to a true value. Optionally, the programmer may provide another block of statements that can be executed only if the test evaluates to false. The following is a simple example from Ada:

```
if (x = 2) then
  y := 3;
else
  y := 6;
end if;
```

The variable y is set to either 3 or 6 depending on the value of x .

In most languages, if statements can be nested within other control structures, including other if statements. However, nested if statements can result in awkward, deeply nested code. Thus, many languages provide a special construct (e.g., `elsif` in Ada) to represent *else if* constructs without requiring further nesting. The two Ada examples given next are equivalent semantically, though the first, which uses `elsif`, is easier to read than the second, which uses nested conditionals:

```

if (x = 2) then          if (x = 2) then
  y := 3;                y := 3;
elsif (x = 3) then      else
  y := 15;               if (x = 3) then
elsif (x = 5) then      y := 15;
  y :=18;               else
else                     if (x = 5) then
  y := 6;                y := 18;
end if;                 else
                        y := 6;
                        end if;
                        end if;
                        end if;
end if;

```

63.3.1.2 Case Statements

This conditional combines case-by-case expression examination with a restricted multiway conditional. This conditional may be seen to be simply a syntactic convenience, but in many cases its implementation results in a much faster determination at run time of the actual block of code to be executed. Consider the following case statement from Ada:

```

case y is
  when 2 => y := 3;
  when 3 => y := 15;
  when 15 => y := 18;
  when others => y := 6;
end case;

```

An expression (y in this case) of an ordinal type occurs after the keyword `case`. Each `when` clause contains a guard, which is a list of one or more constants of the same type as the expression. Most languages require that there be no overlap between these guards. The expression after the keyword `case` is evaluated, and the resulting value is compared to the guards. The block of statements connected with the first matched alternative is executed. If the value does not correspond to any of the guards, the statements in the `others` clause is executed. Note that the semantics of this example is identical to that of the previous example.

The case statement may be implemented in the same way as a multiway if statement, but in most languages it will be implemented via table lookup, resulting in a constant time determination of which block of code is to be executed.

C's `switch` statement differs from the case previously described in that if the programmer does not explicitly exit at the end of a particular clause of the `switch`, program execution will continue with the code in the next clause.

63.3.2 Iterative Structures

One of the most powerful features of an imperative language is the specification of *iteration* or statement repetition. *Iterative structures* can be classified as either definite or indefinite, depending on whether the number of iterations to be executed is known before the execution of the iterative command begins:

- *Indefinite iteration*: The different forms of indefinite iteration control structures differ by where the test for termination is placed and whether the success of the test indicates the continuation or termination of the loop. For instance, in Pascal the *while-do* control structure places the test before the beginning of the loop body (a pretest), and a successful test determines that the

execution of the loop shall continue (a continuation test). Pascal's *repeat-until* control structure, on the other hand, supports a posttest, which is a termination test. That is, the test is evaluated at the end of the loop and a success results in termination of the loop.

Some languages also provide control structures that allow termination anywhere in the loop. The following example is from Ada:

```
loop
  ...
  exit when test;
  ...
end loop
```

The `exit when test` statement is equivalent to `if test then exit.`

A few languages also provide a construct to allow the programmer to terminate the execution of the body of the loop and proceed to the next iteration (e.g., C's `continue` statement), whereas some provide a construct to allow the user to exit from many levels of nested loop statements (e.g., Ada's named `exit` statements).

- *Definite iteration*: The oldest form of iteration construct is the definite or fixed-count iteration form, whose origins date back to FORTRAN. This type of iteration is appropriate for situations where the number of iterations called for is known in advance. A variable, called the *iteration control variable* (ICV), is initialized with a value and then incremented or decremented by regular intervals for each iteration of the loop. A test is performed before each loop body execution to determine if the ICV has gone over a final, boundary value. Ada provides fixed-count iteration as a `for` loop; an example is shown next:

```
for i in 1..10 loop
  y := y + i;
  z := z * i;
end loop;
```

Here, `i` is initialized to 1, and incremented by 1 for each iteration of the loop, until it exceeds 10. Note that this type of loop is a pretest iterative structure and is essentially a syntactic sugar for an equivalent `while` loop.

An ambiguity that may arise with a `for` loop is what value the ICV has after termination of the loop. Most languages specify that the value is formally undetermined after termination of the loop, though in practice it usually contains either the upper limit of the ICV or the value assigned that first passes the boundary value. Ada eliminates this ambiguity by treating the introduction of the control variable as a variable declaration for a block containing only the `for` loop.

Some modern programming languages have introduced a more general form of `for` loop called an *iterator* construct. Iterators allow the programmer to control the scheme for providing the ICV with successive values. The following example is from CLU (Liskov et al. 1977). We first define the iterator:

```
string_chars = iter (s : string) yields (char);
index: Int := 1;
limit: Int := string$size (s);
while index <= limit do
  yield (string$fetch(s, index));
  index := index + 1;
end;
end string_chars;
```

which can be used in a `for` loop as follows:

```
for c: char in string_chars(s) do LoopBody end;
```

When the for loop controlled by an iterator is encountered, control is passed to the iterator, which runs until a `yield` statement is executed. The value associated with the `yield` statement is used as the initial value of the iterator control variable `c`, and the body of the loop is executed. Control is then passed back to the iterator, which resumes execution with the statement following the `yield`. Control is passed to the loop body each time a `yield` statement is executed and back to the iterator each time the loop body finishes execution. Thus, iterators behave as a restricted form of coroutine, passing control back and forth between the two blocks of code. The loop is terminated when the iterator runs to completion. In the preceding examples, this will occur when `index > limit`.

63.3.3 Unconstrained Control Structures: Goto and Exceptions

Unconstrained control structures, generally known as `goto` constructs, cause control to be passed to the statement labeled by the *identifier* or line number given in the `goto` statement. Dijkstra (1968) first questioned the use of `goto` statements in his famous letter, “Goto statement considered harmful,” to the editor of the *Communications of ACM*. The controversy over the `goto` mostly centers on readability of code and handling of the arbitrary transfer of control into and out of otherwise structured sections of program code.

For example, if a `goto` statement passes control into the middle of a loop block, how will the loop be initialized, especially if it is a fixed-count loop? Even worse, what happens when a `goto` statement causes control to enter or exit in the middle of a procedure or function? The problems with readability arise because a program with many `goto` statements can be very hard to understand if the dynamic (run time) flow of control of the program differs significantly from the static (textual) layout of the program. Programs with undisciplined use of `gotos` have earned the name of *spaghetti code* for their similarity in structure to a plate of spaghetti.

Although some argue for the continued importance of `goto` statements, most languages either greatly restrict their use (e.g., do not allow `gotos` into other blocks) or eliminate them altogether. In order to handle situations where `gotos` might be called for, other more restrictive language constructs have been introduced to make the resulting code more easily readable. These include the `continue` and `exit` statements (particularly labeled `exit` statements) referred to earlier.

Another construct that has been introduced in some languages in order to replace some uses of the `goto` statement is the *exception*. An exception is a condition or event that requires immediate action on the part of the program. An exception is *raised* or *signaled* implicitly by an event such as arithmetic overflow or an index out of range error, or it can be explicitly raised by the programmer.

The raising of an exception results in a search for an exception *handler*, a block of code defined to handle the exceptional condition and (hopefully) allow normal processing to resume. The search for an appropriate handler generally starts with the routine that is executing when the exception is raised. If no appropriate handler is found there, the search continues with the routine that called the one that contained the exception. The search continues through the chain of routine calls until an appropriate handler is found, or the end of call chain is passed without finding a handler.

If no handler is found, the program terminates, but if a handler is found, the code associated with the handler is executed. Different languages support different models for resuming execution of the program. The termination model of exception handling results in termination of the routine containing the handler, with execution resuming with the caller of that routine. The continuation model typically resumes execution at the point in the routine containing the handler that occurs immediately after the statement whose execution caused the exception.

The following is an example of the use of exceptions in Ada (which uses the termination model):

```
procedure pop(s: stack) is
begin
  if empty(s) then raise emptyStack
  else ...
end;
```

```

procedure balance (parens: string) return boolean is
  pStack: stack
begin
  ...
  if ... then pop(s) ...
exception
  when emptyStack => return false
end

```

Many variations on exceptions are found in existing languages. However, the main characteristics of exception mechanisms are the same. When an exception is raised, execution of a statement is abandoned and control is passed to the nearest handler. (Here “nearest” refers to the dynamic execution path of the program, not the static structure.) After the code associated with the handler is executed, normal execution of the program resumes.

The use of exceptions has been criticized by some as introducing the same problems as goto statements. However, it appears that disciplined use of exceptions for truly exceptional conditions (e.g., error handling) can result in much clearer code than other ways of handling these problems.

We complete our discussion of control structures by noting that, although many control structures exist, only very few are actually necessary. At one extreme, simple conditionals and a goto statement are sufficient to replace any control structure. On the other hand, it has been shown (Boehm and Jacopini 1966) that a two-way conditional and a while loop are sufficient to replace any control structure. This result has led some to point out that a language has no need for a goto statement; indeed, there are languages that do not have one.

63.3.4 Procedural Abstraction

Support for abstraction is very useful in programming languages, allowing the programmer to hide details and definitions of objects while focusing on functionality and ease of use. *Procedural abstraction* (Liskov and Guttag 1986) involves separating out the details of an execution unit into a procedure and referencing this abstraction in a program statement or expression. The result is a program that is easier to understand, write, and maintain.

The role of procedural abstraction is best understood by considering the relationships between the four levels of execution units described earlier: expressions, statements, blocks, and programs. A statement can contain several expressions; a block contains several statements; a program may contain several blocks. Following this model, a procedural abstraction replaces one execution unit with another one that is simpler. In practice, it typically replaces a block of statements with a single statement or expression.

The *definition* of a procedure binds the abstraction to a name and to an executable block of statements called the *body*. These bindings are compile-time, declarative bindings. In Ada, such a binding is made by specifying code such as the following:

```

procedure area (height, width: real; result: out real) is
begin
  result := height * width;
end;

```

The *invocation* of a procedure creates an activation of that procedure at run time. The *activation record* for a procedure contains data bound to a particular invocation of a procedure. It includes slots for parameters, local variables, other information necessary to access nonlocal variables, and data to enable the return of control to the caller. In languages supporting recursive procedures, more than one activation record can exist at the same time for a given procedure. In those languages, the lifetime of the activation record is the duration of the procedure activation.

Although scoping rules provide access to nonlocal variables, it is generally preferable to access nonlocal information via *parameter* passing. Parameter-passing mechanisms can be classified by the direction

in which the information flows: *in parameters*, where the caller passes data to the procedure, but the procedure does not pass data back; *out parameters*, where the procedure returns data values to the caller, but no data are passed in; and *in out parameters*, where data flow in both directions.

Formal parameters are specified in the declaration of a procedure. The *actual parameters* to be used in the procedure activation are specified in the procedural invocation. The procedure passing mechanism creates an association between corresponding formal and actual parameters. The precise information flow that occurs during procedure invocation depends on the parameter-passing mechanism.

The association or mapping of formal to actual parameters can be done in one of three ways. The most common method is *positional parameter association*, where the actual parameters in the invocation are matched, one by one in a left-to-right fashion, to the formal parameters in the procedural definition. *Named parameter association* also can be used, where a name accompanies each actual parameter and determines to which formal parameter it is associated. Using this method, any ordering can be used to specify parameter values. Finally, *default parameter association* can be used, where some actual parameter values are given and some are not. In this case, the unmatched formal parameters are simply given a default value, which is generally specified in the formal parameter declaration.

Note that in a procedural invocation, the actual parameter for an in parameter may be any expression of the appropriate type, since data do not flow back, but the actual parameter for either an out or an in out parameter must be a variable, because the data that are returned from a procedural invocation must have somewhere to go.

Parameter passing is usually implemented as being one of copy, reference, and name. There are two copy parameter-passing mechanisms. The first, labeled *call by value*, copies a value from the actual to the formal parameter before the execution of the procedure's code. This is appropriate for in parameters. A second mode, called *call by result*, copies a value from the formal parameter to the actual parameter after the termination of the procedure. This is appropriate for out parameters. It is also possible to combine these two mechanisms, obtaining *call by value result*, providing a mechanism that is appropriate for in out parameters.

The *call by reference* passes the address of the actual parameter in place of its value. In this way, the transfer of values occurs not by copying but by virtue of the formal parameter and the actual parameter referencing the same location in memory. Call by reference makes the sharing of values between the formal and actual a two-way, immediate transfer, because the formal parameter becomes an alias for the actual parameter.

Call by name was introduced in ALGOL 60 and is the most complex of the parameter-passing mechanisms described here. Although it has some theoretical advantages, it is both harder to implement and generally more difficult for programmers to understand. In call by name, the actual parameter is reevaluated every time the formal parameter is referenced. If any of the constituents of the actual parameter expression has changed in value since the last reference to the formal parameter, a different value may be returned at successive accesses of the formal parameter. This mechanism also allows information to flow back to the main program with an assignment to a formal parameter. Although call by name is no longer used in most imperative languages, a variant is used in functional languages that employ lazy evaluation.

Several issues crop up when we consider parameters and their use. The first is a problem called *aliasing*, where the same memory location is referenced with two or more names. Consider the following Ada code:

```
procedure MAIN is
  a: integer;
  procedure p(x, y: in out integer) is
    begin
      a := 2;
      x := y + a;
    end;
```

```

begin
  a := 10;
  p(a, a);
  ...
end;
```

During the call of $p(a, a)$, the actual parameter a is bound to both of the formal parameters x and y . Because x and y are in out parameters, the value for a will change after the procedure returns. It is not clear, however, which value a will have after the procedure call. If the parameter-passing mechanism is call by value result, then the semantics of this program depend on the order in which values are copied back to the caller. If they are copied into the parameters from left to right, the value of a will be 10 after the call. The results with call by reference will be unambiguous (though perhaps surprising to the programmer), with the value of a being 4 after the call. In Ada, a parameter specified to be passed as in out may be passed using either call by value result or call by reference. The preceding code provides an example where, because of aliasing, these parameter-passing mechanisms give different answers. Ada terms such programs to be erroneous and considers them not to be legal, even though the compiler may not be able to detect such programs.

Most imperative programming languages support the use of procedures as parameters (Ada is one of the few exceptions). In this case, the parameter declaration must include a specification of the number and types of parameters of the procedure parameter. MODULA-2, for example, supports procedure types that may be used to specify procedural parameters. There are few implementation problems in supporting procedure parameters, though the implementation must ensure that nonlocal variables are accessed properly in the procedure passed as a parameter.

There are two kinds of procedural abstractions. One kind, usually known simply as a *procedure*, is an abstraction of a program statement. Its invocation is like a statement, and control passes to the next statement after the invocation. The other type is called a *value returning procedure* or *function*. Functions are abstractions for an operand in an expression. They return a value when invoked, and, upon return, evaluation of the expression containing the call continues.

Many programming languages restrict the values that may be returned by functions. In most cases, this is simply a convenience for the compiler implementor. However, although common in functional languages, most imperative languages that support nested procedures or functions do not allow functions to return other functions or procedures. The reason has to do with the stack-based implementation of block-structured languages. If allowed, it might be possible to return a nested procedure or function that depends on a nonlocal variable that is no longer available when the procedure is actually invoked.

To avoid confusion, most languages allow a name to be bound to only one procedural abstraction within a particular scope. Some languages, however, permit the *overloading* of names. Overloading permits several procedures to have the same name as long as they can be distinguished in some manner. Distinguishing characteristics may include the number and types of parameters or the data type of the return value for a function. In some circumstances, overloading can increase program readability, whereas in others it can make it difficult to understand which operation is actually being invoked.

Program mechanisms to support concurrent execution of program units are discussed in Chapter 52. However, we mention briefly *coroutines* (Marlin 1980), which can be used to support pseudoparallel execution on a single processor. The normal behavior for procedural invocation is to create the procedural instance and its activation record (runtime environment) upon the call and to destroy the instance and the activation record when the procedure returns. With coroutines, procedural instances are first created and then invoked. Return from a coroutine to the calling unit only suspends its execution; it does not destroy the instance. A resume command from the caller results in the coroutine resuming execution at the statement after the last return.

Coroutines provide an environment much like that of parallel programming; each coroutine unit can be viewed as a process running on a single processor machine, with control passing between processes.

Despite their interesting nature (and clear advantages in writing operating systems), most programming languages do not support coroutines. MODULA-2 is an example of a language that supports coroutines. As mentioned earlier, iterators can be seen as a restricted case of coroutines.

63.3.5 Data Abstraction

Earlier in this chapter, we introduced the idea of data types as specifying a set of values and operations on them. Here we extend that notion of values and operations to ADTs and their definitional structures in imperative languages.

The primitive data types of a language are specified by both a set of values and a collection of operations that may be applied to them. Clearly, the set of integers would be useless without the simultaneous provision of operation on those integers. It is characteristic of primitive data types that the programmer is not allowed access to their representations.

Many modern programming languages provide a mechanism for a programmer to specify a new type that behaves as though it were a primitive type. An ADT is a collection of data objects and operations on those data objects whose representation is hidden in such a way that the new data objects may be manipulated only using the operations provided in the ADT. ADTs abstract away the implementation of a complex data structure in much the same way primitive data types abstract away the details of the underlying hardware implementation.

The *specification* of an ADT presents interface details relevant to the users of the ADT, whereas the *implementation* contains the remaining implementation details that should not be exported to users of the ADT. *Encapsulation* involves the bundling together of all definitions in the specification of the ADT in one place. Because the specification does not depend on any implementation details, the implementation of the ADT may be included in the same program unit with the specification or it may be contained in a separately compiled unit. This encapsulation of the ADT typically supports information hiding so that the user of the ADT (1) need not know the hidden information in order to use the ADT and (2) is forbidden from using the hidden information so that the implementation can be changed without impact on correctness to users of the ADT (at least if the specifications of the operations are still satisfied in the new implementation). Of course, one would expect a change in implementation to affect the efficiency of programs using the ADT. A further advantage of information hiding is that, by forbidding direct access to the implementation, it is also possible to protect the integrity of the data structure.

CLU was among the earliest languages providing explicit language support for ADTs through its clusters. Ada also provides facilities to support ADTs via packages. Let us consider an example from MODULA-2, a successor language to Pascal designed by Niklaus Wirth. The stack ADT provides a stack type as well as operations *init*, *push*, *pop*, *top*, and *empty*. A MODULA-2 specification for a stack of integers resembles the following:

```
DEFINITION MODULE StackADT;
  TYPE stack;
  PROCEDURE init (VAR s: stack);
  PROCEDURE push (VAR s: stack; elt: INTEGER);
  PROCEDURE pop (VAR s: stack);
  PROCEDURE top (s: stack): INTEGER;
  PROCEDURE empty (s: stack): BOOLEAN;
END StackADT.
```

Note the declaration includes the type name and procedural *headers* only. The type *stack* included in the preceding specification is called an *opaque* type in MODULA-2, because users cannot determine the actual implementation of the type from the specification. This ADT specification uses information

hiding to get rid of irrelevant detail. Now, this specification can be placed in a separate file and made available to programmers. By including the following declaration:

```
FROM StackADT IMPORT stack, init, push, pop, top, empty;
```

at the beginning of a module, a programmer could use each of these names as though the complete specification was included in the module. Thus, the user can write

```
var s1, s2: Stack;
begin
  push(s1, 15);
  push(s2, 20);
  if not empty(s1) then pop(s1) ...
```

in such a module.

In MODULA-2, the complete definitions of the type `stack` and its associated operations are provided in an implementation module, which typically is stored in a separate file:

```
IMPLEMENTATION MODULE StackADT;
TYPE stack = POINTER TO stackRecord;
   stackRecord = RECORD
       top: 0..100;
       values: ARRAY[1..100] of INTEGER;
   END;
PROCEDURE init(VAR s: stack);
  BEGIN
    ALLOCATE(s, SIZE(stackRecord));
    S^.top := 0
  END
PROCEDURE push (VAR s: stack; elt: INTEGER);
  BEGIN
    S^.top := S^.top + 1;
    S^.value[S^.top] := elt
  END;
PROCEDURE pop(VAR s: stack); ...
PROCEDURE top(s: stack): INTEGER; ...
PROCEDURE empty(s: stack) BOOLEAN; ...
END StackADT.
```

Notice that the type name `stackRecord` is not exported.

The specification module must be compiled before any module that imports the ADT and before its implementation module, but importing modules and the implementation module of the ADT can be compiled in any order. As previously suggested, the implementation is irrelevant to writing and compiling a program using the ADT, though, of course, the implementation must be compiled and present when the final program is linked and loaded in preparation for execution.

There is one important implementation issue that arises with the use of language mechanisms supporting ADTs. When compiling a module that includes variables of an opaque type imported from an ADT (e.g., `stack`), the compiler must determine how much space to reserve for these variables. Either the language must provide a linguistic mechanism to provide the importing module with enough information to compute the size required for values of each type or there must be a default size that is appropriate for every type defined in an ADT. CLU and MODULA-2 use the latter strategy. Types declared as CLU clusters are represented implicitly as pointers, whereas in MODULA-2 opaque types must be represented explicitly using pointer types as in the `Stack` ADT example just given. In either case, the compiler needs

reserve for a variable of these types only an amount of space sufficient to hold a pointer. The memory needed to hold the actual data pointed to is allocated from the heap at run time. As discussed later, Ada uses a language mechanism to provide size information for each type to importing units.

The definition of ADTs can be *parameterized* in several languages, including CLU, Ada, and C++. Consider the definition of the `stack` ADT. Although the preceding example was specifically given for an integer data type, the implementations of the data type and its operations do not depend essentially on the fact that the stack holds integers. It would be more desirable to provide a parameterized definition of `stack` ADT that can be instantiated to create a stack of any type *T*.

Allocating space for these parameterized data types raises the same problems as previously discussed for regular ADTs. C++ and Ada resolve these difficulties by requiring parameterized ADTs to be instantiated at compile time, whereas CLU again resolves the difficulty by implementing types as implicit references.

63.4 Best Practices

In this section, we will examine three quite different imperative languages to evaluate how the features of imperative languages have been implemented in each. The example languages are FORTRAN (FORTRAN IV for illustrative purposes), Ada 83, and C++. We chose FORTRAN to give a historical perspective on early imperative languages. Ada 83 is chosen as one of the most important modern imperative languages that support ADTs. C++ might be considered a controversial choice for the third example language, as it is a hybrid language that supports both ADT-style and object-oriented features. Nevertheless, the more modern feature contained in the C++ language design makes it a better choice than its predecessor, C (though many of the points that will be made about C++ also apply to C). In this discussion, we ignore most of the object-oriented features of C++, as they are covered in more detail in Chapter 64.

63.4.1 Data Bindings: Variables, Types, Scope, and Lifetime

Like most imperative languages, all three of our languages use static binding and static scope rules. FORTRAN is unique, however, because it supports the *implicit declaration* of variables. An identifier whose name begins with any of the letters *I* through *L* is implicitly declared to be of type integer, whereas any other identifier is implicitly declared to be of type real. These implicit declarations can be overridden by explicit declaration. Therefore, in the fragment

```
INTEGER A
I = 0
A = I
B = C + 2.3
```

A and *I* are integer variables, while *B* and *C* are of type real. Most other statically typed languages (including Ada and C++) require *explicit declaration* of each identifier before use. Aside from providing better documentation, these declarations lessen the danger of errors due to misspellings of variable names.

FORTRAN has a relatively rich collection of numerical types, including integer, *double precision* (real), and *complex*. *Logical* (Boolean) is another built-in type, but FORTRAN IV provided no direct support for characters. However, characters could be stored in integer variables. (The *character* data type was added by FORTRAN 77.) FORTRAN IV supported arrays of up to three dimensions but did not support records. Strings were represented as arrays of integers. FORTRAN IV did not provide any facilities to define new named types.

Later languages provided much richer facilities for defining data types. Pascal, C, MODULA-2, Ada, and C++ all provided a full range of primitive types as well as constructors for arrays, records (structures in C and C++), variant records (unions in C and C++), and pointers (access types in Ada). All provided facilities for naming new types and for constructing types hierarchically (constructing nested types).

Variant records or unions opened up holes in the static type systems of most of these languages, but Ada (and CLU before it) provided restrictions on the access to variants and built-in run time checks in order to prevent type insecurities.

The scope rules for each language, though static in nature, differ significantly. In FORTRAN, the rules are the simplest. The unit of scope for an identifier is either the main program or the procedural unit in which it is declared. Declarations of procedures (subroutines) and functions are straightforward as well in FORTRAN, with no nesting and all parameters passed by reference. Whereas FORTRAN does not support access to nonlocal variables through scoping rules, it allows the programmer to explicitly declare that certain variables are to be more globally available. When two subprograms need to share certain variables, they are listed in a *common* statement that is included in each subprogram. If different combinations of subprograms need to share different collections of variables, several distinct common blocks can be set up, with each subprogram specifying which blocks it wishes access to.

Ada (like Pascal) supports *nested declarations* of procedures and functions. As a result, block structure becomes extremely important to scope determination.

Whereas C and C++ do not provide for nested procedures and functions, they do share with Ada the ability to include declaration statements in local blocks of code. In C++, blocks are syntactically enclosed in bracket {...} symbols, and any declarations that occur between the symbols hold for the duration of the block. Consider the following code:

```
for (i = 0; i<20; i++) {
    int i = 1, j;
    j = 0;
    while (i < 25) {
        j += i*2;
        i ++;
    }
}
```

One might think that when the inner loop is done, the outer loop also will be done, because *i* has the value 26. But since the inner block of statements redeclared *i*, the scope rules state that the new, inner *i* was manipulated, leaving the outer *i* untouched and free to correctly manipulate the for loop.

In FORTRAN IV, the lifetime of all variables is the lifetime of the program. As a result, all memory in a program could be statically allocated, including activation records. Because each subprogram has only one activation record, FORTRAN could not support recursion.

Pascal, Ada, C, and C++ all support recursive functions and procedures. In order to support these, implementations generally rely on stack-allocated activation records. Thus, the lifetime of a local variable in a procedure *p* extends from the call of *p* to the return to its caller. Each of these languages also supports pointer or access types, generally representing data accessed from the heap (though C and C++ also allow pointers to stack-allocated memory). The lifetime of these variables is generally from the time that the programmer executes a creation instruction until a corresponding destruction statement is executed.

63.4.2 Execution Units

FORTRAN and Ada make a strong distinction between expressions and statements, with expressions simply returning a value, but with statements forming the basic unit for program execution. In C and C++, however, these two units of execution are merged, with statements treated as expressions. The statement `x = 5` assigns the value 5 to the variable *x*. But, in C++, the = sign is also an operator, and this assignment statement is actually an expression that returns the value being assigned. Thus, the statement `y = x = 5` assigns the value 5 to *both* *x* and *y*, because the value 5 is assigned to *x* and the expression

$x = 5$ returns 5, which is assigned to y . Although interesting, it can also be very confusing. Because many expressions will have side effects; the order of evaluation will affect the value returned from an expression. Consider the code

```
if ((y = ++x) == (x + 6)) { ... }
```

This code actually has two statements embedded in it; first, $++x$ increments x , then this value is assigned to y , then the value assigned is tested against the value of $x + 6$. If the compiler decides to change the order in which the subexpressions are evaluated (a not unheard of occurrence in C++ compilers), it may change whether the guard on the if statement is true or false.

Allowing statements to be part of expressions also means that typographical errors are more likely to give rise to syntactically correct (but logically incorrect) statements. For instance, if one of the = signs in

```
if (x == 6) { ... }
```

is omitted, then it will assign of value 6 to x and the conditional will always evaluate to true as all non-0 integers in C and C++ are treated as representing true.

63.4.3 Control Structures

Because FORTRAN was one of the earliest high-level languages, it is not surprising that its control structures are much closer to the underlying machine language instructions. Aside from the do loop (which was similar to the for loop in Pascal and Ada), most other control structures were based on the use of goto statements. Thus, the if statement of FORTRAN IV evaluated an integer expression and, depending on whether the result was negative, zero, or positive, resulted in a jump to one of three statement labels included with the statement. Aside from the usual goto statement, FORTRAN IV also included assigned and computed gotos, which provided some of the flexibility of case statements. FORTRAN 77 and the more recent FORTRAN 90 provide more modern control structures such as the if and while statements of other languages.

The control constructs in Ada are similar to those of Pascal, including if, case, while, and for loops, as well as indefinite loops, which are terminated with exit statements. Several of these were described earlier in the general discussion of control structures.

C and C++ include if statements and a switch construct that is similar to the case statement. The while loop is similar to that in Pascal and Ada, but for loops in C and C++ are more general than those in most other languages. For loops have the form

```
for (E1; E2; E3) S;
```

where E_1 is initialization code, E_2 is a test for termination, E_3 contains code to update variables for the next iteration of the loop, and S represents the code to be executed each time through the loop. The test for termination is executed before the update code. Thus, a statement of the form

```
for (i = 1; i < 10, i++) S;
```

will result in S being executed once for each value of i from 1 to 10. (The expression $i++$ is an expression that increments the value of i .) However, much more flexible statements are also possible:

```
for (i = 1; not done and i < 1024; i = 2 * i) S;
```

This statement repeatedly executes S while i ranges through the powers of 2 from 1 to 1024. If done is ever true, it will terminate early.

63.4.4 Procedural Abstraction

Each of Ada, FORTRAN, C, and C++ provides procedural abstraction. Ada and FORTRAN distinguish between functions and procedures, whereas C and C++ do not since procedures are just functions that return an element of type void. FORTRAN IV also supported single-line statement functions, which could be defined local to a program or subprogram. As noted earlier, Ada, C, and C++ all support recursive functions and procedures, whereas FORTRAN does not.

The languages differ in minor ways in how they return values from functions. FORTRAN, like Pascal, treats the name of the function as a pseudovisible that can be assigned to. An explicit return statement returns control to the calling program unit. When the function returns, the last value stored in the function name is returned as the value of the function. Ada, C, and C++ use return statements of the form `return exp` to return control to the calling program unit. The value of the expression associated with the return statement is the value returned from the function.

Most programming languages provide system-defined overloaded functions, such as arithmetic operators (+, -, *, etc.) and comparison functions (e.g., =, <). Ada and C++ are relatively unusual, though, in allowing user-defined overloading. In both, the compiler must be able to disambiguate at compile time whichever of the versions of the overloaded operator are called for at each of its occurrences.

C++ determines which version is called for by looking at the number and types of the actual parameters.

Ada goes further and can also use the return type to determine which version works in the particular context in which it is found. Thus, in Ada one may overload the + operator to take two integer parameters and return a user-defined rational type, even though there already exists a built-in version of + that takes two integer parameters and returns an integer. If + occurs in a context in which only an integer result would make sense, the built-in version would be selected. If + occurs in a context in which only a rational value would make sense, the user-defined version would be selected. If the system cannot tell which should be used, then an error will occur at compile time.

Unlike FORTRAN, Pascal, and C, both Ada and C++ provide language support for exceptions. Ada and C++ both use the termination model for program resumption after handling the exception.

63.4.5 Data Abstraction and Separate Compilation

FORTRAN provides support for separate compilation of subroutines and functions but provides no type checking across compilation unit boundaries. Thus, the main program may call a function *F* with two real parameters, but the definition of *F* in a separately compiled unit may have only one formal parameter, and it might be an integer. Because FORTRAN does not support the definition of new named types, it provides no support for ADTs.

C and C++ provide slightly better support for separate compilation by allowing the programmer to put external function and procedure declarations in a header file, which may be included into compilation units that use them. The header files are treated as though they were textually part of the compilation unit into which they are included. C provides no support for ADTs, though C++ does provide strong support through its class facilities. C++ classes give the programmer control over which aspects of a data type the user will be allowed to see and use. Because C++ is described in some depth in Chapter 64, we omit a detailed description here.

Standard Pascal provides no support for separate compilation, though virtually all Pascal implementations provide support for separately compiled units. These units typically include both interface and implementation sections. The interface of a unit may be explicitly imported into another compilation unit with a *uses* statement. This provides for separate, but not independent, compilation without requiring the programmer to create individual header files by hand. These units generally do not provide support for information hiding.

Ada provides both separate compilation and strong support for ADTs. Like MODULA-2's modules described earlier, Ada packages come in two separately compiled units, the specification and body. Only items listed in the nonprivate part of the package specification are accessible at compile time to units that import the package. The following is an Ada package specification for stacks:

```
package StackADT is
  type stack is private;
  procedure push(s: in out stack; elt: in integer);
  procedure pop(s: in out stack);
  procedure top(s: in stack) return integer;
  procedure empty(s: in stack) return boolean;
private
  type stack is record
    top: integer := 0;
    values: array (1..100) of integer
  end record
end StackADT;
```

The private section of a package specification is necessary to provide a description of private types. This is necessary so that importing programs know how much space to provide for a variable of that type. This is not as clean as the MODULA-2 solution, since any change of representation of the type will require the recompilation of the specification and hence of any program that imports the package. For this particular representation of stack, no initialization routine is necessary because top is initialized to 0 in the declaration of the type.

If the implementation of the private variable is a pointer, then only partial type information need be provided. That is, if we replace the private part of the preceding example by

```
private
  type stackRecord;
  type stack is access StackRecord;
end StackADT;
```

then this would provide sufficient information for importing programs to determine the memory needs for a variable of this type (i.e., the amount of space necessary to hold a pointer).

An implementation of the original package specification is given next:

```
package body StackADT is
  procedure push (s: in out stack; elt: in integer) is
  begin
    s.top := s.top + 1;
    s.value[s.top] := elt
  end push;
  procedure pop(s: in out stack); ...
  function top(s: in stack): integer; ...
  function empty(s: in stack) boolean; ...
end StackADT;
```

The StackADT package specification can be imported into an Ada program unit by including with StackADT at the beginning of the unit. Components can be referred to as record components, for example, StackADT.stack and StackADT.push. The package name prefix can be omitted if use StackADT is also included at the beginning of the unit.

Both Ada and C++ provide mechanisms for supporting parameterized packages (or classes in the case of C++). The C++ template mechanism is quite primitive, with template instantiations being treated as being similar to compile-time macroexpansions. The template is never type checked, only its instantiations.

Ada also requires its generic packages to be instantiated at compile time, but the generics are type checked before, rather than after, instantiation. Thus, a generic package can be compiled and later used in another until that does not have access to the implementation.

The following is an example of the header of a generic `BinarySearchTree` package:

```
generic
  type Element is private;
  with function LessThan (x, y: Element) return boolean;
package BinarySearchTree is type BSTree is private;
...
end BinarySearchTree;
```

This can be used in another unit by instantiating it with a type and appropriate function, for example,

```
package PeopleDict is new BinarySearchTree(People, PeopleComp)
```

where `PeopleComp` is a function taking pairs of type `People` and returning a Boolean. `PeopleDict` can then be used like any other package. The ability to require generic package instantiations to include necessary functions and values as well as types ensures that they will not be instantiated with types which do not support the appropriate operations.

63.5 Research Issues and Summary

Research issues in imperative languages in recent years have tended to focus on many of the new constructs presented in this chapter. These include support for exceptions, iterators, ADTs, and parameterized or generic types. It is fair to say that most current research in programming languages is devoted to implementation and environment issues or to other programming paradigms. There are not many new concepts currently being introduced into imperative programming languages. Many languages that formerly were purely imperative have recently been extended to include object-oriented concepts (e.g., Object Pascal, Objective C, C++, Ada 95). Another series of extensions has provided features for concurrent and distributed programming.

From our earlier discussion, it is clear that support for abstraction plays an important role in imperative language design and use. Variables abstract away details of memory usage; data types (and in particular ADTs) abstract from the representation of values to provide support for operations that are independent from the actual implementation; execution units abstract away details of machine instruction execution and expression computation while providing clean interfaces for sharing information between caller and callee.

A second major focus in the development of modern imperative programming languages has been the enrichment of type systems, especially static type systems. ADTs can be understood as the enrichment of type systems with the so-called existential types, in which the existence of a type is revealed by instantiation with any type (or in Ada and CLU's case any type that comes supplied with the appropriate operations). These more flexible type systems allow for the construction of safe statically typed programming languages that are more expressive than their predecessors. There is hope that we are moving forward to a time when most programmers will see such secure languages as assisting them in their goal of creating correct and efficient software, rather than getting in the way. (See Chapter 69 for a further discussion of type systems.)

We have surveyed the class of programming languages modeled after the sequential organization of the von Neumann architecture. The imperative programming language paradigm is characterized by its sequential, stepwise statement execution.

As discussed in Section 63.4, the imperative programming constructs are implemented in a variety of ways in different languages. There are many languages to choose from; choosing the right language for the applications at hand is an important first step to software implementation.

It could be argued that the object-oriented paradigm is simply a minor variation on the imperative paradigm in which remote procedure and function calls replace the more familiar imperative calls. However, the object-oriented paradigm requires an entirely different way of thinking about the organization of a program, with the traditional conception of a program as a series of operations being applied to values replaced in the object-oriented view by an organization of more distributed responsibility. In this view, values (typically referred to as objects) are responsible for knowing how to perform their own operations, and the programmer is responsible for bringing together a group of objects with appropriate capabilities and organizing a program that relies on these distributed capabilities to accomplish a task. Subtyping and inheritance provide important organizing tools and promote code reuse in ways unavailable in traditional imperative languages.

Most programmers today are initially taught to program in imperative languages. Thus, these languages reflect the way that most programmers currently think about algorithm construction and program execution. Whether this will continue in the face of the challenge of the object-oriented paradigm will be interesting to see.

Key Terms

Abstract data type: A collection of data type and value definitions and operations on those definitions that behave as a primitive data type. The specifications of these types, values, and operations are generally collected in one place, with the implementations hidden from the user.

Binding: A connection between an abstraction used in the language and a data object as it exists in the computer hardware. The usage, establishment, and number of these bindings characterize the various imperative languages and affect their ease of use and performance.

Control structures: Structures or statements that alter the strict sequential ordering in an imperative program, presenting alternatives to sequential control. Control structures can be conditional, iterative, or unconstrained.

Derived type: A new data type constructed by copying a type that already exists. The resulting new type is distinct and not identified as being copied from the existing type, though operations on the old type are automatically inherited in the new type.

Identifier: The name bound to an abstraction.

Parameters: Data objects passed between the caller and the called procedural abstraction.

Procedural abstraction: Separating out the details of an execution unit in such a way that it may be invoked in a program statement or expression.

Scope rules: Rules in a language that define the area or section of a program in which a particular binding is effective.

Subtype: A new data type defined as a copy of another defined type, typically with a restricted subset of its values. It may generally be used in the same contexts as its parent type.

Type: A collection of values with an associated collection of primitive operations on those values.

Type equivalence: Rules that govern when variables or values from two different data types may be used together.

Variable: An abstraction used in imperative languages for a memory location or cell.

Further Information

A good examination of imperative languages, as well as other paradigms, can be found in the following texts:

64.1 Introduction

While invented in the 1960s, it was during the 1990s that *object-oriented programming* (OOP) established itself as the dominant programming paradigm. Although it was first viewed as a revolutionary new programming paradigm, such a characterization is only partly accurate.

OOP is, to be sure, a paradigm in the current sense of that term. It embodies a way of organizing and representing knowledge, “a way of viewing the world” (Budd 2002), that encompasses a wide range of programming activities, including program analysis, design, and implementation. The paradigm derives its power from its view of computation as the simulation of real-world entities. That is, according to Dan Ingalls, “Instead of a bit grinding processor ... plundering data structures, we have a universe of well-behaved objects that courteously ask each other to carry out their various desires” (Ingalls 1981).

Central to this view of computation is the notion of self-contained little systems that work together. OOP tools and languages facilitate the description of *objects* as self-contained systems that maintain their own internal state (data), perform actions (*methods*) in their own interest, and interact with other objects (by sending *messages* to one another). Objects can be low-level programming tools, such as lists, stacks, and trees, akin to traditional abstract data types (ADTs). They can also be higher-level abstractions that reflect what a program is intended to model: an automated teller machine, a deck of playing cards, an elevator, or a collection of graphical objects on a screen.

The primary power of OOP derives from the fact that, once defined, objects enjoy a type-like status (as we will explain later, objects are defined via *classes*, which are very much like types). That is,

- An object can be used without knowing the details of its implementation
- An object’s implementation detail is hidden and therefore protected
- Objects can be used according to a standard notation, using names, symbols, and operators in conventional ways
- Objects can be combined with other objects and types in expressive and efficient ways (composition and hierarchy) to define new, more complex types

Whereas structured programming languages such as C and PASCAL allowed a programmer to define new types, these were primarily a notational convenience. In such languages, user-defined type names served as shorthand to improve readability and as aids to compilers for recognizing type equivalences. These types, though, did not enjoy the status or flexibility of the built-in types. That is, one could not overload operators to apply to these new types and, more importantly, one could not easily hide the implementation details of a new type.

The seeds for the object-oriented paradigm can be found in the languages that developed in the 1970s and 1980s to provide more direct support for building user-defined ADTs. ADA-83, for example, allows one to build clearly specified, modular software components that effectively hide their implementation details. ADA-83 uses the package construct to describe type specifications and subprograms that can belong to a user-defined ADT. Languages that provide this level of support for ADTs are now called object-based.

In many ways, the evolution of the OOP paradigm extends that of the structured paradigm, which preceded it. We saw the structured paradigm, as manifested in a succession of increasingly high-level programming languages, progress from straight-line code laced with unconditional transfers of control, to block-oriented code that exploited control structures, to finer-grained code built from simple subprograms, to top-down, structured code that relied on parameterized, and separately developed libraries of code which distinguished a subprogram's interface from its implementation. The object-based paradigm followed to enable the capture of ADTs. Finally, OOP combines procedural and data abstraction into the notion of a class that can be part of a class hierarchy.

Hindsight being what it is, we can now see how the seeds of OOP have been nurtured by developments in many subfields of computer science (CS) over the past three decades: the basic idea of computation as simulation was first popularized in the programming language SIMULA 67, which also introduced the concepts of class, object, and message. Hardware architectures were developed in the 1970s using an object-based approach to describe the components of the machine and their interactions at a higher, more natural level. This development was further motivated by operating systems and applications that depended increasingly on graphical interfaces, which lend themselves directly to object-oriented descriptions. In the entity-relationship database model, in which a collection of information is described in terms of entities, attributes, and relations among entities, we see yet another manifestation of objects (at least the information content aspect of them). Even in knowledge representation schemes that supported work in artificial intelligence (frames, scripts, and semantic networks), we can clearly see this object orientation. Most clearly, the first purely object-oriented language, Smalltalk, has been around since the early 1970s.

Still, all of the premonitions of OOP did not coalesce into a recognizable influence on programming language and practice until they were motivated to do so by our collective practical experience in software engineering. As we became increasingly adept at exploiting the procedural paradigm and its languages, we recognized more directly their shortcomings. The more we pushed that paradigm, the more difficult it was to support data abstraction to that same degree that algorithm abstraction could be supported. Furthermore, methods of encapsulation were relatively primitive, thus making it difficult to develop safe, reusable code. Finally, software analysis and design techniques that relied on procedural abstraction as the basis for performing decomposition of complex systems were proving increasingly awkward to apply to domains that were increasingly dependent on data, as opposed to algorithms.

In summary, structured methods flourished in the era of application domains that were either algorithm-centric or information-centric. These same methods prove less useful in an increasingly complex application world, where functionality and information structure must be considered in context. The concept of an object is a simple and elegant combination of all informational and algorithmic aspects of an application entity.

Today, all of these technologies have matured and all of the motivations have been established to the extent that OOP is a viable, recognizable, and popular approach to software development. Programming languages and commercial development environments abound. Smalltalk, as an example of a pure OOP

language, is still commercially available; however, Java and C# have become the poster children for pure OOP languages. C++ is also commonly referred to as an object-oriented programming language, while strictly it is a hybrid, that is, it extended an existing language with essential OOP features. Other notable OOP languages are Eiffel, and the hybrids Objective-C and Visual Basic.

Because OOP is rightly referred to as a paradigm, it has spawned the development of many software analysis and design techniques that support the identification and description of objects in a problem specification. As with all paradigms, OOP languages and techniques are best suited for problems that match the paradigm's view of the world. The use and popularity of OOP rises with the increased demand for complex, interface-intensive systems, ones that can be modeled in real-world terms.

Finally, if OOP raises the level of abstraction to bridge the gap between programmer and machine, it may be that novice programmers would stand to benefit the most from its use. Indeed, Smalltalk was developed based on research detailing how young children describe and interact with the world in solving problems. OOP is now influencing significantly how we teach and learn programming. There is a growing recognition that object orientation makes learning to program easier for the novice. Many universities are teaching object orientation as part of the CS introduction. Java is widely used throughout the CS curriculum.

However, it is also recognized that there is a pool of experienced programmers and software engineers that must be retrained significantly: not because object orientation is hard, but because of their experience in traditional, function-centered (or information-centered) problem solving. These programmers must, as Bertrand Meyer puts it, reacquire an object-oriented frame of mind (Meyer 2000).

Proponents of OOP claim that the paradigm represents the state of the art in terms of bridging the language gap between programmer and machine. It offers the prospect for achieving many of the software quality goals to which all programmers aspire: easily designed, safe, efficient, and uniform software.

64.2 Underlying Principles

OOP takes a quite natural, but also quite different, view of programming. In a process-state view of computing (which reflects both the machine's fetch-execute cycle and its data processing nature), one thinks about programs as lists of instructions executed sequentially, and serving to manipulate and change the state of memory is the fundamental strategy of imperative languages. In contrast, OOP sees a software system as set of collaborating objects. Old-style programming involves thinking in terms of algorithms and data structures separately. OOP languages, on the other hand, permit the programmer to take a broader view and think of a program as a collection of cooperating objects, each of which encapsulates both structure and function.

Each object has three aspects: what it is, what it does, and what it is called. We illustrate these aspects by considering a geometric object, a circle. Most programming languages do not have circles as built-in data type, so if we want to write a program that manipulates circles, we must write our own description of circle objects in a program. The descriptive information associated with an object, called its state, includes its properties and the values of these properties. For most objects, the state properties do not change, although the state values may very well be modified during the object's lifetime. For instance, a circle has a radius and a center, and at a given time, these might have the values 4.67 and (0, 0). A circle object will always have a radius and a center, although their values will change if the circle's size or location changes.

The collection of actions an object may perform on itself is called its behavior. In our example, we may want to use a circle as part of a program that draws on a computer screen, and so we would need to be able to set the center and radius of the object and instruct the circle to draw itself on the screen. Notice that we said a circle would draw itself on the screen. This is an important feature of the object-oriented approach. In a language with an algorithmic approach, one could describe circles by radius and center, as we have, but the description of the methods to perform on a circle would not be as tightly associated with the state data as it is here. That is, the drawing method would not be part of the circle object itself.

Encapsulating data and methods together in an object helps us design and understand a program because, for instance, all circle-related data and methods are collected in one place. If we had to modify a circle object's definition, we would know exactly where the modifications would go. Furthermore, we would know that we would not have to modify any other part of the program.

Finally, each object has an identity, which serves to distinguish it from all others. One can refer to an object uniquely via its identity. In most programming languages, we identify an object by giving it a name, so we might call our circle *theCircle*—*theCircle* is our reference to the object.

It is entirely reasonable to assume that a program that would use one circle object might use several. All of these circle objects would be similar, in that they would have the similar collection of data and methods. It would clearly be a wasteful duplication of effort to describe each separately, since they would differ only in their data values and names. Object-oriented languages allow one to describe a stencil, if you will, for an entire set of objects. Such a stencil is called a *class*.

A class is used to generate a set of objects that share common properties. Continuing our example, we could describe a class, *circles*, by describing the state properties (but generally not the state values) and behaviors of all objects that belong to that class. Then, we could describe as many circle objects as we needed merely by declaring that they are *instances* of the *circles* class, that is, they are circle objects. An object can never exist in isolation; every object must be an instance of some class. This means that if we are going to use an object in a program, we must first provide the class to which the object belongs.

One can think of a class as a means for implementing an ADT. That is, to describe a class, we identify the properties that any instance of the class (a particular object) must have. These properties consist of state information (referred to as data fields) and a collection of behaviors (referred to as methods) that such objects are capable of performing. Methods typically involve accessing, setting, or otherwise manipulating the object's data fields.

Methods are invoked by an object in response to a message (i.e., a request of the object to perform one of its methods). Message passing as a means for invoking methods differs subtly from subprogram invocation in most other programming paradigms. In OOP, there is a formal distinction between the subprogram call (the sending of a message) and the invocation of the subprogram (when the message is received). It is the responsibility of the receiver of a message to interpret the message, that is, to determine which of its methods to perform in response. Think of OOP as programming by sending messages to objects.

Taken together, these two mechanisms support the description of full-fledged ADTs in a more general and extensible way than was provided by the first object-based languages. In particular, classes provide an abstraction mechanism that can be used to model a wide range of information structures and information processing agents. Using classes as the primary descriptive vehicle also characterizes an OOP approach to program design that has proved extremely effective for many real-world applications.

Not only are classes a rich descriptive tool they are also safe, in the software engineering sense of that term. That is, classes effectively encapsulate the abstractions they model by controlling (either implicitly or explicitly, depending on the language being used) access to an object's data fields and methods. Some of an object's data fields and methods will be public in nature (visible and accessible to other objects), and some will be private to the object itself (visible and accessible only to other methods). Many OOP languages also support a formal distinction between a class's interface and its implementation.

Classes are also an efficient means of representation by virtue of the fact that they can be related to one another both compositionally (an object of one class can serve as a member field of an object of another class) and hierarchically (to express is-a relationships). This latter feature is unique to OOP, and it affords a means for describing directly any information that is hierarchical in nature.

In cases where classes are arranged in a hierarchy, a *subclass* is said to *inherit* from its *superclass*. That is, instances of the subclass contain (either directly as copies or indirectly via the superclass) both the data fields and methods described by the superclass. These same general properties are associated with all subclasses of the particular superclass. Each subclass extends the descriptions of its superclass by adding specialized data fields and methods that differentiate it from the superclass and from other subclasses.

Going back to our geometric example, we do not have to limit our objects to just circles; we could equally well have objects that are rectangles, triangles, and so on. We could augment our program by including declarations and definitions for the classes rectangles and triangles, just as we did when we defined the circles class. In doing so, we notice that all of these are what we might call geometric objects.

Object-oriented languages allow a class like rectangles to inherit the data fields and methods from a parent class, such as GeometricObjects. For example, because every object in our hierarchy has an extent (a bounding rectangle inside which the object fits as closely as possible), we could declare the method ReportBounds and some appropriate data fields within a superclass named GeometricObjects. These would apply to all the subclasses rectangles, triangles, and circles. Doing this, we would not need to re-declare the method and data fields in any of these subclasses. They would be inherited from the superclass GeometricObjects. Indeed, it is sometimes useful to define a superclass, such as GeometricObjects, knowing full well that we will never be interested in generating direct instances of it. That is, the only instances of GeometricObjects that we will use in our programming are those that are also instances of its subclasses: circles, triangles, or rectangles. In such a case, the superclass is referred to as *abstract class*.

Inheritance is not only distinctive of OOP languages it is also the means by which the paradigm addresses many software engineering concerns. For example, inheritance is an efficient, non-redundant notation for representing information that is hierarchical in nature. It is natural in the sense that it reflects how we humans tend to describe such information (which explains in part why OOP has spawned so many related program design techniques). The efficiency of the notation derives from the ability to reuse code that was used in defining a superclass when defining a subclass. This, in turn, allows the inherited data fields and methods of classes that are derived from one another to project consistent interfaces to their consumers. That is, data and methods can be referred to by the same names in both the super- and subclasses.

There are times, though, when a superclass method or state might not be appropriate for use by a subclass. All of the classes in our hierarchy would have draw methods, but drawing a rectangle might involve different strategies than drawing a circle. OOP languages allow a derived class to redefine, or *override*, a method inherited from a base class. If, for example, we have an object called *theShape* and send it a message to draw itself, how is the computer to know which draw method to use? Whereas procedural languages and object-based ones would resolve this ambiguity statically (i.e., based on the declared type of *theShape*), an OOP language solves this problem at run time, by looking up the class to which *theShape* belongs and finding an appropriate draw method.

This ability to use the same name for methods on objects of different classes is an example of a kind of *polymorphism* (called inclusion polymorphism) that is common to all OOP languages. In the OOP sense of the term, polymorphism describes the fact that a superclass includes all instances of its subclasses. Thus, the notion of a geometric object contains all circle, rectangle, and triangle objects. As a result, a generic entity can take on different types of information during the execution of a program. For example, a geometric object can be a circle, a rectangle, or a triangle at any point during our program.

The concept of interface is related to the polymorphic use of the class concept. An interface is a listing of methods where, for each method, one only lists its name and any potential parameters. OO languages allow classes to implement an interface, that is, the classes provide explicit bodies for all methods listed in the interface.

Other forms of polymorphism often supported in OO languages include the following:

- Overloading: two or more functions or operators can share the same name, so the + operator is allowed to apply to both integers and real numbers.
- Parametric polymorphism: a parameter is used to establish choices: for example, C++ class templates use parameters to allow another level of abstraction.
- Coercion polymorphism: C type casting is an example.

The following characteristics are the essence of OOP:

- Objects—As a means for encapsulation of state and behavior
- Classes—As stencil for generating objects
- Message passing—As the mechanism by which computation takes place
- Dynamic method invocation—As the means by which methods are bound and interpreted
- Inheritance—As a technique for modifying classes and creating subclasses
- Inclusion polymorphism—As a means for allowing expressions of one type to be used in place of expressions of a supertype

Each contributes significantly to the overall utility of the paradigm, and each allows the paradigm to address one of the many software engineering concerns that motivated it. Whereas different programming languages implement them in various combinations and to varying degrees, any language that implements them all is considered object oriented.

64.3 Impact on Practice

To illustrate these characteristics of OOP, let us construct a very simple application to deal with queues of packets as they might appear in a network simulation. Packets in our program maintain their names and priorities and allow their observation and comparison. Different kinds of packets are modeled as subclasses: one for packets that carry protocol information (Ack) and one for packets that carry data (data). The subclasses specialize how packets are observed. The second set of classes models the queue concept. Class `FifoQueue` represents the algorithmic and data abstraction of a standard first-in-first-out queue. Internally, it employs a doubly linked list—anchored by a head and tail data field—to maintain the packets currently queued. The methods `enter` and `remove` implement the standard protocol of such a queue. The `FifoQueue` class ignores the packet's priority information but also serves as a superclass for two additional subclasses, `PriQueue` and `QueuePri`, which use the packet's comparison abilities to handle packets of different degrees of importance.

We will develop the example in terms of Java, C++, C#, and Objective-C. The four major OOP languages are in use today. Our intention here is to provide quick overviews of these languages and to illustrate the different notations and styles for implementing the object-oriented paradigm.

64.3.1 Java

Java is perhaps the most compelling entry into the landscape of OOP languages. Java was developed in the mid-1990s by James Gosling at Sun Microsystems (which is now part of Oracle Corporation) (Gosling et al. 2005). The language was positioned to empower developers to write software independently of specific platforms: “Write once, run anywhere” was a slogan to illustrate the cross-platform benefits of the Java language. Today, Java is one of the most popular programming languages, especially for client-server web applications.

From an object-oriented perspective, Java can be seen as a distillation of many of the good features from Smalltalk and C++. From C++, it inherits its style of syntax, but with great simplifications. From Smalltalk, it inherits its execution model: all objects carry a unique identifier, and all methods are dynamically bound. It is compiled into byte codes that are interpreted within the target environment, and all class information is available at run time, which provides additional type-checking capability and robustness. Java also provides automatic garbage collection, which simplifies a programmer's task significantly and tends to reduce many errors related to memory management. And of course, Java comes with a large class library that contains support for graphical user interfaces (GUIs), networking, web application development, and much more.

Let us develop a Java program for our network/packet/queue example. We start by describing the class *packet*:

```
public class Packet {
    int priority;
    String name;
    public Packet(String n, int p) {
        name = n;
        priority = p;
    }
    public void list() {
        System.out.print(name + " packet: ");
    }
    public boolean more(Packet other) {
        return priority > other.priority;
    }
    public boolean less(Packet other) {
        return priority <= other.priority;
    }
}
```

The basic syntactic style is borrowed from the C programming language. The keyword *class* precedes the name *packet* of the class that is defined here. The keyword *public* denotes that this class is visible beyond the scope of the package in which it is defined. The *packet* class defines two data fields and four methods. Java data fields are explicitly typed: *priority* is of atomic type *int* for *integer*, *name* is of class *String*. The first method is special, it has the same name as the class: *Packet*. It is called a *constructor* and serves to initialize a new instance of the class when it is created. The constructor parameters (*n* and *p*) are used to give initial values to the data fields *priority* and *name*. The method *list* prints the name of the packet followed by some text. The boolean methods *more* and *less* implement the comparison capability of packet objects. All four methods use the keyword *public* to denote that they are accessible or visible outside of the packet class. Data fields *priority* and *name* do not have an access specifier, that is, they are only visible within the current package.

Java insists on a closed-class hierarchy: all classes must have a superclass. If a superclass is not specified as in the *packet* class declaration, then it defaults to class *object*. In effect, all Java objects can be thought of as instances of that class. This superclass enables broad run-time support, such as automatic garbage collection.

Class *Ack* is defined as a subclass to *packet*. The *extends* clause defines the inheritance relationship among classes. Java allows a class to have a single superclass only.

```
public class Ack extends Packet {
    public Ack() {
        super("Ack",10);
    }
    public void list() {
        System.out.println(" acknowledged");
    }
}
```

It defines two methods: the constructor and *list*. The constructor uses the keyword *super* to invoke the constructor of the superclass. The *list* method redefines the *list* method that would normally be inherited from the *packet* class.

Class *data* is just slightly more complicated: it also extends class *packet*. It defines a data field *body* of class *string*. The two methods are the constructor and a redefined version of *list*.

```
public class Data extends Packet {
    private String body;

    public Data(String b, int p) {
        super("Data", p);
        body = new String(b);
    }

    public void list() {
        super.list();
        System.out.println(body);
    }
}
```

The keyword *super* refers to the method of the same name in the superclass. Method *list* first invokes the superclass version of *list* and then adds the string stored as *body*.

The *packet* class hierarchy is now complete. Before we construct our queue class, we need one more helper class: *node*, which will be used to implement a doubly linked list. The *node* class defines three data fields: *value* to hold a packet object, *next* to refer to the next node in the list, and *previous* to refer to the previous node in the doubly linked list. The *node* constructor sets *value* packet and initializes the *next* and previous links.

```
class Node {
    Packet value;
    Node next, previous;
    Node(Packet p) {
        value = p;
        next = previous = null;
    }
}
```

Notable here are the types associated with fields *next* and *previous*. Both are defined as being of type *node*. This does not mean that a *node* object will contain other *node* objects. They will, however, contain the object identifiers of other *node* objects. Thinking of object identifiers as pointers to objects yields the conventional linked list metaphor. Moreover, a true OOP language does not need pointers at all. Since all objects carry their unique identity, it can be used instead. That is why Java need not support pointers.

Now, we can construct the class *FifoQueue* to implement our first-in-first-out queue abstraction. Class *FifoQueue* defines two data fields: *head*, to refer to the beginning of the list of nodes, and *tail*, to hold on to the end of the list. Fields *head* and *tail* are specified as *protected*, which extends their visibility to all subclasses. Protected data fields or methods are accessible in subclasses, whereas private ones are not. The class also defines a constructor and three public methods: *enter*, *remove*, and *list*. The constructor simply initializes the *head* and *tail* to *null* to create an empty queue.

```
public class FifoQueue {
    protected Node head, tail;
    public FifoQueue() {
        head = tail = null;
    }

    public void enter(Packet it) {
        Node tmp = new Node(it);
        tmp.previous = tail;
```

```

        tail = tmp;
        if (head != null)
            tmp.previous.next = tail;
        else
            head = tmp;
    }

    public Packet remove() {
        Packet it = head.value;
        if (head == tail)
            head = tail = null;
        else if (head.next != null) {
            head = head.next;
            head.previous = null;
        }
        return it;
    }

    public void list() {
        for (Node tmp = head; tmp != null; tmp = tmp.next)
            tmp.value.list();
    }
}

```

Method *enter* first creates a new *node* object *tmp* to hold the parameter packet object *it*. Object *tmp* is then added to the end of the existing linked list. If the list is empty, that is, *head* is *null*, then it will become the only object in the list. Method *remove* first captures the packet that is to be removed and stored as *value* of the *head* node. It then removes the first node from the linked list and reconnects the links. Method *list* walks through all nodes in the list and sends message *list* to the packet stored in the node's value.

The next class doubles as the main program. Java does not allow the definition of stand-alone functions. The class has a single static method called *main*, which creates a few objects and starts execution. The purpose of our main program is to exercise and test our queue class. The main function defines five objects: two data packets, two Ack packets, and one *FifoQueue*. Objects are entered into the queue in this order: *d1*, *a1*, *d2*, and *a2*.

```

class Main {
    public static void main(String args[]) {
        Data d1 = new Data("first packet", 5);
        Ack a1 = new Ack(), a2 = new Ack();
        Data d2 = new Data("second packet", 6);

        FifoQueue q = new FifoQueue();

        q.enter(d1);
        q.enter(a1);
        q.enter(d2);
        q.enter(a2);

        System.out.println("The FIFO queue:");
        q.list();

        System.out.println("Order of leaving:");
        q.remove().list();
        q.remove().list();
        q.remove().list();
        q.remove().list();
    }
}

```

Once all four packet objects are entered, sending message *list* to object *q* will produce this output:

```
The FIFO queue:
Data packet: first packet
    acknowledged
Data packet: second packet
    acknowledged
```

which is followed by:

```
Order of leaving:
Data packet: first packet
    acknowledged
Data packet: second packet
    acknowledged
```

Not surprisingly, the packet objects are stored by the queue object in the order in which they were entered, and then they are released in exactly the same order. Since our queue class was meant to implement a first-in-first-out sequence, we notice that our programming effort was successful.

To continue our example, we can now extend our queue abstraction by taking the importance (i.e., priority) of packets into account. Class *PriQueue* is defined as a subclass of *FifoQueue*. It inherits all data fields and methods, but specializes the *enter* method:

```
public class PriQueue extends FifoQueue {
    public void enter(Packet it) {
        Node tmp = new Node(it);

        if (tail == null) {
            tail = tmp;
            head = tmp;
        } else {
            Node p = tail;
            for (; p != null; p = p.previous)
                if (it.less(p.value))
                    break;
            if (p == null) {
                tmp.next = head;
                head.previous = tmp;
                head = tmp;
            } else {
                tmp.previous = p;
                tmp.next = p.next;
                if (p == tail)
                    tail = tmp;
                else
                    p.next.previous = tmp;
                p.next = tmp;
            }
        }
    }
}
```

The implementation of *enter* for priority queues is significantly more complex. It traverses the existing linked list for each packet that is to be entered to determine its relative importance. The *enter* method uses the *less* method defined for packet objects.

While the *PriQueue* class specializes the *enter* instance method of class *FifoQueue*, another way of providing a queue with priority handling would be to specialize the *remove* method rather than *enter*. Class *QueuePri*, described next, does that:

```
public class QueuePri extends FifoQueue {
    public Packet remove() {
        Node it = head;
        if (head == tail)
            head = tail = null;
        else {
            // find the highest priority
            for (Node p = head; p != null; p = p.next)
                if (p.value.more(it.value))
                    it = p;
            if (it == tail) {
                tail = it.previous;
                tail.next = null;
            } else if (it == head) {
                head = it.next;
                it.next.previous = null;
            } else {
                it.previous.next = it.next;
                it.next.previous = it.previous;
            }
        }
        return it.value;
    }
}
```

The strategy for implementing a priority queue is straight forward. Whenever a packet is to be removed from the queue, we traverse the linked list and determine which of the packets has the highest priority. The good news is that *FifoQueue*, *PriQueue*, and *QueuePri* objects can now be used interchangeably, depending on what kind of queuing strategy is desired. All three classes provide the same protocol; that is, their objects understand the same set of messages.

In summary, Java is a complete and truly OOP language. It also supports a very open and flexible style of encapsulation via the access specifiers *public*, *protected*, and *private* and an unspecified default: *package*. All data fields and methods are of access right *package* unless explicitly stated otherwise. All classes in Java belong to packages, and all package-defined fields and methods are accessible from within any class within the package. Java also uses packages to organize its source and compiled code. Java also provides garbage collection as a means to reclaim obsolete objects. Java does not have a delete operator: objects cannot be deleted explicitly.

Java does not support multiple inheritance, where a class can have more than one superclass. Java supports the notion of interface, a specification of the public methods that an object can respond to. The interface does not include any data fields or method bodies. Multiple inheritance is supported for interfaces. Classes can be declared to implement interfaces. Interfaces allow the programmer to establish declared relationships between modules, which in turn can change their underlying implementation as the class changes.

64.3.2 C++

Our next OOP language is C++ developed at Bell Laboratories. C++ is an evolutionary enhancement to the C language to support OOP features. It is most accurately described as a hybrid language

(i.e., one that extends a traditional procedural language and remains compatible with that language, to include a variety of OOP features). Basically, this is C with classes, inheritance, and polymorphism. As Bjarne Stroustrup, the designer of the language, likes to point out, C++ is not an OOP language, but a language with which one can write an object-oriented program (Stroustrup 1994).

In C++, a class specification is separated into two files: a header file that contains a class declaration (listing the class name, fields, and method signatures) and a body file that contains all method bodies. C++ uses the C preprocessor to unite the two files upon compilation. It also enables that client code need only to include the header file to be able to use a class.

As our first example, we list the header for class *packet*. The keyword *public* indicates that the methods, now called member functions in C++ terminology are publicly visible. The data fields (or, as referred to in C++, member fields) are private by default. That is, they are not visible outside of this class.

```
class Packet {
    const char *name;
    int priority;
public:
    Packet(const char *n, int p) :
        name(n), priority(p) {
    }
    virtual void list();
    int operator>(Packet &);
    int operator<=(Packet &);
};
```

The class header declares the member fields and member functions, along with their accessibility. *Priority* is defined as an integer number (*int*); *name* is a string (*const char **). The comparisons are defined as operator functions—the ampersand (&) denotes call by reference. The header shows one other important member function: it has the same name as the class and is referred to as the constructor. The constructor serves to initialize a new instance of the class when it is created. Here, a new packet needs a name and a priority. The keyword *virtual* in the declaration of member function *list* enables dynamic binding in C++. It is needed to allow inclusion polymorphism to work. Without it, C++ will use static binding, as in conventional programming languages.

The class body elaborates the bodies of the member functions:

```
int Packet::operator>(Packet &other) {
    return priority > other.priority;
}

int Packet::operator<=(Packet &other) {
    return priority <= other.priority;
}

void Packet::list() {
    cout << name << " packet: ";
}
```

where *cout* is the predefined output object in C++. It receives message << and prints out its parameters. Subclass *Ack* is very simple:

```
class Ack: public Packet {
public:
    Ack() :
        Packet("Ack", 10) {
    }
}
```

```

    void list() {
        cout << " acknowledged\n";
    }
};

```

Its constructor uses a special syntax to invoke the constructor of its superclass *packet*. This class header also shows that a member function can (if it is short enough) be fully defined right away.

Similarly, for class *data*:

```

class Data: public Packet {
    const char *body;
public:
    Data(const char *b, int p) :
        Packet("Data", p), body(b) {
    }
    void list() {
        Packet::list();
        cout << body << endl;
    }
};

```

The constructor for class *data* is defined with two parameters: one to initialize the *body* field and one for the *priority* field. The member function *list* refers to *packet::list()*, which is the *list* function defined in the *packet* class. Java uses the simpler approach of using the keyword *super* to refer to a method defined in a superclass. The word *endl* ensures that the output ends with a new line.

The next class, *FifoQueue*, first needs the definition of class *node*:

```

class Node {
    Packet & value;
    Node *next, *previous;
    Node(Packet &p) :
        value(p) {
        next = previous = NULL;
    }
    friend class FifoQueue;
};

```

The member fields of class *node* default to private. Since class *FifoQueue* needs to be able to access these fields, we include a *friend* clause to extend their visibility to class *FifoQueue*.

Here now is class *FifoQueue*

```

class FifoQueue {
protected:
    Node *head, *tail;
public:
    FifoQueue() :
        head(NULL), tail(NULL) {
    }
    ;
    virtual void enter(Packet &);
    virtual Packet& remove();
    void list();
};

```

The member fields *head* and *tail* are specified as *protected*. C++ allows explicit control whether subclasses have access to inherited members. Protected members are accessible in subclasses, whereas private members are not. The body of class *FifoQueue* details the member functions *enter*, *remove*, and *list*:

```
void FifoQueue::enter(Packet &it) {
    Node *tmp = new Node(it);
    tmp->previous = tail;
    tail = tmp;
    if (head)
        tmp->previous->next = tail;
    else
        head = tmp;
}
Packet& FifoQueue::remove() {
    Packet &it = head->value;
    if (head == tail)
        head = tail = NULL;
    else if (head->next) {
        head = head->next;
        head->previous = NULL;
    }
    return it;
}
void FifoQueue::list() {
    for (Node* tmp = head; tmp; tmp = tmp->next)
        tmp->value.list();
}
```

We can now exercise our objects. This program produces the same output as our previous example written in Java:

```
int main() {
    Data d1("first packet", 5);
    Ack a1, a2;
    Data d2("second packet", 6);

    FifoQueue *q = new FifoQueue();

    q->enter(d1);
    q->enter(a1);
    q->enter(d2);
    q->enter(a2);

    cout << "The FIFO queue:\n";
    q->list();

    cout << "Order of leaving:\n";
    q->remove().list();
    q->remove().list();
    q->remove().list();
    q->remove().list();
}
```

Again, we can use *FifoQueue* as the base class for subclass *PriQueue* to refine the *enter* member function:

```
class PriQueue: public FifoQueue {
public:
    void enter(Packet &) {
```

```

        // logic as before
    }
};

```

In addition, of course, a similar class *QueuePri* is also possible, as follows:

```

class QueuePri: public FifoQueue {
public:
    Packet& remove(){
        // logic as before
    }
};

```

In summary, C++ provides detailed support for specifying the degree of access to its members. C++ goes beyond what we have illustrated so far—it allows one to specify the type of inheritance that is used: public, protected, or private. All our examples use public inheritance, which propagates the accessibility of members to the subclass. Protected and private inheritance allows one to hide the fact that a class is based on a superclass. C++ supports both single and multiple inheritance. It requires that dynamic binding (i.e., the object-oriented behavior of an object to search for a suitable method for a message at run-time) be explicitly requested per member function. C++ uses the keyword *virtual* to request dynamic binding; otherwise, it defaults to static binding. C++ leaves memory management to the programmer, as garbage collection is not supported.

64.3.3 C#

C# (pronounced C sharp) is the latest significant entry into the landscape of OOP languages. C# was developed by Anders Hejlsberg of Microsoft as part of its .NET initiative (Hejlsberg et al. 2010). From an object-oriented perspective, C# can be seen as a distillation of many of the good features of Java and C++, plus influences from ObjectPascal.

Like Java, C# is compiled into byte codes from a common language run-time specification. All class information is available at run time, which provides additional type-checking capability and robustness. C# also provides automatic garbage collection, which simplifies a programmer's task significantly and tends to reduce many errors related to memory management. In addition, of course, C# comes with a large class library, called common language infrastructure, which contains support for common data structures, GUIs, database access, networking, and much more.

Consider this C# version of our *packet* class:

```

public class Packet {
    private int priority;
    private String name;
    public Packet(String n, int p) {
        name = n;
        priority = p;
    }
    virtual public void list() {
        Console.Write(name + " packet: ");
    }
    public bool more(Packet other) {
        return priority > other.priority;
    }
    public bool less(Packet other) {
        return priority < other.priority;
    }
}

```

The resemblance to Java is clear. The basic syntax, including declarations and control structures, use the C++ style. All object handling is done by reference. Access specifiers (like `private`, `protected`, or `public`) are listed per field or method. As in C++, dynamic binding must be requested using the `virtual` keyword. C# comes with a significant set of predefined classes to allow input and output. The example lists the `console` class, which defines the `write` method. C# insists on a closed-class hierarchy: all classes must have a superclass. If a superclass is not specified in the class declaration, then it defaults to class `object`.

A C# subclass specification resembles C++ more closely than Java. In the following example, class `Ack` is defined as a subclass of `packet`. The colon is used to designate the superclass. The constructor uses the `base` reference to denote the invocation of the superclass constructor. The `list` method is explicit about redefining the superclass's virtual `list` method by using the keyword `override`. If the superclass did not have a `list` method, the compiler would flag an error.

```
public class Ack : Packet {
    public Ack() : base("Ack", 10) { }
    override public void list() {
        Console.WriteLine(" acknowledged");
    }
}
```

Class `data` is just slightly more complicated. It inherits from class `packet` and redefines the `list` method. The keyword `base` is used to refer to methods defined in the superclass.

```
public class Data : Packet {
    private String body;
    public Data(String b, int p): base("Data", p) {
        body = String.Copy(b);
    }
    override public void list() {
        base.list();
        Console.WriteLine(body);
    }
}
```

Again, before we can define the `FifoQueue` class, we need the `node` class. Class `node` is defined here as a simple class with a data field of class `packet`. This limits our queues to contain only `packet` objects. The fields `next` and `previous` embody out doubly-linked list implementation. Like Java, C# does not need pointers.

```
public class Node {
    public Packet value;
    public Node next, previous;
    public Node(Packet p){
        value = p;
        next = previous = null;
    }
}
```

Class `FifoQueue` makes use of these classes to implement our first-in-first-out queue abstraction. The code closely resembles Java. The keyword `virtual` ensures that subclasses can override the methods, and that dynamic binding is used.

```
public class FifoQueue {
    protected Node head, tail;

    public FifoQueue() {
```

```

        head = tail = null;
    }
    public virtual void enter(Packet it) {
        Node tmp = new Node(it);
        tmp.previous = tail;
        tail = tmp;
        if (head != null)
            tmp.previous.next = tail;
        else
            head = tmp;
    }
    public virtual Packet remove() {
        Packet it = head.value;
        if (head == tail)
            head = tail = null;
        else if (head.next != null) {
            head = head.next;
            head.previous = null;
        }
        return it;
    }
    public void list() {
        for (Node tmp = head; tmp != null; tmp = tmp.next)
            tmp.value.list();
    }
}

```

As in the Java version of the example, our main program is a class with a static method *main*, where we assemble a few objects and send messages to test our *packet* and *FifoQueue* classes:

```

class Main {
    public static void Main(String[] args) {
        Data d1 = new Data("first packet", 5);
        Ack a1 = new Ack(), a2 = new Ack();
        Data d2 = new Data("second packet", 6);

        FifoQueue q = new FifoQueue();
        q.enter(d1);
        q.enter(a1);
        q.enter(d2);
        q.enter(a2);

        Console.WriteLine("The FIFO queue:");
        q.list();

        Console.WriteLine("Order of leaving:");
        q.remove().list();
        q.remove().list();
        q.remove().list();
        q.remove().list();
    }
}

```

This program produces the same output as in our Java discussion. Classes *PriQueue* and *QueuePri* can be defined as follows. Both classes inherit from *FifoQueue*, one redefining method *enter* and the other *remove*. Because the superclass did define both methods as virtual, C# needs the keyword *override* here. Dynamic binding is enabled for the *enter* and *remove* methods, that is, given a variable of type *FifoQueue*

that holds a reference to a *PriQueue*, it would respond to an incoming message *enter* with the correctly redefined, that is via *override*, method defined in the *PriQueue* class.

```
public class PriQueue : FifoQueue {
    override public void enter(Packet it) {
        // logic as before
    }
}
public class QueuePri : FifoQueue {
    override public Packet remove() {
        // logic as before
    }
}
```

In summary, C# is a complete and truly OOP language. C# also provides garbage collection as a means to reclaim obsolete objects. C# also supports the notion of interface, a specification of the public methods that an object can respond to. The interface does not include any data fields or method bodies. Multiple inheritance is supported for interfaces. Classes can be declared to implement interfaces. Interfaces allow the programmer to establish declared relationships between modules, which in turn can change their underlying implementation as the class changes.

C# supports some additional novel features: it allows programs to treat values of atomic types, such as *int* or *char*, as objects with a process called boxing. Boxing automatically converts an atomic value that is being stored in the execution stack to wrapper objects that are allocated on the heap and referenced from the stack. The reverse process, unboxing, is also done automatically. The advantage of this boxing feature is that values of atomic types can be passed by reference as parameters to methods.

64.3.4 Objective-C

Objective-C is another interesting entry into the landscape of OOP languages. It was developed in the early 1980s by Brad Cox and Tom Love. Like C++, it extends the C language with OOP concepts. However, its style is heavily influenced by Smalltalk. Cox relates the concept of class to that of an integrated circuit (IC), where “Software ICs”, that is off-the-shelf classes, could dramatically increase software productivity (Cox et al. 1991).

While Objective-C is an old OOP language, it has only recently come out of obscurity by virtue of being the main programming language in the Apple OS X and iOS operating systems. The Apple Cocoa framework and class library is written in Objective-C.

An Objective-C class is written in two separate parts: a class interface and a class implementation. The interface lists the class name, its superclass, data fields, and method headers. Our *packet* class interface looks like this:

```
@interface Packet : NSObject {
    int priority;
    char *name;
}
+ (Packet *) new: (char *) n pri: (int) p;
- (BOOL) more: (Packet *) other;
- (BOOL) less: (Packet *) other;
- (void) list;
@end
```

Class *packet* is defined as a subclass of *NSObject*. *NSObject* is the typical root of the Objective-C class hierarchy. Most built-in classes feature the “NS” prefix, which is short for NextStep, which is the ancestor

of the OS X operating system and framework. The methods are automatically “public.” The “+” denotes a class-level method, that is, it is invoked for the class, much like a constructor, whereas “-” methods are regular methods invoked for an instance of a class. Now, consider the *packet* class implementation:

```
@implementation Packet
+ (Packet *) new: (char *) n pri: (int) p {
    Packet *id = [super new];
    id->name = n;
    id->priority = p;
    return id;
}
- (BOOL) more: (Packet *) other {
    return priority > other->priority;
}
- (BOOL) less: (Packet *) other {
    return priority <= other->priority;
}
- (void) list{
    printf("%s packet: ", name);
}
@end
```

It contains the bodies of the methods. Note, how parameters are not enclosed in parenthesis, but rather labeled, such as *new:* and *pri:*. That is Smalltalk style. The phrase *[super new]* is also borrowed from Smalltalk: code enclosed in brackets denotes a message-sending expression. Here, message *new* is sent to object *super*. *super* refers to the superclass of *packet*, here *NSObject*, which implements the basic *new* method to create a new object. The other methods are prefixed with a “-”, indicating regular instance methods. Note, in method *print*, good old C standard library function *printf* is used for output. On to subclass *Ack*:

```
@interface Ack : Packet
+ (Ack *) new;
- (void) list;
@end

@implementation Ack
+ (Ack *) new {
    return [ super new: "Ack" pri: 10 ];
}
- (void) list {
    printf(" acknowledged\n");
}
@end
```

The *new* method creates a new instance by sending a message to the *new:pri:* method of the superclass, that is, *packet*. Similarly, for class *data*

```
@interface Data : Packet {
    char * body;
}
+ (Data *) new: (char *) b pri: (int) p;
- (void) list;
@end

@implementation Data
+ new: (char *) b pri: (int) p {
```

```

    Data * id = [ super new: "Data" pri: p ];
    id->body = b;
    return id;
}
- (void) list {
    [ super list ];
    printf("%s\n", body);
}
@end

```

Both the *new:pri:* method and the *list* method take advantage of methods inherited from the *packet* superclass.

The next class, *FifoQueue*, first needs the definition of class *Node*:

```

@interface Node : NSObject {
    @public
    Packet * value;
    Node * next, * previous;
}
@end

```

By default, the data fields of class *node* would not be accessible from the outside of the class. Since class *FifoQueue* needs to be able to access these fields, we include a “@public” clause to make them accessible.

Here now is class *FifoQueue*, first the class interface

```

@interface FifoQueue : NSObject {
    Node * head, *tail;
}
- (void) enter: (Packet *) aPacket;
- (Packet *) remove;
- (void) list;
@end

```

followed by the class implementation

```

@implementation FifoQueue
- (void) enter: (Packet *) aPacket {
    Node * tmp = [ Node new ];
    tmp->value = aPacket;
    tmp->previous = tail;
    tail = tmp;
    if (head)
        tmp->previous->next = tail;
    else
        head = tmp;
}
- (Packet *) remove {
    Packet * it = head->value;
    if (head == tail)
        head = tail = NULL;
    else if (head->next) {
        head = head->next;
        head->previous = NULL;
    }
    return it;
}

```

```

}
- (void) list {
    for (Node *tmp = head; tmp; tmp = tmp->next)
        [ tmp->value list ];
}
@end

```

Most of the method implementations feature straight C-style code, with the occasional message-send expression enclosed in brackets.

We can now exercise our objects. This program produces the same output as our previous examples written in Java, C++, and C#:

```

int main (int argc, const char * argv[]) {

    Data *d1 = [ Data new: "first packet" pri: 5 ];
    Ack *a1 = [ Ack new ];
    Data *d2 = [ Data new: "second packet" pri: 6 ];
    Ack *a2 = [ Ack new ];

    FifoQueue *q = [ FifoQueue new ];

    [ q enter: d1 ];
    [ q enter: a1 ];
    [ q enter: d2 ];
    [ q enter: a2 ];

    printf("The FIFO queue:\n");
    [ q list ];

    printf("Order of leaving:\n");
    [[ q remove ] list ];
    [[ q remove ] list ];
    [[ q remove ] list ];
    [[ q remove ] list ];
}

```

In summary, Objective-C has a unique style, which traces its Smalltalk heritage. Objective-C supports garbage collection; however, it is at the discretion of the programmer. Instead of garbage collection, a programmer can also opt for explicit reference counting to determine when an object becomes obsolete. Like the other OOP languages, Objective-C can draw upon a large library of classes, which make it easy to add animation, networking, and the native platform appearance and behavior to applications with only a few lines of code.

64.4 Language Implementation Issues

In evolutionary terms, OOP languages can be described as either pure or hybrid. The hybrid approach adds object-oriented features on top of a procedural core: C++ and Objective-C are representatives of this approach. The pure approach, Java and C#, limits the language features to those that are strictly object oriented. C# presents a compromise in that it enforces its object-oriented principles but allows unsafe code, as long as it is clearly labeled.

In theoretical terms, the primary distinction between these kinds of languages lies in their interpretation of the concept of type. Because of their origins, hybrid languages rely on a traditional approach to typing. That is, the type of something resides with its container. Thus, when we declare an integer variable *i* in C++, for example, as *int i*, variable *i* is of basic type *integer*. In Smalltalk, variables do not carry the type of what they contain. That is, variables are untyped: they can contain any object. Rather, the command *Integer new* returns an integer object. The type in this case is seen to reside with the object, and if we store a reference to it in a variable, the variable could be said to be of type *Integer*. Objective-C

retains this Smalltalk approach: it features a type *id*, which can refer to any object. In code, any message can be sent to a variable of type *id*. Only at run time, when the message is actually received by the object, might we notice an error, if the object's class does not implement the corresponding method.

In implementation terms, representing values of basic types as objects carries penalties in storage amount and performance: if an integer value is stored as an object, it will occupy about double the amount of storage, let us say four bytes for its value and four bytes for the object reference. To access the value as an object, we first must dereference the object reference, then retrieve the value from the object. Java stores all values of basic types as simple values and does not treat them as objects. The programmer must explicitly create a wrapper object to treat the value as an object. C# does this implicitly through its boxing and unboxing mechanisms.

Another critical distinction between OOP languages is in how they handle the binding of messages to methods. The purest approach is to perform this binding dynamically (at run time): an object receives a message, and the search for an appropriate method begins at the class of the object. The search continues through superclasses until the message can be processed. Although this approach affords the programmer tremendous flexibility, it can cause instability at run time. A more efficient approach is to leave the binding choice to the system (i.e., the compiler and linker). That is, the system tries to determine at compile time which method should be invoked for each message sent. In cases where inclusion polymorphism is used (and it may be unclear which class to refer to), binding can be performed at run time using techniques varying from simple case statements to a more complex system of virtual method tables. In any case, it is still up to the compiler to detect and indicate the need for run-time binding.

Another important issue to consider in the context of language implementation is the approach one adopts in regards to memory management. OO languages are relatively uniform in their approaches to memory allocation (object creation). Creating objects and all that that entails (determining how much memory to allocate, the types of data fields, etc.) is performed by the system. Initialization, on the other hand, is left to the programmer. Many languages provide direct support for initializing objects: we have constructors in C++, Java, and C#, and *new* methods in Objective-C. There are two common approaches to deleting objects from memory (deallocation). In the programmer-controlled approach, one uses a delete operator. The system-enabled approach to deleting objects uses the concept of garbage collection. All objects that are unknown to other objects are garbage. To check whether an object is referred to by another is quite compute-intensive. To lighten the impact on system performance, garbage collection is typically done either during times of idling or when some threshold of memory usage is reached. On the other hand, memory leaks, that is, memory that is occupied by deleted objects, can occur easily in large bodies of code written without garbage collection.

64.5 Summary

OOP languages have matured dramatically and have gained a significant degree of acceptance over their 40 years of history. Many of the original motivations for the OOP paradigm have been justified by our practical experience with it. OOP has been seen to

- Embody useful analysis and design techniques
- Revise the traditional software life cycle toward analysis and design, instead of coding, testing, and debugging
- Encourage software reuse through the development of useful code libraries of related classes
- Improve the workability of a system so that it is easier to debug, modify, and extend
- Appeal to human instincts in problem solving and description—in particular, to problems that model real-world phenomena

That OOP has become the predominant software development paradigm is evidenced by the multitude of conferences, journals, texts, and websites devoted to both general and language-specific topics. The two most prominent conferences, both of which address a wide range of OOP issues, are the conference on

OOP Systems, Languages, and Applications (www.oopsla.org) and the European Conference on OOP (www.ecoop.org). The *Journal of Object Technology* provides contemporary coverage of OOP languages, applications, and research (www.jot.fm). Perhaps, the most general of the references listed are Budd (2002) and Meyer (2000).

Key Terms

Abstract class: A class that has no direct instances but is used as a base class from which subclasses are derived. These subclasses will add to its structure and behavior, typically by providing implementations for the methods described in the abstract class.

Class: A description of the data and behavior common to a collection of objects. Objects are instances of classes.

Constructor: An operation associated with a class that creates and/or initializes new instances of the class.

Dynamic binding: Binding performed at run time. In OOP, this typically refers to the resolution of a particular name within the scope of a class, so that the method to be invoked in response to a message can be determined by the class to which it belongs at run time.

Inheritance: A relationship among classes, wherein one class shares the structure or behavior defined in an is-a hierarchy. Subclasses are said to inherit both the data and methods from one or more generalized superclasses. The subclass typically specializes its superclasses by adding to its structure and by redefining its behavior.

Instance: A specific example that conforms to a description of a class. An instance of a class is an object.

Interface: A named listing of method headers to be implemented by a class.

Member field: A data item that is associated with (and is local to) each instance of a class.

Message: A means for invoking a subprogram or behavior associated with an object.

Method: A procedure or function that is defined as part of a class and is invoked in a message-passing style. Every instance of a class exhibits the behavior described by the methods of the class.

Object: An object is an instance of a class described by its state, behavior, and identity.

Object-oriented programming (OOP): A method of implementation in which a program is described as a sequence of messages to cooperating collections of objects, each of which represents an instance of some class. Classes can be related through inheritance, and objects can exhibit polymorphic behavior.

Override: The action that occurs when a method in a subclass with the same name as a method in a superclass takes precedence over the method in the superclass.

Polymorphism (or many shapes): That feature of a variable that can take on values of several different types or a feature of a function that can be executed using arguments of a variety of types.

Subclass: A class that inherits data fields and methods from another class (called the superclass).

Virtual function: Most generally, a method of a class that may be overridden by a subclass to the class. In languages in which dynamic binding is not the default, this may also mean that a function is subject to dynamic binding.

65.1 Introduction

Logic programming (LP) is a language paradigm based on logic. Its constructs are Boolean *implications* (e.g., *q implies p* meaning that *p* is true if *q* is true), compositions using the Boolean operators *and* (called conjunctions) and *or* (called disjunctions). LP can also be viewed as a procedural language in which the procedures are actually Boolean functions, the result of a program always being either true or false.

In the case of implications, a major restriction applies: when q implies p , written $p:-q$, then q can consist of conjunctions, but p has to be a singleton, representing the (sole) Boolean function being defined. The Boolean operator *not* is disallowed, but there is a similar construct that may be used in certain cases.

The Boolean functions in LP may contain parameters, and the parameter matching mechanism is called unification. This type of general pattern matching implies, for example, that a variable representing a formal parameter may be bound to another variable or even to a complex data structure, representing an actual parameter (and vice versa). When an LP program yields a *yes* answer, the bindings of the variables are displayed, indicating that those bindings make the program logically correct and provide a solution to the problem expressed as a logic program.

An important recent extension of LP is *constraint logic programming* (CLP). In this extension, unification can be replaced or complemented by other forms of constraints, depending on the domains of the variables involved. For example, in CLP a relationship such as $X > Y$ can be expressed even in the case where X and Y are unbound real variables. As in LP, a CLP program yields answers expressing that the resulting constraints (e.g., $Z < Y + 4$) must be satisfied for the program to be logically correct.

This chapter includes sections describing the main aspects of LP and CLP. It includes examples, historical remarks, theoretical foundations, implementation techniques, and metalevel interpretation and concludes with the most recent proposed extensions to this language paradigm.

65.2 Introductory Example

Let us consider a simple program written in PROLOG, the main representative among LP languages. The program's objective is to check if a date given by the three parameters, *Month* (a string), *Day*, and *Year* (integers), is valid. For example, *date* (*oct*, 15, 1996) is valid whereas *date* (*june*, 31, 1921) is not. The program can be expressed as follows:

```

date (Month, Day, Year):- member (Month, [jan, march, may, july, aug, oct, dec]),
                           comprised (Day, 1,31).
date (Month, Day, Year):- member (Month, [april, june, oct, sept, nov]),
                           comprised (Day, 1,30).
date (feb, Day, Year):- leap (Year), comprised (Day, 1, 29).
date (feb, Day, Year):- comprised (Day, 1, 28).
comprised (Day, Start, End):- Day >=Start, Day =<End.
leap (Year):- (Year/4) × 4 = Year.

```

The variables in the preceding program start with a capital letter, for example, *Month*; in this simple example, the constants either start with small case letters (strings) or are integers. The symbol *-* can be read as is defined by, and it separates the procedure heading from its body, which consists of calls to other procedures. More precisely, it is convenient to view every procedure as a Boolean function yielding *true* or *false*. The body of such a function is made up of conjunctions of calls to functions. Therefore, a comma separating the calls on the right-hand side correspond to the Boolean operator *and*.

The following remarks also apply to the program. There are multiple definitions of *date*, each of which tests for the corresponding month and the compatible number of days. Therefore, the program is non-deterministic in the sense that several possibilities have to be considered either one at a time or in parallel. In many cases there might be several solutions to a given program. Also note that the right-hand side of a rule could be empty. In that case, the rule indicates that the left-hand side is always true.

Let us for the time being assume that *member* (*Element*, *List*) is a built-in function testing if an *Element* is a member of a *List*. The Boolean function *leap* tests if its parameter is a multiple of 4. One could also add a function *year* (*Year*), which would test if an integer defined by *Year* is positive. Notice that the ordering of the statements in this particular version of the program is important, since a leap year is tested before a nonleap year. Ideally, pure PROLOG programs should be declarative; from a syntactic point of view, that means that the order of the rules and the order of the calls on the right-hand

sides should not matter. A new version of the program satisfying this criteria is one in which the Boolean function *nonleap* (*Year*):- $(Year/4) \times 4 \neq Year$ is called in the definition applicable to the month of February, in the case of a nonleap year.

The preceding program is used with queries (equivalent to main programs) to test the validity of given dates. The answers are either *yes* or *no*. Note that in PROLOG one is allowed to have queries containing variables. In the present example, the query *date* (*X*, 31, 1996) yields as results the successive strings that the variable *X* is bound to for the months that have 31 days. More specifically, the results are as follows:

```
yes X = jan, More?
yes X = march, More?
...
Yes X = dec, More?
No.
```

Similarly, the query *date* (*X*, 29, 1996) yields all the months in a year. Note that the built-in functions such as $=<$ and $>=$ require that their arguments be ground; that is, they cannot contain unbound variables.

This is satisfied by the query *date* (*X*, 31, 1996). However, a call *date* (*feb*, *Y*, 1996) entails a problem that provides insight into the desirability of extending PROLOG to handle constraints such as it is done in PROLOG IV. The last query fails in standard PROLOG because the variable *Y* remains unbound. The right answer as provided by a CLP processor consists of the two constraints:

```
Yes Y >= 1, Y =< 29, More?
No.
```

Similarly, the correct answer to the query *date* (*feb*, *Y*, *Z*) submitted to a CLP processor should yield two pairs of constraints corresponding to leap and nonleap years represented by *Z*. These results are obtained by keeping lists of satisfiable constraints and triggering a failure when the constraints become unsatisfiable. This failure may entail exploring the remaining nondeterministic possibilities.

It is now appropriate to present the recursive Boolean function *member*. It has two parameters: an *Element* and a *List*; the function succeeds if the *Element* appears in the *List*. Lists are represented using the constructor *cons* as in functional languages. This means that a list [*a*, *b*] can be represented by

```
cons (a, cons (b, nil))
```

Note that the *cons* in the preceding representation is simply any user-selected identifier describing a data structure (or record) consisting of two fields: (1) a string and (2) a pointer to another such record or to *nil*. In the case of lists there are special built-in features such as [*a*, *b*] simplifying their description. The program for *member* consists of two rules:

```
member (X, cons (X, T)).
member (X, cons (Y, T)):- X /= Y, member (X, T).
```

The first rule states that if the head of a list contains the element *X*, then *member* succeeds. The second rule uses recursion to inspect the remaining elements of the list. Note that the query *member* (*X*, *cons* (*a*, *cons* (*b*, *nil*))), equivalent to *member* (*X*, [*a*, *b*]), provides two solutions, namely, $X = a$ or $X = b$. It should be obvious that *member* (*Y*, [*a*, *a*]) also yields two (identical) solutions.

Finally, notice that *member* can search for more complex data structures. For example, *member* (*member* (*a*, *Y*), *Z*) succeeds if the list *Z* contains an element such as *member* (*a*, *U*); if so, the variable *Y* is bound to the variable *U*. The reader should consider the embedded term *member* as the identifier of a record or data structure having two fields. In contrast, the first identifier *member* represents a Boolean function having two parameters. This example illustrates that, in PROLOG, program and data have the same form.

An inquisitive reader will remark that *member* can also be used to place elements in a list if they are not already present in that list. A clue in understanding this property is that the query *member* (*a*, *Z*) will

bind Z to a record $cons(a, W)$ in which W is a new unbound variable created by the PROLOG processor when applying the first rule defining the Boolean function *member*.

65.3 Features of Logic Programming Languages

Summarized next are some of the features whose combination renders PROLOG unique among languages:

1. Procedures may contain parameters that are both input and output.
2. Procedures may return results containing unbound variables.
3. *Backtracking* is built-in, therefore allowing the determination of multiple solutions to a given problem.
4. General pattern-matching capabilities operate in conjunction with a goal-seeking search mechanism.
5. Program and data are presented in similar forms.

The preceding listing of the features of PROLOG does not fully convey the subjective advantages of the language. There are at least three such advantages:

1. Having its foundations in logic, PROLOG encourages the programmer to describe problems in a logical manner that facilitates checking for correctness and, consequently, reduces the debugging effort.
2. The algorithms needed to interpret PROLOG programs are particularly amenable to parallel processing.
3. The conciseness of PROLOG programs, with the resulting decrease in development time, makes it an ideal language for prototyping.

Another important characteristic of PROLOG that deserves extension, and is now being extended, is the ability to postpone variable bindings as much as is deemed necessary (lazy evaluation). Failure and backtracking are triggered only when the interpreter is confronted with a logically unsatisfiable set of constraints. In this respect, PROLOG's notion of variables approaches that used in mathematics.

The price to be paid for the advantages offered by the language amounts to the increasing demands for larger memories and faster central processing units (CPUs). The history of programming language evolution has demonstrated that, with the consistent trend toward less expensive and faster computers with larger memories, this price becomes not only acceptable but also advantageous because the savings achieved by program conciseness and by a reduced programming effort largely compensate for the space and execution time overheads. Furthermore, the quest for increased efficiency of PROLOG programs encourages new and important research in the areas of optimization and parallelism.

65.4 Historical Remarks

The birth of LP can be viewed as the confluence of two different research endeavors: one in artificial or natural language processing and the other in automatic theorem proving. These endeavors contributed to the genesis of the PROLOG language, the principal representative of LP.

Alain Colmerauer, assisted by Philippe Roussel, is credited as the originator of PROLOG, a language that was first developed in the early 1970s and continues to be substantially extended. Colmerauer's contributions stemmed from his interest in language processing using theorem-proving techniques. Robert Kowalski was also a major contributor to the development of L.P. Kowalski had an interest in logic and theorem proving (Cohen 1988, Bergin 1996). In their collaboration, Kowalski and Colmerauer became interested in problem solving and automated reasoning using resolution theorem proving.

Kowalski's main research was based on the work of Alan Robinson (1965). Robinson had the foresight to distinguish the importance of two components in automatic theorem proving: a single inference rule called *resolution* and the testing for equality of trees called *unification*.

Theorems to be proved using Robinson's approach are placed in a special form consisting of conjunctions of *clauses*. Clauses are disjunctions of positive or negated literals; in the case of Boolean algebra (propositional calculus), the literals correspond to variables. In the more general case of the predicate calculus, literals correspond to a potentially infinite number of Boolean variables, one for each combination of values that the literal has as parameters. A *Horn clause* is one containing (at most) one positive literal; all of the others (if any) are negated.

According to the informal description in the introductory example, a Horn clause corresponds to the definition and body of a Boolean function. The positive literal is the left-hand side of a rule (called *Head*); the negative literals appear on the right-hand side of the rule (called *Body*). A non-Horn clause is one in which (logical) negations can appear qualifying a call in the *Body*. An example of a Horn clause is as follows:

date (feb, Day, Year):- leap (Year), comprised (Day, 1, 29).

because it is equivalent to

leap (Year) and comprised (Day, 1, 29) implies date (feb, Day, Year)

or

date (feb, Day, Year) or not (leap (Year)) or not (comprised (Day, 1, 29))

If one wished to express the clause

date (feb, Day, Year):- not leap (Year), comprisesd (Day, 1, 28).

in which the *not* is the logical Boolean operation, the preceding example would be logically equivalent to

date (feb, Day, Year) and leap (Year) or comprised (Day, 1, 28)

which is not a Horn clause because it has two (positive) elements in the head (and there is no procedural equivalent to it).

Kowalski concentrated his research on reducing the search space in resolution-based theorem proving. With this purpose, he developed with Kuehner a variant of the linear resolution algorithm called SL resolution (for linear resolution with selection function [Kowalski and Kuehner 1970]). Kowalski's view is that, from the automatic theorem-proving perspective, this work paved the way for the development of PROLOG. Having this more efficient (but still general) predicate calculus theorem prover available to them, the Marseilles and Edinburgh groups started using it to experiment with problem-solving tasks. To further increase the efficiency of their prover, the Marseilles group resorted to daring simplifications that would be inadmissible to logicians. These audacious attempts turned out to open new vistas for the future of LP.

Several formulations for solving a given problem were attempted. Almost invariably, the formulations that happened to be written in Horn clause form turned out to be much more natural than those that used non-Horn clauses. A case in which the Horn clause formulation was particularly effective occurred in parsing strings defined by grammar rules. Recall that context-free grammars have a single nonterminal being defined on the left-hand side of each of its rules, therefore establishing a strong similarity with Horn clauses.

The SL inference mechanism applicable to a slight variant of Horn clauses led to the present PROLOG inference mechanism: *selective linear definite (SLD) clause resolution*. The word *definite* refers to Horn clauses with exactly one positive literal, whereas general Horn clauses may contain entirely negative clauses. (Because the term "Horn clause" is more widely used than definite clause, the former is often used to denote the latter.)

As a final historical note, one should mention that LP gained renewed impetus by its adoption as the language paradigm for the Japanese fifth-generation program. PROLOG and, in particular, its CLP extensions now count on a significant number of loyal and enthusiastic users.

65.5 Resolution and Unification

Resolution and unification appear in different guises in various algorithms used in computer science. This section first describes these two components separately and then their combination as it is used in LP. In doing so it is useful to consider first the case of the propositional calculus (Boolean algebra) in which unification is immaterial. It is well known that there exist algorithms that can always decide if a system of Boolean formulas is satisfiable or not, albeit with exponential complexity.

In terms of the informal example considered in the introduction, one can view resolution as a (non-deterministic) call of a user-defined Boolean function. Unification is the general operation of matching the formal and actual parameters of a call. Consequently, unification does not occur in the case of parameterless Boolean functions.

The *predicate calculus* includes the quantifiers \forall and \exists ; it can be viewed as a general case of the propositional calculus for which each predicate variable (a literal) can represent a potentially infinite number of Boolean variables. Unification is only used in this latter context. Theorem-proving algorithms for the predicate calculus are not guaranteed to provide a yes-or-no answer because they may not terminate.

65.5.1 Resolution

In the propositional calculus, a simple form of resolution is expressed by the inference rule:

$$\begin{aligned} &\text{if } a \rightarrow b \text{ and } b \rightarrow c \text{ then } a \rightarrow c, \text{ or} \\ &(\neg a \vee b) \wedge (\neg b \vee c) \rightarrow (\neg a \vee c) \end{aligned}$$

Recall that a implies b is equivalent to *not* a or b . The final disjunction $\neg a \vee c$ is called a *resolvent*. In particular, resolving $a \wedge \neg a$ implies the empty clause (i.e., falsity).

To better understand the meaning of the empty clause, consider the implication $a \rightarrow a$, which is equivalent to *(not* $a)$ or a . This expression is always true; therefore, its negation *not* $([not\ a] \text{ or } a)$ equivalent to $(a \text{ and } [not\ a])$ is always false. If a Boolean expression is always *true*, its negation is always *false*. Resolution theorem proving consists of showing that if the expression is always true, its negation results in contradictions of the type $(a \text{ and } [not\ a])$, which is always false. The empty clause is simply the resolvent of $(a \text{ and } [not\ a])$.

Observe the similarity between resolution and the elimination of variables in algebra, for example,

$$a + b = 3 \quad \text{and} \quad -b + c = 5 \quad \text{imply} \quad a + c = 8$$

Another intriguing example occurs in matching a procedure definition with its call. Consider, for example,

```
procedure b; a
...
call b; c
```

in which a is the body of b , and c is the code to be executed after the call of b . If one views the definition of b and its call as complementary, a (pseudo)resolution yields: $a; c$ in which concatenation is noncommutative, and the resolution corresponds to replacing a procedure call by its body. Actually, the last example provides an intuitive procedural view of resolution as used in PROLOG.

In the case of pure PROLOG programs, only Horn clauses are allowed. For example, if $a, b, c, d,$ and f are Boolean variables (literals), then

$$b \wedge c \wedge d \rightarrow a \text{ and } f$$

are readily transformed in Horn clauses because they correspond, respectively, to

$$a \vee \neg b \vee \neg c \vee \neg d \text{ and } f$$

where the clause f is called unit clause or a fact. The preceding example is written in PROLOG as

$$a:- b, c, d. \text{ and } f.$$

where the symbols:- and “,” correspond to the logical connectors *only if* and *and*. They are read as follows: a is true only if b and c and d are true. The previous conjunction also requires that f be true; equivalently $b \wedge c \wedge d \rightarrow a$ and f are true.

The resolution mechanism applicable to Horn clauses takes as input a conjunction of Horn clauses $H = h_1 \wedge h_2 \wedge \dots \wedge h_n$, and a query Q , which is the negation of a theorem to be proved. Q consists of the negation of a conjunction of positive literals or, equivalently, a disjunction of negated literals. Therefore, a query is itself in a Horn clause form in which the head is empty.

A theorem is proved by contradiction, namely, the goal is to prove that $H \wedge Q$ is inconsistent, implying that the result of successive resolutions involving the negated literals of Q inevitably—in the case of the propositional calculus—leads to falsity (i.e., the empty clause). In other words, if H implies the nonnegated Q is always true, then H and the negated Q are always false.

Consider, for example, the query *date* (*oct*, 15, 1996) in our introductory example. Its negation is *not date* (*oct*, 15, 1996). This resolves with the first rule yielding the bindings *Month* = *oct*, *Day* = 15, *Year* = 1996. The resolvent is the disjunction *not member* (*oct*, [*jan*, *march*, *may*, *july*, *aug*, *oct.*, *dec*]) or *not comprised* (15, 1, 31).

Although not elaborated here, the reader can easily find out that the successive resolutions using the definition of *member* will fail because *oct* is a member of the list of months containing 31 days. Similarly, day 15 is comprised between 1 and 31. Therefore, the empty (falsity) clause will be reached for both disjuncts of the resolvent.

In what follows, the resolution inference mechanism is applied to Horn clauses representing a PROLOG program. One concrete syntax for PROLOG rules is given by

$$\begin{aligned} \langle \text{rule} \rangle &::= \langle \text{clause} \rangle. | \langle \text{unit clause} \rangle. \\ \langle \text{clause} \rangle &::= \langle \text{head} \rangle :- \langle \text{tail} \rangle \\ \langle \text{head} \rangle &::= \langle \text{literal} \rangle \\ \langle \text{tail} \rangle &::= \langle \text{literal} \rangle \{, \langle \text{literal} \rangle \} \\ \langle \text{unit clause} \rangle &::= \langle \text{literal} \rangle \end{aligned}$$

where the braces { } denote any number of repetitions (including none) of the sequence enclosed by the brackets <>. First consider the simplest case, where a *literal* is a single letter. For example, consider the following PROLOG program in which rules are numbered for future reference:

1. $a:- b, c, d.$
2. $a:- e, f.$
3. $b:- f.$
4. $e.$
5. $f.$
6. $a:- f.$

In the first rule, a is the *<head>*, and b, c, d is the *<tail>*, also called the *body*. The fourth and fifth rules are unit clauses; that is, the body is empty. A query Q is syntactically equivalent to a *<tail>*. For example, $a, e.$ is a query and it corresponds to the Horn clause $\neg a \vee \neg e$. The result of querying the program is one

(or multiple) *yes* or a single *no* answer indicating the success or failure of the query. In this particular example, the query a, e yields two *yes* answers. Note that a is defined by three rules; the second and the third yield the two solutions; the first fails because c is undefined. The successful sequence of the list of goals is as follows:

- Solution 1: $a, e \Rightarrow e, f, e \Rightarrow f, e \Rightarrow e \Rightarrow nil$;
- Solution 2: $a, e \Rightarrow f, e \Rightarrow e \Rightarrow nil$.

Let us follow in detail the development of the second solution. The negated query *not a or not e* resolves with the sixth rule *a or not f*, yielding the resolvent *not f or not e*. Now the last expression is resolved with the *f* in the fifth rule, yielding *not e* as the resolvent. Finally, *not e* is resolved with the *e* in the fourth rule, yielding the empty clause, which implies the falsity of the negation of the query, using the program rules. The entire search space is shown in Figure 65.1 in the form of a tree. In nondeterministic algorithms, that tree is called the tree of choices. Its leaves are nodes representing failures or successes. The internal nodes are labeled with the list of goals that remain to be satisfied. Note that if the tree of choices is finite, the order of the goals in the list of goals is irrelevant insofar as the presence and number of solutions are concerned. Figure 65.2 shows a proof tree for the first solution of the example. The proof tree is an *and* tree depicting how the proof has been achieved.

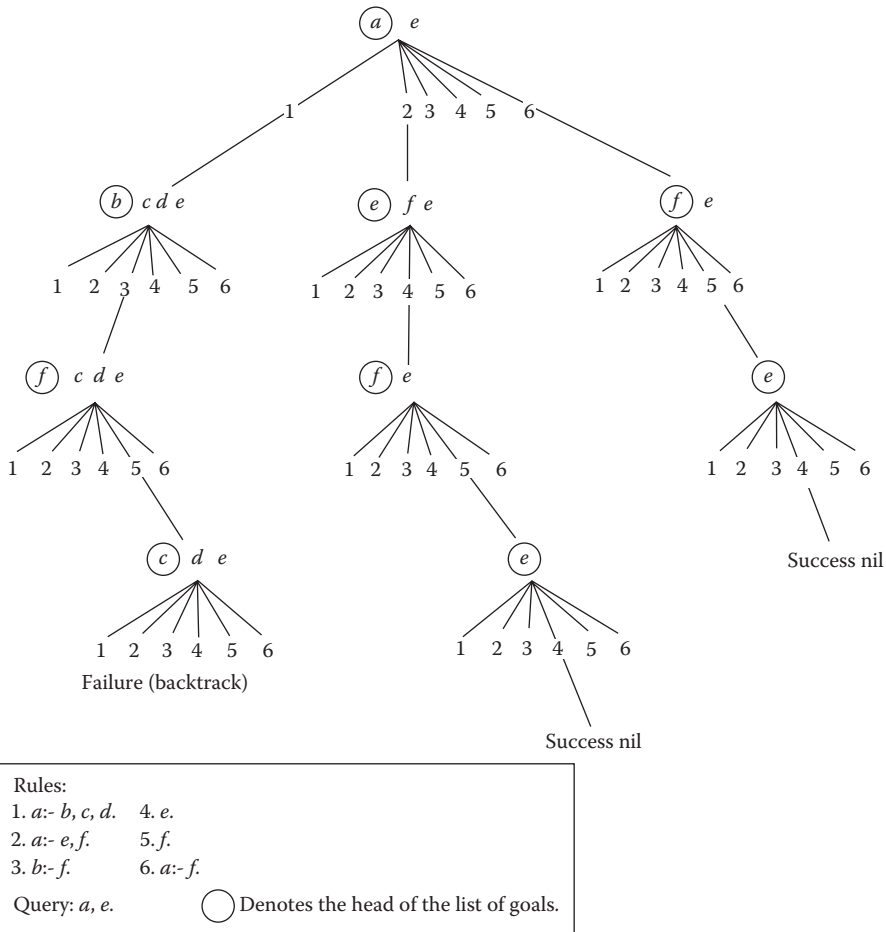

FIGURE 65.1 Tree of choices.

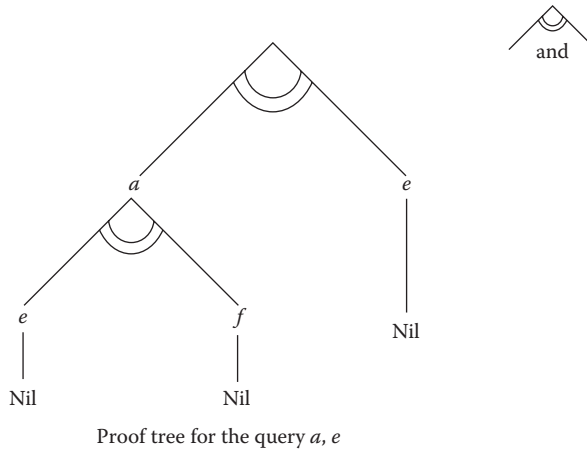

FIGURE 65.2 Proof tree.

There are three ways of interpreting the semantics of PROLOG rules and queries. The first is based on logic, in this particular case on Boolean algebra. The literals are Boolean variables, and the rules express formulas. The PROLOG program is viewed as the conjunction of formulas it defines. The query Q succeeds if it can be implied by the program. In a second (called procedural) interpretation of a PROLOG rule, it is assumed that a *<literal>* is a goal to be satisfied. For example, the first rule states that

goal a can be satisfied if goals b, c, and d can be satisfied.

The unit clause states that the defined goal can be satisfied. The program defines a conjunction of goals to be satisfied. The query succeeds if the goals can be satisfied using the rules of the program. Finally, a third interpretation is based on the similarity between PROLOG rules and context-free grammar rules. A PROLOG program is associated with a context-free grammar in which a *<literal>* is a nonterminal and a *<rule>* corresponds to a grammar rule in which the *<head>* rewrites into the *<tail>*; a unit clause is viewed as a grammar rule in which a nonterminal rewrites into the empty symbol ϵ . Under this interpretation, a query succeeds if it can be rewritten into the empty string.

Although the preceding three interpretations are all helpful in explaining the semantics of this simplified version of PROLOG, the logic interpretation is the most widely used among theoreticians, and the procedural by language designers and implementors.

The algorithms that test if a query Q can be derived from a Horn clause program P can be classified in various manners. An analogy with parsing algorithms is relevant: P corresponds to a grammar G , and Q corresponds to the string (of nonterminals) to be parsed (i.e., the sequence of nonterminals that may be rewritten into the empty string using G). *Backward-chaining* theorems correspond to top-down parsers and are by far the preferred approach presently used in LP. *Forward-chaining* provers correspond to bottom-up parsers. Hybrid algorithms have also been proposed.

In a top-down algorithm, the list of goals in a query is examined from left to right, and the corresponding (recursive) procedures are successively called the equivalent of resolution, until the list of goals becomes empty. Note that the algorithm is essentially nondeterministic because there are usually several choices for the goals (see rules 1 and 2). Another nondeterministic choice occurs when selecting the (next) element of the list of goals to be considered after processing a goal.

Notice that if one had a program consisting of the sole rule $a:- a.$ and the query a , the top-down approach would not terminate. The program states that either a or $\neg a$ is true. Because the query does not specify a , it could be either true or false. A semantically correct interpreter should provide the following constraints as answers $a = true$ or $a = false$. PROLOG programmers have learned to live with these unpalatable characteristics of top-down provers.

Contrary to what usually happens in parsing, bottom-up provers can be very inefficient unless the algorithm contains selectivity features that prevent the inspection of dead-end paths. In the case of database (DB) applications, the bottom-up approach using magic sets has yielded interesting results (Minker 1987).

Also note the correspondence between nondeterministic grammars and nondeterministic PROLOG programs. In many applications the programs can be made deterministic and therefore more efficient. However, ambiguous grammars that correspond to programs having multiple solutions are also useful and therefore nondeterminism has its advantages.

65.5.2 Unification

The operation of unification is akin to that of pattern matching. Robinson's unification algorithm brings rigor to the notion of pattern matching, and it has a deep meaning: it replaces a set of fairly intricate predicate calculus axioms specifying the equality of trees by an efficient algorithm, which is easily implementable in a computer. As mentioned earlier, unification can be viewed as a very general matching of actual and formal parameters.

From the logic point of view, unification is used in theorem proving to equate terms that usually result from the elimination of existential quantifiers when placing a predicate calculus formula in clausal form.

For example,

$$\forall X \exists Y \text{ such that } p(X, Y) \text{ is always true}$$

is replaced by

$$\forall X p(X, g(X))$$

where $g(x)$ is the Skolem function for y (sometimes referred to as an uninterpreted function symbol). The role of unification is to test the equality of literals containing Skolem functions and, in so doing, bind values to variables.

Consider, for example, the statement "for all positive integer variables X there is always a variable Y representing the successor of X ." The predicate p expressing this statement is $p(X, s(X)):- integer(X)$, where $s(X)$ is the Skolem function representing Y , the successor of X . This representation is commonly used to specify positive integers from a theoretical perspective. (It is called a Peano representation of integers (e.g., $s(s(0))$ represents the integer 2).)

To show the effect of unification, the definition of a literal in the previous subsection on resolution is now generalized to encompass labeled tree structures.

```

<literal> ::= <composite>
<composite> ::= <functor>(<term>{, <term>}) | <functor>
<functor> ::= <lower case identifiers>
<term> ::= <constant> | <variable> | <composite>
<constant> ::= <integers and lower case identifiers>
<variable> ::= <identifiers starting with an upper case letter or _ >

```

Examples of terms are *constant*, *Var*, 319, *line*(*point*(X , 3), *point*(4, 3)). It is usual to refer to a single rule in a PROLOG program as a clause. A PROLOG procedure (or predicate) is defined as the set of rules whose head has the same <functor> and arity. Unification tests whether two terms $T1$ and $T2$ can be matched by binding some of the variables in $T1$ and $T2$. The simplest algorithm uses the rules summarized in Table 65.1 to match the terms. If both terms are composite and have the same <functor>, it recurses on their components. This algorithm only binds variables if it is *absolutely necessary*, so there may be variables that remain unbound. This property is referred to as the most general unifier (mgu).

TABLE 65.1 Summary of Tests for the Unification of Two Terms

Terms $1 \downarrow, 2 \rightarrow$	<constant> C2	<variable> X2	<composite> T2
<constant> C1	succeed if C1 = C2	succeed with X2 = C1	fail
<variable> X1	succeed with X1 = C2	succeed with X1 = X2	succeed with X1 = T2
<composite> T1	fail	succeed with X2 = T1	succeed if (1) T1 and T2 have the same functor and arity (2) The matching of corresponding children succeeds

One can write a recursive function *unify*, which, given two terms, tests for the result of unification using the contents of Table 65.1. The unification of the two terms $f(X, g(Y), T)$ and $f(f(a, b), g(g(a, c), Z))$ succeeds with the following bindings $X = f(a, b)$, $Y = g(a, c)$, and $T = Z$. Note that if one had $g(Y, c)$ instead of $g(a, c)$ in the second term, the binding would have been $Y = g(Y, c)$.

PROLOG interpreters would usually carry out this circular binding but would soon get into difficulties because most implementations of the described unification algorithm cannot handle circular structures (called *infinite trees*). Manipulating these structures (e.g., printing, copying) would result in an infinite loop unless the so-called *occur check* was incorporated to test for circularity. This is an expensive test: unification is linear with the size of the terms unified, and incorporation of the occur check renders unification quadratic.

There are versions of the unification algorithm that use a representation called *solved form*. Essentially, new variables are created whenever necessary to define terms, for example, the system

$$X1 = f(X2, g(X3, X2)) \quad X5 = g(X4, X2)$$

A solved form is immediately known to be satisfiable because $X2, X3$, and $X4$ can be bound to any terms formed by using the function symbols f and g and again replacing (*ad infinitum*) their variable arguments by the functions f and g . This is called an element of the *Herbrand universe* for the given set of terms. The solved form version of the unification algorithm is presented by Lassez in Minker (1987).

To further clarify the notion of solved forms, consider the equation in the domain of reals specified by the single constraint $X + Y = 5$. This is equivalent to $X = 5 - Y$, which is in solved form and satisfiable for any real value of Y . Basically a constraint in solved form contains definitions in terms of free variables, that is, those that are not constrained. This form is very useful when unification is extended to be applicable to domains other than trees. For example, linear equations may be expressed in solved form.

65.5.3 Combining Resolution and Unification

Consider now general clauses in which the literals contain arguments that are represented by terms. The result of resolving

$$p(\dots) \vee r(\dots)$$

with

$$\neg p(\dots) \vee s(\dots)$$

is

$$r(\dots) \vee s(\dots)$$

if and only if the arguments of p and $\neg p$ are unifiable and the resulting variables are substituted in the corresponding arguments of r and s .

Using programming language terminology, the combination of resolution and unification corresponds to a Boolean function call in which a variable in the head of a rule is matched (i.e., unified) with its corresponding actual parameter; once this is done, the value to which the variable is bound replaces the instances of that variable appearing in the body. Note that a variable can be bound to another variable or to a complex term. Remark also that when unification fails, another head of a rule has to be tried and so on. For example, consider the query $p(a)$ and the program

```
p(b).
p(X):- q(X).
q(a).
```

The first unification of the query $p(a)$ with $p(b)$ fails. The second attempt binds X to a starting a search for $q(a)$ that succeeds. Had the query been $p(Y)$, the two solutions would be $Y = b$ or $Y = a$. The first solution is a consequence of the unit clause $p(b)$; the second follows from binding Y to a (a new variable X in the second clause). A search is then made for $q(X)$, which succeeds with the last clause, therefore binding both Y and X to a .

From a logical point of view, when the result of a resolution is the empty clause (corresponding to the head of a rule with an empty body) and no more literals remain to be examined, the list of bindings is presented as the answer, that is, the bindings (*constraints*) that result from proving that the query is deducible from the program.

65.6 Procedural Interpretation: Examples

It is worthwhile to first understand the importance of the procedure *append* as used in symbolic functional languages. In PROLOG the word procedure is a commonly used misnomer because it always corresponds to a Boolean function, as mentioned in the introductory example; *append* is often used to concatenate two lists. Because one has to avoid destructive assignments, which have very complex semantic meaning, *append* resorts to copying the first list to be appended and making its last element point to the second list. This preserves the original first list. It should be kept in mind that the avoidance of a destructive assignment forces one to produce results that are *constructed* from a given data using a LISP-like *cons*. Notice that LP also avoids destructive assignment by having variables bound only once during unification.

This section first demonstrates the transformation of a functional specification of *append* into its PROLOG counterpart corresponding to the previous clauses. Examples of inventive usage of *append* are then presented to further illustrate the procedural interpretation of logic programs. Consider the LISP-like function *append* that concatenates two lists, $L1$ and $L2$:

```
function append(L1, L2: pLIST): pLIST;
  if L1 = nil then append: = L2
  else append: = cons(head(L1), append(tail(L1), L2));
```

In the preceding display, $L1$ and $L2$ are pointers to lists; a list is a record containing the two fields *head* and *tail*, which themselves contain pointers to other lists or to atoms. The tail must point to a list or to the special atom *nil*. The constructor *cons* (H , T) creates the list whose *head* and *tail* are, respectively, H and T . The function *append* can be rewritten into a procedure having an explicit third parameter $L3$ that will contain the desired result. The local variable T is used to store intermediate results:

```
procedure append(L1, L2: pLIST: var L3: pLIST);
  begin local T: pLIST;
  if L1 = nil then L3: = L2
  else begin append(tail(L1), L2, T); L3:= cons(head(L1), T) end
  end
```

The former procedure can be transformed into a Boolean function that, in addition to building $L3$, checks if *append* produces the correct result.

```
function append(L1, L2: pLIST: var L3: pLIST): Boolean;
begin local H1, T1, T: pLIST;
      if L1 = nil then begin L3:= L2; append:= true end
      else if {There exists an H1 and a T1 such that
              H1 = head(L1) and T1 = tail(L1)}
              then begin append:= append(T1, L2, T); L3:= cons(H1, T) end
              else append:= false
end
```

The Boolean in the conditional surrounded by braces has been presented informally, but it could actually have been programmed in detail. Note that the assignments in the preceding program are executed at most once for each recursive call. The function returns *false* if $L1$ is not a list (e.g., if $L1 = cons(a, b)$ for some atom $b \neq nil$).

One can now transform the last function into a PROLOG-like counterpart in which rules of assignments and conditionals are subsumed by unification and specified by the equality sign. The statement $E1 = E2$ succeeds if $E1$ and $E2$ can be matched. In addition, some of the variables in $E1$ and $E2$ may be bound if necessary:

```
append(L1, L2, L3) is true if L1 = nil and L3 = L2
                        otherwise
append(L1, L2, L3) is true
                        if L1 = cons(H1, T1) and append(T1, L2, T) and L3 = cons(H1, T)
                        otherwise append is false.
```

The reader can now compare the preceding results with the previous description of the subset of PROLOG. This comparison yields the PROLOG program

```
append(L1, L2, L3):- L1 = nil, L3 = L2.
append(L1, L2, L3):- L1 = cons(H1, T1), append(T1, L2, T), L3 = cons(H1, T).
```

This version is particularly significant because it clearly separates resolution from unification. In this case, the equality sign is the operator that commands a unification between its left and right operands.

This could also be done using the unit clause *unify* (X, X) and substituting $L1 = nil$ by *unify* ($L1, nil$), and so on. Replacing $L1$ and $L3$ with their respective values on the right-hand side of a clause, one obtains the following:

```
append(nil, L2, L2).
append(cons(H1, T1), L2, cons(H1, T)):- append(T1, L2, T).
```

The explicit calls to *unify* have now been replaced by implicit calls that will be triggered by the PROLOG interpreter when it tries to match a goal with the head of a rule. Notice that a *<literal>* now becomes a function name followed by a list of parameters, each of which is syntactically similar to a *<literal>*. In the predicate calculus, the preceding program corresponds to the following:

```
 $\forall L2$  append (nil, L2, L2).
 $\forall H1, T1, L2, T$  append(cons(H1, T1), L2, cons(H1, T))  $\vee$   $\neg$  append(T1, L2, T)
```

A word of caution about types is in order. The preceding version of *append* would produce a perhaps unwanted result if the list $L2$ is a term, say $g(a)$. For example, *append*(*nil*, $g(a)$, Z) would yield as result $Z = g(a)$. To ensure that this result would not be considered valid, one would have to make explicit the calls to functions that test if the two lists to be appended are indeed lists, namely,

```
is-a-list (nil).
is-a-list (cons(H, T)):- is-a-list (T).
```

The Edinburgh PROLOG representation of $cons(H, T)$ is $[H|T]$, and nil is $[\]$. The Marseilles counterparts are $H.T$ and nil . In the Edinburgh dialect, *append* is presented by

```
append([ ], L2, L2).
append([H1|T1], L2, [H1|T1]):- append(T1, L2, T).
```

The query applicable to the program that uses the term *cons* is *append* (*cons*(*a*, *cons*(*b*, *nil*)), *cons*(*c*, *nil*), *Z*), and it yields $Z = cons(a, cons(b, cons(c, nil)))$. In the Edinburgh PROLOG, the preceding query is stated as *append*([*a*, *b*], [*c*], *Z*), and the result becomes $Z = [a, b, c]$.

A remarkable difference between the original PASCAL-like version and the PROLOG version of *append* is the ability of the latter to determine (unknown) lists that, when appended, yield a given list as a result. For example, the query *append*(*X*, *Y*, [*a*]) yields two solutions: $X = [\]$ $Y = [a]$ and $X = [a]$ $Y = [\]$.

The preceding capability is due to the generality of the search and pattern-matching mechanism of PROLOG. An often-asked question is: Is the generality useful? The answer is definitely yes! A few examples will provide supporting evidence. The first is a procedure for determining a list *LLL*, which is the concatenation of *L* with *L* the result itself being again concatenated with *L*:

```
triple(L, LLL):- append(L, LL, LLL), append(L, L, LL).
```

Note that the first *append* is executed even though *LL* has not yet been bound. This amounts to copying the list *L* and having the variable *LL* as its last element. After the second *append* is finished, *LL* is bound, and the list *LLL* becomes fully known. This property of postponing binding times can be very useful. For example, a dictionary may contain entries whose values are unknown. Identical entries will have values that are bound among themselves. When a value is actually determined, all communally unbound variables are bound to that value.

Another interesting example is *sublist*(*X*, *Y*), which is true when *X* is a sublist of *Y*. Let *U* and *W* be the lists at the left and right of the sublist *X*. Then the program becomes

```
sublist(X, Y):- append(Z, W, Y), append(U, X, Z).
```

where the variables represent the sublists indicated as follows:

An additional role for *append* is to simulate the behavior of *member* as used in the introductory example. One could state that *member*(*X*, *L*):- *append*(*Start*, [*X*]*End*), *L*), in which *Start* and *End* are variables representing lists, which, when surrounding *X*, produce *L*. This approach is expensive because it may use a quadratic number of *conses*.

A final example is a bubblesort program. The specification of two adjacent elements *A* and *B* in a list *L* is done by a call:

```
append(., [A, B | _], L)
```

The underscores stand for different variables whose names are irrelevant to the computation, and the notation $[A, B | C]$ stands for $cons(A, cons(B, C))$. The rules to bubblesort then become

```
bbsort(L, S):- append (U, [A, B | X], L), B < A, append (U, [B, A | X], M), bbsort(M, S).
bbsort(L, L).
```

The first *append* generates all pairs of adjacent elements in *L*. The literal $B < A$ is a built-in predicate that tests whether *B* is lexicographically smaller than *A*. (Note that both *A* and *B* must be bound, otherwise a failure occurs! There will be more discussion of this limitation later.) The second *append* reconstructs the modified list, which becomes the argument in a recursive call to *bbsort*. If the first clause is no longer

applicable, then all pairs of adjacent elements are in order, and the second clause then provides the desired result. This version of bubblesort is space and time inefficient because U , the initial segment of the list, is copied twice at each level of recursion. However, the brevity of the program is indicative of the savings that can be accrued in programming and debugging. It should be now clear to the reader that the translation of a functional program into its PROLOG counterpart is easily done, but the reverse translation becomes more difficult because the functional program has to simulate nondeterminism and backtracking.

A unique property of some PROLOG programs is their ability to perform inverse computations. For example, if $p(X, Y)$ defines a procedure p taking an input X and producing an output Y , it can (in certain cases) determine which input X produces Y . Therefore, if p is a differentiation program, it can also perform integration. This is easier said than done, because the use of impure features and simplifications may result in operations that are not correctly backtrackable.

The inverse computation of parsing is string generation, and parsers are now available to perform both operations. A compiler carefully written in PROLOG can also be useful in decompiling. The difficulties encountered in doing the inverse operations are frequently due to the use of impure features.

65.7 Impure Features

In the previous sections, the so-called pure features of PROLOG were described, namely, those that conform with the logic interpretation. A few impure features have been added to the language to make its use more practical. (This situation parallels the introduction of *setq*, *rplaca*, and other impure LISP functions.) However, a word of warning is in order. Some of these impure features vary from one implementation to another (O'Keefe, 1990 is an excellent reference on extralogical features).

The most prominent of these impure features is the *cut*, represented by an exclamation point. Its purpose is to let the programmer change the search control mechanism embodied by the procedure *solve* in Figure 65.3. Reconsider the example in Section 65.5. Assuming that a :- b , $!$, c , d ., then in the forward mode, b , c , and d would, as before, be placed in the list of goals and matched with heads of clauses in the DB. If, however, a goal following the *cut* fails (e.g., c , or d), then no further matching of clauses defining a or b would take place. The *cut* is often used to increase the efficiency of programs and to prevent the consideration of alternate solutions. PROLOG purists avoid the use of cuts.

Another useful predicate is *fail*, which automatically triggers a failure. To implement it, one simply forbids its presence in the DB. Other built-in predicates that need to be introduced are the input-output commands *read* and *write*.

Once *cut* and *fail* are available, negation by failure is accomplished by the clauses:

```
not(X):- X,!,fail.
not(X).
```

which fails if X succeeds and vice versa. It is important to note that this artifice does not always follow the rules of true negation in logic. This version of negation illustrates that a term in the head of a rule can appear in the body as a call to a function; therefore, in PROLOG, program and data have the same form.

```
procedure solve. L: pLIST/;
begin local i: integer;
  if L ≠ nil
  then
    for i := 1 to n do
      if match(head(Rule[i]), head(L)) then
        solve(append(tail(Rule[i]), tail(L)));
      else write ('yes')
    end;
end;
```

FIGURE 65.3 An initial version of the interpreter.

The built-in predicates *assert* and *retract* are used to add or remove a clause from the DB; they are often used to simulate assignments. For example, the unit clause *value* (*Variable*, *Value*). can be asserted using bound parameters (e.g., *value*[*Z*, 37]); it can be subsequently retracted to change the actual *Value*, and then reasserted with a new value. Another use of *assert* and *retract* is associated with the built-in function *setof* that collects the multiple answers of a program and places them in a list.

The assignment is introduced using a built-in binary infix operator such as *is*. For example, *Y is X + 1* is only valid if *X* has been bound to a number in which case the right-hand side is evaluated and unified with *Y*; otherwise the *is* fails. To have a fully backtrackable addition, one would have to use CLP. Note that $I = I + 1$ is invalid in CLP, as it should be. The equality $Z = X + Y$ in CLP is, of course, valid with some or all variables unbound.

65.8 Constraint Logic Programming

Major extensions of the unification component of PROLOG became very significant and resulted in a new area of LP called constraint logic programming or CLP. It may well have had its roots in Colmerauer's approach in generalizing the unification algorithm by making it capable of determining the satisfiability of equalities and disequalities of infinite trees (these are actually graphs containing special loops.) However, the notion of backpropagation (Sussman and Steele) dates back to the 1970s. In the case of PROLOG, the backtracking mode is triggered only in the case of unsatisfiability of a given unification. A logical extension of this approach is to make similar backtracking decisions for other (built-in) predicates, say, inequalities (i.e., \leq , \geq , ...) in the domain of rationals.

The first CLP example presented here is the classic program for computing Fibonacci series. Before presenting the program, it is helpful to consider the program's PROLOG counterpart (the annotation *is* corresponds to an assignment and it has been discussed in Section 65.7):

```
fib(0,1).
fib(1,1).
fib(N, R):- N1 is N - 1.
            fib(N1, R1),
            N2 is N - 2,
            fib(N2, R2),
            R is R1 + R2.
```

The *is* predicate prevents the program from being invertible: the query *fib* (10, *X*) succeeds in producing $X = 89$ as a result, but the query *fib* (*Y*, 89) yields an error because *N* is unbound and the assignment to *N1* is not performed. Note that if we had placed the predicate $N1 \geq 2$ prior to the first recursive call, the query *fib* (*Y*, 89) would also lead to an error, because the value of *N* is unbound and the test of inequality cannot be accomplished by the PROLOG interpreter.

The modified CLP version of the program illustrates the invertibility capabilities of CLP interpreters ($N \geq 2$ is a constraint):

```
fib(0,1).
fib(1,1).
fib(N, R1 + R2):- N >= 2,
                 fib(N - 1, R1),
                 fib(N - 2, R2).
```

The query $?- \text{fib}(10, \text{Fib})$ yields $\text{Fib} = 89$, and the query $?- \text{fib}(N, 89)$ yields $N = 10$. The latter result is accomplished by solving systems of linear equations and in equations that are generated when an explicit or implicit constraint must be satisfied. In this example, the matching of actual and formal parameters results in equations. Let us perform an initial determination of those equations. The query $?- \text{fib}(N, 89)$ matches only the third clause. New variables *R1* and *R2* are created as well as the

constraint $R1 + R2 = 89$. The further constraint $N \geq 2$ is added to the list of satisfiable constraints, which are now $R1 + R2 = 89$ and $N \geq 2$.

The recursive calls of *fib* generate further constraints that are added to the previous ones. These are $N1 = N - 1$, $N2 = N - 2$, and so forth. Recall that each recursive call is equivalent to a call by value in which new variables are created and new constraints are added (see the section on Implementation).

Therefore, unification is replaced by testing the satisfiability of systems of equations and inequations. A nontrivial implementation problem is how to determine if the constraints are satisfiable, only resorting to expensive general methods such as Gaussian elimination and the simplex method as a last resource.

The second example presented is a sorting program. For the purposes of this presentation, it is unnecessary to provide the code of this procedure (Sterling and Shapiro 1994); *qsort(L, S)* sorts an input list L by constructing the sorted list S . When L is a list of variables, a PROLOG interpreter would fail because unbound variables cannot be compared using the relational operator \leq . In CLP, the query $?- \text{qsort}([X1, X2, X3], S)$ yields as result $S = [X1, X2, X3]$, $X1 \leq X2$, $X2 \leq X3$. When requested to provide all solutions, the interpreter will generate all of the permutations of L as well as the applicable constraints.

Jaffar and Lassez (1987) proved that the theoretical foundations of LP languages (see Section 65.11) remain valid for CLP languages. Several CLP languages are now widely used among LP practitioners. Among them one should mention PROLOG III and IV designed by the Marseilles group, CLP(R) designed in Australia and at IBM, CHIP created by members of the European Research Community, and CLP (BNR) designed in Canada at Bell Northern Research.

The subsequent summary describes the main CLP languages and their domains:

PROLOG IV: trees, reals, intervals, linear constraints, rationals, finite domains (including Booleans), strings

CLP(R): trees, linear constraints, floating-point arithmetic

CHIP: trees, linear constraints, floating-point arithmetic, finite domains

CLP(BNR): trees, intervals

The languages considering intervals (defined by their lower and upper bounds) deal with numeric non-linear constraints; symbolic linear constraints are handled by the first three languages. (Additional information about interval constraints is provided in Section 65.14.)

65.9 Recent Developments in CLP (2002)

The single most important development in CLP is its amalgamation with an area of artificial intelligence (AI) that has been consistently explored since the late 1970s, namely, constraint satisfaction problems or CSPs. This merging has shown to be very fruitful because the two areas CLP and CSP share many common goals, such as concise declarative statements of combinatorial problems and efficient search strategies. In addition, the new combined areas benefit from research that has been done for decades in the field of operations research (OR).

The following subsections summarize the recent developments under the umbrella of the CLP-CSP paradigms. Highly recommended material has appeared in the textbook by Marriot and Stuckey (1998) and in the survey by Rossi (2000). Research articles have been published in the proceedings of the conferences on principles and practice of constraint programming held in 2002 (Van Hentenryck 2002).

65.9.1 CSP and CLP

Consider a set of constraints C containing a set of variables x_i ; the x_i 's are defined in their respective domains D_i . Usually, D_i is a finite set of integers. A CSP involves assigning values to the variables so that C is satisfied. CSP is known to be an NP-complete problem (see Chapter 5 of this handbook).

Consider now the cases where the constraints C are (1) unary, that is, they contain a single variable (e.g., $x > 0$), and (2) binary, that is, they contain two variables (e.g., $x^2 + y = 92$) and so forth. It is possible to specify a set of constraints by an undirected graph whose nodes designate each variable and an edge specifies a constraint that is applicable between any two variables. This is often called a constraint network. The notions of node consistency, arc consistency, and path consistency follow from the previous concepts. Furthermore, one can also illustrate the concept of constraint propagation, also called narrowing: it amounts to deleting from a given domain the values that do not satisfy the constraints being specified. More specifically node consistency consists of considering each node of the constraint graph and its associated unary constraints and performing a narrowing: let $c(x_i)$ be the unary constraint applicable to node x_i ; then the values satisfying *not* ($c(x_i)$) are deleted from D_i .

Arc consistency consists of considering each edge, the associated binary constraint, and performing a narrowing. In the binary case, the constraints are $c(x_i, x_j)$ and the values satisfying *not* ($c(x_i, x_j)$) are deleted from D_i and D_j .

The previous text can be generalized to define k -consistency by considering constraints involving k variables (the case $k = 3$ is called path consistency, and $k > 3$ hyper-arc consistency).

One should view node and arc consistency as preprocessing the domains of a set of variables in an attempt to eliminate unfeasible values. How much narrowing can be accomplished depends on the constraint problem being considered. However, if after narrowing there remain no feasible values specified for one or more variables, then there is obviously no solution to the given set of constraints.

It is straightforward to write a CLP program that, given the unary and binary constraints pertaining to a problem, would attempt to reduce the domains of its variables. Then one could check if any of the domains becomes empty thus determining that the given constraints are unfeasible. Note that if there is a single value remaining in a domain, then one could replace the corresponding variable by its value and reattempt narrowing using node and arc consistency in the reduced constraint network. This is a typical situation that can occur in many constraint domains, including the case of systems of linear equations and inequations. To further narrow the values of the variables, one could resort to k -consistency. However, it can be shown that for k greater or equal to three, the consistency check is itself exponential. Therefore, one has to ask the following question: Is it worth to attempt further narrowing, known to be computationally expensive and possibly fruitless, or should one proceed directly to an exhaustive search and determine if a given CSP is satisfiable or not? The answer is, of course, problem dependent.

Another type of narrowing occurs when dealing with interval constraints, those whose variables are integers or floating-point numbers defined within lower and upper bounds. Whenever an arithmetic expression is evaluated, the variables' bounds may narrow according to the operations being performed. This is called *bound consistency*, and as in the case of other types of consistencies, it is incomplete: failures may be detected (e.g., if the upper bound becomes lower than the lower bound), but bounds may remain unchanged. In those cases, splitting the intervals is the only resource in attempting to solve an interval constraint problem.

Much of the effort in CSP has been done in pruning the search tree by avoiding backtracking as much as possible. The reader is referred to Chapters 63 and 67 for details on how pruning can be accomplished.

65.9.2 Special Constraints

One can distinguish two kinds of special constraints: the first, called global constraints, are very useful in solving OR problems; the second, quadratic constraints, can be viewed as an effort to widen the scope of linear constraints without resorting to methods for handling general nonlinear constraints (e.g., interval constraints in Section 65.14.3).

Global constraints are essentially consistency constraints involving many variables and are implemented using specific and efficient algorithms. They perform the narrowing to each variable given as a parameter. A typical example is the predicate *all_different*, having n variables as parameters; *all_different* only succeeds if all its variables are assigned different values within a given domain.

Another useful global constraint is *cumulative*. Its parameters specify (1) the possible starting times for n tasks; (2) their durations; (3) the resources, machines, or personnel needed to perform each task; and (4) the total resources available. This constraint has proven its usefulness in large scheduling problems.

Algorithms for solving linear equations and inequations have been thoroughly studied in algebra and in OR. The latter field has also evidenced significant interest in quadratic programming, whereby one extends the notion of optimality to quadratic objective functions.

A way of handling quadratic constraints is through the use of interval constraints and linearization, followed by multiple applications of the simplex method. More specifically, one can attempt to linearize quadratic terms by introducing new variables and finding their minimal and maximal values using the classic simplex algorithm. This process is repeated until convergence is reached. (See paper by Lebbah et al. in Van Hentenryck (2002).) Therefore, quadratic constraints can be viewed as a variant of global constraints. An earlier interesting algebraic approach to quadratic constraints is described in Pesant and Boyer (1994).

65.9.3 Control Issues

In LP or CLP, one has limited control of control viewed as a component of the pseudo-equations $LP = logic + control$ or $CLP = constraints + control$. In the LP-CLP paradigm, control is achieved through (1) ordering of rules, (2) ordering of predicates on the right-hand side of a rule, (3) usage of the *cut* or special predicates like *freeze*, and (4) metalevel interpretation. Most processors for LP-CLP utilize a rather rigid, depth-first, top-down search. (A notable exception is the XSB (Stony Brook) PROLOG processor that uses a tabling approach.)

The issues of backtracking and control have been more thoroughly investigated in CSP than in LP-CLP. This is not surprising because general LP-CLP processors usually utilize a fixed set of strategies. Control in CSP is achieved through (1) ordering of variables, (2) ordering of the values to be assigned to each variable, (3) deciding how much backtracking is performed before resuming a forward execution, and (4) utilizing information gathered at failure states to avoid them in future searches.

In CSP processors, efforts have been made to have language constructs that specify various control strategies available to a user. These have been called *indexicals* and dictate the order in which various alternative narrowing methods are applied.

A trend in control strategies is to use stochastic searches: random numbers and probability criteria are used to select starting nodes of the search tree; information gathered at failure states is also used to redirect searches. Stochastic searches are not complete (i.e., they do not ensure a solution if one exists). Therefore, one must specify a limited time for performing random searches; once that time is reached, the search can restart using new random numbers and information gathered in previous runs. Stochastic searches have proven highly successful in dealing with very large CSP.

Frequently, problems expressed as CSP have multiple successful and unsuccessful situations that are symmetric. The goal of *symmetry breaking* is to bypass searches that, due to the symmetrical nature of a problem, are uninteresting to pursue. A typical example is the n -queens problem in which a multitude of equivalent symmetrical solutions are found but have to be discarded; the same occurs with unsuccessful configurations that have already been proven to yield no solutions.

65.9.4 Optimization

CSP may have a large number of valid solutions. This parallels the situation where LP-CLP processors are used to solve combinatorial problems. In those cases, it is important to select one or a few among multiple solutions by specifying an objective function that has to be maximized or minimized. In the case of finite domains or interval constraints, one may have to resort to exhaustive searches.

For interval constraints, this amounts to splitting a given interval into two or more subintervals. When dealing with small finite domains, one may have to explore each possible value within the domain. The reader is referred to Chapters 15 and 63 of this Handbook where searches and combinatorial optimization are covered in greater detail. In particular, the *branch-and-bound* strategies are often used in CSP with objective functions. In the CLP paradigm, it is often up to the user to perform optimization searches by developing specific programs.

65.9.5 Soft Constraints

It is not uncommon that, in trying to establish a set of constraints, one is confronted with an overconstrained configuration that is unsatisfiable. It is then relevant to attempt to modify certain constraints so that the system becomes satisfiable.

There are several criteria for “relaxing” an overconstrained system. In general, those criteria involve some sort of optimization; for example, one may choose to violate the least number of individual constraints. Another possibility is to assign a weight to each constraint, specifying the tolerated “degree of unsatisfaction.” In that case, one minimizes some function combining those specified weights.

Alternatively, one can assign probabilities to the desirability that a given constraint should be satisfied and then maximize a function expressing the combined probability for satisfying all the constraints (this is referred to as fuzzy constraints).

The usage of “preferences” is another way of loosening overconstrained systems. Consider, for example, the case of the n -queens problem: one may wish to allow solutions that accept attacking queens provided they are far apart. Whenever there are solutions with non-attacking queens, those are preferred over the ones having attacking but distant queens. Preferences are specified by an ordering stipulating that constraint C_1 is preferable to constraint C_2 (e.g., $C_1 > C_2$).

A work in the area of soft constraints provides a general framework for relaxing overconstrained systems (see Bistarelli et al. in Van Hentenryck, 2002). That framework ensures that if certain algebraic (semiring) properties are respected, one can define soft constraints expressing most variants of the previously illustrated constraint relaxation approaches.

65.9.6 Satisfiability Problems

The satisfiability problem can be described as follows: given a Boolean formula B with n variables, are there *true* or *false* assignments to the variables that render B true? (see Chapters 6 and 66 for further details.) It is usual to have B expressed in conjunctive normal form (CNF), consisting of conjunctions of disjunctions of variables or their negations.

Boolean formulas in CNF can be further transformed into equivalent ones whose disjunctions contain three variables negated or not or the constants *true* and *false*. That variant of the satisfiability problem is known as 3SAT and enjoys remarkable properties. The class NP-complete (see Chapter 6) congregates combinatorial problems that can be reduced to SAT problems in polynomial time. Therefore, 3SAT can be viewed as a valid standard for studying the practical complexity of hard problems. Furthermore, it is possible to show that 3SAT problems can be transformed into CSP.

Consider a random 3SAT problem with n variables and m clauses. It is intuitive to check that when n is large and m is small, the likelihood of satisfiability is high. On the other hand, when m is large and n is small, that likelihood is low. The curve expressing the ratio m/n versus the probabilities of satisfaction consists of two relatively flat horizontal components indicating high or low probabilities of satisfaction.

It has been empirically determined that in the region around $m/n = 4.5$, the curve decreases sharply; problems in that region have around 50% probability of being satisfiable. These are the computationally intensive problems for 3SAT. The problems where m/n is small or large are in general easily solvable.

The implication of this result is that there are “islands of tractability” within very hard problems. From a theoretical viewpoint, 2SAT is polynomial and the determination of other tractability islands remains of great interest. Unfortunately, the transformation of an NP-complete problem into 3SAT distorts the

corresponding values of the m/n ratio. It has become important to find the boundaries of individual NP problems that allow their solutions using inexpensive, moderate, or expensive computational means.

The term *phase transition* establishes an analogy between algorithmic complexity and the physical properties of matter where temperatures and pressures are used to distinguish gaseous, liquid, and solid forms of states. Finding the boundary values delimiting regions of computational easiness and difficulty has become one of the important aims of CSP.

65.9.7 Future Developments

The novel and valuable future developments in CLP–CSP appear to be oriented in melding machine learning and data-mining approaches to the existing models. These developments parallel those that have occurred in the area of inductive logic programming (ILP) vis-a-vis LP. In ILP, Prolog programs are generated from positive and negative examples (Muggleton 1991, Bratko 2001).

In the case of CLP–CSP, the major question becomes: *Can constraints be learned or inferred from data?* If that is the case, then probabilistic or soft constraints are likely to play important roles in providing answers to that quest.

65.10 Applications

The main areas in which LP and CLP have proven successful are summed up in the following:

Symbolic manipulation. Although LISP and PROLOG are currently the main languages in this area, it is probable that a CLP language may replace PROLOG in the next few years. There is a close relationship between the aims of CLP and symbolic languages such as MAPLE, MATHEMATICA, and MACSYMA.

Numerical analysis and OR. The proposed CLP languages allow their users to generate and refine hundreds of equations and inequations having special characteristics (e.g., the generation of linear equations approximating Laplace's differential equations). The possibility of expressing inequations in a computer language has attracted the interest of specialists in OR. Difficult problems in scheduling have been solved using CLP in finite domains.

Combinatorics. Nondeterministic languages such as PROLOG have been successful in the solution of combinatorial problems. The availability of constraints extends the scope of problems that can be expressed by CLP programs.

Artificial intelligence applications. Boolean constraints have been utilized in the design of expert systems. Constraints have also been used in natural language processing and in parsing. The increased potential for invertibility makes CLP languages unique in programming certain applications. For example, the inverse operation of parsing is string generation.

Deductive databases. These applications have attracted a considerable number of researchers and developers who are now extending the DB domains to include constraints. The language DATALOG is the main representative, and its programs contain only variables or constants (no composite terms are allowed).

Engineering applications. The ease with which CLP can be used for generating and refining large numbers of equations and inequations makes it useful in the solution of engineering problems. Ohm's and Kirchhoff's laws can readily be used to generate equations describing the behavior of electrical circuits.

65.11 Theoretical Foundations

This section provides a summary of the fundamental results applicable to logic programs (Apt 1990, Lloyd 1987). It will be shown later that these results remain applicable to a wide class of constraint logic programs.

The semantics of LP and CLP are usually defined using either logic or sets. In the logic approach, one establishes that given both (1) a Horn clause program P and (2) a query Q , Q can be shown to be a consequence of P . In other words, $\neg P \vee Q$ is always true, or equivalently, using contradiction, $P \wedge \neg Q$ is always false. This relates the logical and operational meaning of programs; that is, that Q is a consequence of P can be proved by a resolution-based *breadth-first* theorem prover. (This is because a *depth-first* prover could loop in trying to determine a first solution, being therefore incapable of finding other solutions that may well exist.)

Logic-based semantics are accomplished in two steps. The first considers that a program yields a *yes* answer. In that case, the results (i.e., the bindings of variables to terms as the result of successive unifications) are the constraints that P and Q must satisfy so that Q becomes deducible from P . This is accomplished by Horn clause resolutions that render $P \wedge \neg Q$ unsatisfiable.

The second step of the proof is concerned with logic programs that yield a *no* answer and therefore do not specify bindings or constraints. In that case, it becomes important to make a stronger statement about the meaning of a clause.

Recall that in the case of *yes* answers, a Horn clause specifies that the *Head* is a consequence of the *Body* or equivalently that the *Head* is true if the *Body* is true. In the case of a *no* answer, the so-called Clark completion becomes applicable. That means that the *Head* is true *if and only if* the *Body* is true. Then the semantics of programs yielding a *no* answer amount to proving that *not* Q is a consequence of the completion of P . This amounts to considering the implication in *Body implies Head* in every clause of P as being replaced by *Body equivalent to Head*.

It should be noted that the preceding results are only applicable to queries that do not contain logic negation. For example, the query $\neg \text{date}(X, Y, Z)$ in the introductory example is invalid because a negative query is not in Horn clause form. Therefore, only positive queries are allowed and the behavior of the prover satisfies the so-called closed world assumption: only positive queries deducible from the program provide *yes* answers. Recent developments in the so-called nonmonotonic logic extend programs to handle negative queries.

The second approach in defining the semantics of LP and CLP uses sets. Consider the set S_0 of all unit clauses in a program P . This set involves assigning any variables in these unit clauses to elements of the Herbrand universe. Consider then the clauses whose bodies contain elements of that initial set S_0 . Obviously the *Head* of those clauses is now deducible from the program and the new set S_1 is constructed by taking the union of S_0 with the heads of clauses that have been found to be true.

This process continues by computing the sets S_2, S_3 , etc. Notice that $S(i)$ always contains $S(i - 1)$. Eventually these sets will not change because all the logical information about a finite program P is contained in them. This is called a least fixed point. Then Q is a consequence of P if and only if each conjunct in Q is in the least fixed point of P .

Consider, for example, the PROLOG program for adding two positive numbers specified by a successor function $s(X)$ denoting the successor of X :

```
add(0, X, X).
add(s(X), Y, s(Z)):- add(X, Y, Z).
```

First, notice the similarity of the preceding example with *append*. Adding 0 to a number X yields X (first rule). Adding the successor of X to a number Y amounts to adding one to the result Z obtained by adding X to Y .

In this simple example, the Herbrand universe consists of 0, $s(0)$, $s(s(0))$, and so on, namely, the positive natural numbers including the constant 0. The so-called Herbrand base considers all of the literals (in this case *add*) for which a binding of a variable to elements of the Herbrand universe satisfies the program rules. Using the set approach S_0 consists of all natural numbers because any number can be added to zero. The fixed point corresponds to the infinite set of bindings of X, Y , and Z to elements of the Herbrand universe, which satisfies both rules.

The meaning of a program P and query Q yielding a *no* answer can also be specified using set theory. In that case, one starts with the set corresponding to the Herbrand universe H_0 . Then this set is reduced to a smaller set by using once the rules in P . Call this new set H_1 . By applying again the rules in P , one obtains H_2 , and so on. In this case there is not necessarily a fixed point H_n . The property pertaining to programs yielding *no* answers then consists of the following statement: *not* Q is a logical consequence of the completion of Q if and only if some conjunct of Q is not a member of H_n .

In addition to programs yielding *yes* or *no* answers, there are those that loop. The halting problem tells us that we cannot hope to detect all of the programs that will eventually loop. Let us consider, as an example, the program P_1 :

$$\begin{aligned} & p(a). \\ & p(b): \neg p(b). \end{aligned}$$

As expected, the queries $Q_1: p(a)$ and $Q_2: p(c)$ yield, respectively, *yes* and *no* because $p(a)$ is a consequence of P_1 , and $\neg p(c)$ is a consequence of the completion of p_1 ; that is,

$$p(X) \equiv (X = a) \vee (X = b \wedge p(b))$$

However, the interpreter will loop for the query $Q_3: p(b)$, or when all solutions of $Q_4: p(X)$ are requested. As mentioned earlier, the preceding theoretical results can be extended to CLP languages. Jaffar and Lassez (1987) established two conditions that a CLP extension to PROLOG must satisfy so that the semantic meaning (using logic or sets) is still applicable. The first is that the replacement of unification by an algorithm that tests the satisfiability of constraints should always yield a *yes* or *no* answer. This property is called *satisfaction-completeness* and it is obviously satisfied by the unification algorithm in the domain of trees. Similarly, the property applies to systems of linear equations in the domain of rationals and even to polynomial equations but with a significantly larger computational cost.

The second of Jaffar and Lassez's conditions is called *solution-compactness*. It basically states that elements of a domain (say, irrational numbers) can be defined by a potentially infinite number of more stringent constraints that bound their actual values by increasingly finer approximations. For example, the real numbers satisfy this requirement. For more detail on Jaffar and Lassez's theory, see Jaffar and Maher (1994) and Cohen (1990). Existing CLP languages satisfy the two conditions established by Jaffar and Lassez.

The beauty of the Jaffar and Lassez metatheory is that they have established conditions under which the basic theorems of LP remain valid, provided that the set of proposed axioms specifying constraints satisfy the described properties.

A convenient (although incomplete) taxonomy for CLP languages is to classify them according to their domains or combinations thereof. One can have CLP (rationals) or CLP (Booleans, reals). PROLOG can be described as CLP (trees) and CLP (R) as CLP (reals, trees). A complete specification of CLP language would also have to include the predicates and operations allowed in establishing valid constraints.

From the language design perspective, the designer would have to demonstrate the correctness of an efficient algorithm implementing the test for constraint satisfiability. This is equivalent to proving the satisfiability of the constraints specified by the axioms.

65.12 Metalevel Interpretation

Metalevel interpretation allows the description of interpreters for the languages (such as LISP or PROLOG), using the languages themselves. In PROLOG, the metalevel interpreter for pure programs consists of a few lines of code. The procedure `solve` has as a parameter a list of PROLOG goals to be processed. The interpreter assumes that the program rules are stored as unit clauses:

$$\text{clause}(\text{Head}, \text{Body}).$$

each corresponding to a rule: *Head:- Body.*, where *Head* is a literal and *Body* is a list of literals. Unit clauses are stored as *clause(Head, [])*. The interpreter is

```

solve([ ]).
solve([Goal|Restgoal]):- solve(Goal), solve(Restgoal).
solve(Goal):- clause(Goal, Body), solve(Body).

```

The first rule states that an empty list of goals is logically correct. (In that case, the interpreter should print the latest bindings of the variables.) The second rule states that when processing (i.e., *solving*) a list of goals, the *head* and then the *tail* of the list should be processed. The third rule specifies that when a single *Goal* is to be processed, one has to look up the database containing the clauses and process the *Body* of the applicable clause. In the preceding interpreter, metainterpreter unification is implicit. One could write metainterpreters in which the built-in unification is replaced by an explicit sequence of PROLOG constructs using the impure features.

A very useful extension often incorporated into interpreters is the notion of co-routining or lazy evaluation. The built-in procedure *freeze(X, P)* tests whether the variable *X* has been bound. If so, *P* is executed; otherwise, the pair (*X, P*) is placed in a freezer. As soon as *X* becomes bound, *P* is placed at the head of the list of goals for immediate execution.

The procedure *freeze* can be easily implemented by expressing it as a variant of *solve* also written in PROLOG. Although this metalevel programming will of course considerably slow down the execution, this capability can and has been used for fast prototyping extensions to the language (Sterling and Shapiro 1994, Cohen 1990).

Another important application of metalevel programming is partial evaluation. Its objective is to transform a given program (a set of procedures) into an optimized version in which one of the procedures has one or more parameters that are bound to a known value. An example of partial evaluation is the automatic translation of a simple (inefficient) pattern-matching algorithm, which tests if a given pattern appears in a text. When the pattern is known, a partial evaluator applied to the simple matching algorithm produces the equivalent of the more sophisticated Knuth–Morris–Pratt pattern-matching algorithm.

In a metalevel interpreter for a CLP language, a rule is represented by *clause(Head, Body, Constraints)*. Corresponding to a rule *Head:- Body {Constraints}*.

The modified procedure *solve* contains three parameters: (1) the list of goals to be processed, (2) the current set of constraints, and (3) the new set of constraints obtained by updating the previous set. The metalevel interpreter for CLP, written in PROLOG becomes

```

solve([], C, C).
solve([Goal | Restgoal], Previous_C, New_C):-
    solve(Goal, Previous_C, Temp_C),
    solve(Restgoal, Temp_C, New_C).
solve(Goal, Previous_C, New_C):-
    clause(Goal, Body, Current_C),
    merge_constraints(Previous_C, Current_C, Temp_C),
    solve(Body, Temp_C, New_C).

```

The heart of the interpreter is the procedure *merge_constraints*, which merges two sets of constraints: (1) the previous constraints, *Previous_C*, and (2) the constraints introduced by the current clause, *Current_C*. If there is no solution to this new set of constraints, the procedure fails; otherwise, it simplifies the resulting constraints, and it binds any variables that have been constrained to take a unique value. For example, the constraints $X \leq 0 \wedge X \geq 0$ simplify to the constraint $X = 0$, which implies that *X* can now be bound to 0.

The design considerations that influence the implementation of this procedure will be discussed in Section 65.13. Note that the controversial unit logical inference steps per second (LIPS), often used to

estimate the speed of PROLOG processors, loses its significance in the case of a constraint language. The number of LIPS is established by counting how many times per second the procedure *clause* is activated; in the case of CLP, this time to process *clause* and *merge_constraints* may vary significantly, depending on the constraints being processed.

65.13 Implementation

It is worthwhile to present the basic LP implementation features by describing an interpreter for the simplified PROLOG of Section 65.5 written in a Pascal or C-like language. The reader should note the similarities between the metalevel interpreter *solve* of the previous section and the one about to be described. The rules will be stored sequentially in a database implemented as a 1D array *Rule[l..n]* and containing pointers to a special type of linear list. Such a list is a record with two fields, the first storing a letter and the second being either *nil* or a pointer to a linear list. Let the (pointer) function *cons* be the constructor of a list element, and assume that its fields are accessible via the (pointer) functions *head* and *tail*. The first rule is stored in the database by

$$\text{Rule}[1] := \text{cons}('a', \text{cons}('b', \text{cons}('c', \text{cons}('d', \text{nil}))))).$$

The fifth rule defining a unit clause is stored as $\text{Rule}[5] := \text{cons}('e', \text{nil})$. Similar assignments are used to store the remaining rules.

The procedure *solve* that has as a parameter a pointer to a linear list is capable of determining whether or not a query is successful. The query itself is the list with which *solve* is first called. The procedure uses two auxiliary procedures *match* and *append*; *match* (*A*, *B*) simply tests if the alphanumeric *A* equals the alphanumeric *B*; *append*(*L1*, *L2*) produces the list representing the concatenation of *L1* with *L2* (this is equivalent to the familiar *append* function in LISP: it basically copies *L1* and makes its last element point to *L2*).

The procedure *solve*, written in a Pascal-like language, appears in Figure 65.3. Recall that the variable *n* represents the number of rules stored in the array *Rule*. The procedure performs a depth-first search of the problem space where the local variable is used for continuing the search in case of a failure. The head of the list of goals *L* is matched with the head of each rule. If a match is found, the procedure is called recursively with a new list of goals formed by adding (through a call of *append*) the elements of the tail of the matching rule to the goals that remain to be satisfied. When the list of goals is *nil*, all goals have been satisfied and a success message is issued. If the attempts to match fail, the search is continued in the previous recursion level until the zeroth level is reached, in which case no more solutions are possible. For example, the query *a, e.* is expressed by $\text{solve}(\text{cons}('a', \text{cons}('e', \text{nil})))$ and yields the two solutions presented in Section 65.5 on resolution of Horn clauses.

Note that if the tree of choices is finite, the order of the goals in the list of goals is irrelevant insofar as the presence and number of solutions are concerned. Thus, the order of the parameters of *append* in Figure 65.3 could be switched, and the two existing solutions would still be found. Note that if the last rule were replaced by *a:-f, a.*, the tree of choices would be infinite and solutions similar to the first solution would be found repeatedly. The procedure *solve* in Figure 65.3 can handle these situations by generating an infinite sequence of solutions. However, had the preceding rule appeared as the first one, the procedure *solve* would also loop, but without yielding any solutions. This last example shows how important the ordering of the rules is to the outcome of a query. This explains Kowalski's dictum program = logic + control, in which control stands for the ordering and (impure) control features such as the cut (Kowalski 1979).

It is not difficult to write a recursive function *unify*, which, given two terms, tests for the result of unification using the contents of Table 65.1 (Section 65.5). For this purpose, one has to select a suitable data structure. In a sophisticated version, terms are represented by variable-sized records containing pointers to other records, to constants, or to variables. Remark that the extensive updating of linked data

structures inevitably leads to unreferenced structures that can be recovered by a garbage collection. It is frequently used in most PROLOG and CLP processors.

A simpler data structure uses linked lists and the so-called Cambridge Polish notation. For example, the term $f(X, g(Y, c))$ is represented by $(f(var\ x)(g(var\ y)(const\ c)))$, which can be constructed with *conses*.

As mentioned in Section 65.5, if the result of unification results in the binding $Y = g(Y, c)$, then (most) PROLOG interpreters would soon get into difficulties because most implementations of the described unification algorithm cannot handle circular structures. Manipulating these structures (e.g., printing, copying) would result in an infinite loop unless the so-called occur check is incorporated to test for circularity.

The additional machinery needed to incorporate unification into the procedure *solve* of Figure 65.3 is described in Cohen (1985). An important remark is in order: when introducing unification, it is necessary to *copy* the clauses in the program and introduce new variables (which correspond to parameters that should be called by value). The frequent copying and updating of lists makes it almost mandatory to use garbage collection, which is often incorporated to LP processors.

65.13.1 Warren Abstract Machine

D.H.D. Warren, a pioneer in the compilation of PROLOG programs, proposed in 1983 a set of primitive instructions that can be generated by a PROLOG compiler, usually written using PROLOG. (Warren's approach parallels that of P-code used in early Pascal compilers.) The *Warren abstract machine* (WAM) primitives can be efficiently interpreted using specific machines.

The main data structures used by the WAM are (1) the recursion stack, (2) the heap, and (3) the trail. The heap is used for storing terms and the trail for backtracking purposes. The WAM uses the copying approach mentioned in the beginning of this section. A local garbage collector takes advantage of the cut by freeing space in the trail.

The WAM has been used extensively by various groups developing PROLOG compilers. Its primitives are of great efficiency in implementing features such as tail-recursion elimination, indexing of the head of the clause to be considered when processing a goal, the cut, and other extralogical features of PROLOG. A useful reference in describing the WAM is the one by Ait-Kaci (1991). A reference on implementation is by Van Roy (1994).

65.13.2 Parallelism

Whereas for most languages it is fairly difficult to write programs that automatically take advantage of operations and instructions that can be executed in parallel, PROLOG offers an abundance of opportunities for parallelization. There are at least three possibilities for performing PROLOG operations in parallel:

1. *Unification*. Because this is one of the most frequent operations in running PROLOG programs, it would seem worthwhile to search for efficient parallel unification algorithms. Some work has already been done in this area (Jaffar et al. 1992). However, the results have not been encouraging.
2. *And parallelism*. This consists of simultaneously executing each procedure in the tail of a clause. For example, in $a(X, Y, U) :- b(X, Z), c(X, Y), d(T, U)$, an attempt is made to continue the execution in parallel for the clauses defining b , c , and d . The first two share the common variable X ; therefore, if unification fails in one but not in the other, or if the unification yields different bindings, then some of the labor done in parallel is lost. However, the last clause in the tail can be executed independently because it does not share variables with the other two.
3. *Or parallelism*. When a given predicate is defined by several rules, it is possible to attempt to apply the rules simultaneously. This is the most common type of parallelism used in PROLOG processors. Kergommeaux and Codognet (1994) is a recommended survey of parallelism in PROLOG.

65.13.3 Design and Implementation Issues in Constraint Logic Programming

There is an important implementation consideration that appears to be fulfilled in both CLP(R) and PROLOG IV: the efficiency of processing PROLOG programs (without constraints) should approach that of current PROLOG interpreters; that is, the overhead for *recognizing* more general constraints should be small.

There are three factors that should be considered when selecting algorithms for testing the satisfiability of systems of constraints used in conjunction with CLP processors. They are (1) incrementality, (2) simplification, and (3) canonical forms. The first is a desirable property that allows an increase in efficiency of multiple tests of satisfiability (by avoiding recomputations). This can be explained in terms of the metalevel interpreter for CLP languages described in Section 65.11: if the current system of constraints S is known to be satisfiable, the test of satisfiability should be incremental, minimizing the computational effort required to check if the formula remains satisfiable or not. Classic PROLOG interpreters have this property because previously performed unifications are not recomputed at each inference step. There are modifications of Gaussian methods for solving linear equations that also satisfy this property. This is accomplished by introducing temporary variables and replacing the original system of equations by an equivalent solved form (see Section 65.5): *variable = linear terms involving only the temporary variables*.

The simplex method can also be modified to satisfy incrementality. Similarly, the SL resolution method for testing the satisfiability of Boolean equations and the Gröbner method for testing the satisfiability of polynomial equations have this property.

In nearly all the domains considered in CLP, it may be possible to replace a set of constraints by a simpler set. This simplification can be time-consuming but is sometimes necessary. The implementor of CLP languages may have to make a difficult choice as to what level of simplification should occur at each step verifying constraint satisfaction. It may turn out that a system of constraints eventually becomes unsatisfiable, and all of the work done in simplification is lost. When a final result has to be output, it becomes essential to simplify it and present it to the reader in the clearest, most readable form.

An important function of simplification is to detect the assignment of a variable to a single value (e.g., from $X \geq 1$ and $X \leq 1$ one infers $X = 1$). This property is essential when implementing a modified simplex method that detects when a variable is assigned to a single value. Note that this detection is necessary when using lazy evaluation.

The incremental algorithms for testing the satisfiability of linear equations and inequations, as well as that used in the Gröbner method for polynomial equations, are capable of discarding redundant equations; therefore, they perform some simplifications (Sato and Aiba 1993).

The canonical (solved) forms referred to earlier in this section can be viewed as (internal) representations of the constraints, which facilitate both the tests of satisfiability and the ensuing simplifications. For example, in the case of the Gröbner method for solving polynomial equations, the input polynomials are internally represented in a normal form, such that variables are lexicographically ordered and the terms of the polynomials are ordered according to their degrees. This ordering is essential in performing the required computations. Also note that if two seemingly different constraints have the same canonical form, only one of them needs to be considered. Therefore, the choice of appropriate canonical forms deserves an important consideration in the implementation of CLP languages (Jaffar and Maher 1994).

65.13.4 Optimization Using Abstract Interpretation

Abstract interpretation is an enticing area of computer science initially developed by Cousot and Cousot (1992); it consists of considering a subdomain of the variables of a program (usually a Boolean variable, e.g., one representing the evenness or oddness of the final result). Program operations and constructs are performed using only the desired subdomain. Cousot proved that if certain conditions are applicable

to the subdomains and the operations acting on their variables, the execution is guaranteed to terminate. Dataflow analyses, partial evaluation, detection of safe parallelism, etc., can be viewed as instances of abstract interpretation. The research group at the University of Louvain, Belgium, has been active in exploring the capabilities of abstract interpretation in LP and CLP.

65.14 Research Issues

It is worthwhile to classify the numerous extensions of PROLOG into three main categories, namely, those related to (1) resolution beyond Horn clauses, (2) unification, and (3) others (e.g., concurrency). Major extensions of the unification became very significant and resulted in a new area of LP called constraint logic programming or CLP that was dealt with in Section 65.8; nevertheless, the more recent addition to CLP dealing with the domain of intervals is discussed in this section.

65.14.1 Resolution beyond Horn Clauses

Several researchers have suggested extensions for dealing with more general clauses and for developing semantics for negation that are more general than that of negation by failure (see Section 65.7). Experience has shown that the most general extension, that is, to the general predicate calculus, poses difficult combinatorial search problems. Nevertheless, substantial progress has been made in extending LP beyond pure Horn clauses. Two such extensions deserve mention: stratified programs and generalized predicate calculus formulas in the *body* part of a clause.

Stratified programs are variants of Horn clause programs that are particularly applicable in deductive databases; true negation may appear in the body of clauses, provided that it satisfies certain conditions. These stratified programs have clean semantics based on logic and avoid the undesirable features of negation by failure (see Minker 1987).

To briefly describe the second extension, it is worthwhile to recall that the procedural interpretation of resolution applied to Horn clauses is based on the substitution model: a procedure call consists of replacing the call by the body of the procedure in which the formal parameters are substituted by the actual parameters via unification. The generalization proposed by Ueda and others can use the substitution model to deal with the clauses of the type *head*:- (a general formula in the predicate calculus containing quantifiers and negation).

65.14.2 Concurrent Logic Programming and Constraint Logic Programming

A significant extension of LP has been pursued by several groups. A premise of their effort can be stated as follows: a programming language worth its salt should be expressive enough to allow its users to write complex but efficient operating systems software (as is the case of the C language). With that goal in mind, they incorporated into LP the concepts of *don't care nondeterminism* as advocated by Dijkstra. The resulting languages are called concurrent LP languages. The variants proposed by these groups were implemented and refined; they have now converged to a common model that is a specialized version of the original designs.

Most of these concurrent languages use special punctuation marks “?” and “|”. The question mark is a shorthand notation for *freezes*. For example, the literal $p(X ?, Y)$ can be viewed as a form of $\text{freeze}(X, p(X, Y))$. The vertical bar is called *commit* and usually appears once in the tail of clauses defining a given procedure. Consider, for example,

$$a:- b, c \mid d, e.$$

$$a:- p \mid q.$$

The literals b , c , and d , e are executed using *and* parallelism. However, the computation using *or* parallelism for the two clauses defining a continues only with the clause that first reaches the *commit* sign.

For example, if the computation of b , c proceeds faster than p , then the second clause is abandoned, and execution continues with d , e only (see Saraswat 1993).

65.14.3 Interval Constraints

The domain of interval arithmetic has become a very fruitful area of research in CLP. Older has been a pioneer in this area (Older and Vellino 1993). This domain specifies reals as being defined between lower and upper bounds that can be large integers or rational numbers. The theory of solving most nonlinear and trigonometric equations using intervals guarantees that *if* there is a solution, that solution must lie within the computed intervals. Furthermore, it is also guaranteed that *no* solution exists outside the computed interval or unions of intervals.

The computations involve the operation of *narrowing* that consists of finding new bounds for a quantity denoting the result of an operation (say, $+$, $*$, \sin , etc.) involving operands, which are also defined by their lower and upper bounds. The narrowing operation also involves intersecting intervals obtained by various computations defining the same variable. The intersection may well fail (e.g., the equality operation applying to operands whose intervals are disjoint). The narrowing is guaranteed to either converge or fail. This, however, may not be sufficient to find possible solutions of interest. One can nevertheless split a given interval into two or more unions of intervals and proceed to find a more precise solution, if one exists. This is akin to enumeration of results in CLP.

The process of splitting is a *don't know nondeterministic* choice, an existing component of LP. The failure of the narrowing operation is analogous to that encountered in CLP when a constraint is unsatisfiable and backtracking occurs. Therefore, there is a natural interaction between LP and the domain of intervals. Interval arithmetic is known to yield valuable results in computing the satisfiability of nonlinear constraints or in the case of finite domains. Its use in linear constraints is an active area of research because results indicate a poor convergence of narrowing. In the case of polynomials, constraints interval arithmetic may well be a strong competitor to Gröebner base techniques.

65.14.4 Constraint Logic Programming Language Design

A current challenge in the design and implementation of CLP is to blend computations in different domains in a harmonious and sound manner. For example, the reals can be represented by intervals whose bounds are floating-point numbers (these have to be carefully implemented to retain soundness due to rounding operations). Actually, floating-point numbers are nothing more than (approximate) very large integers or fractions. This set is, of course, a superset of finite domains, which in turn is a superset of Booleans. Problems in CLP language design that still remain to be solved include how to handle the interaction of these different domains and subdomains. This situation is further complicated by efficiency considerations. Linear inequations, equations, and disequations can be efficiently solved using rational arithmetic, but research remains to be done in adapting simplex-like methods to deal with interval arithmetic.

65.15 Conclusion

As in most sciences, there has always been a valuable symbiosis among the theoretical and experimental practitioners of computer science, including, of course, those working in LP. Three examples come to mind: the elimination of the occur test in unifications, the cut, and the *not* operator as defined in PROLOG. These features were created by practical programmers and are here to stay. They provide a vast amount of food for thought for theoreticians. As mentioned earlier, the elimination of the occur test was instrumental in the development of algorithms for unification of *infinite trees*. Although the concept of the cut has resisted repeated attempts for a clean semantic definition, its use is unavoidable

in increasing the efficiency of programs. Finally, PROLOG's *not* operator has played a key role in extending logic programs beyond Horn clauses.

CLP is one of the most promising and stimulating new areas in computer science. It amalgamates the knowledge and experience gained in areas as varied as numerical analysis, OR, artificial languages, symbolic processing, artificial intelligence, logic, and mathematics.

During the past 20 years, LP has followed a creative and productive course. It is not unusual for a fundamental scientific endeavor to branch out into many interesting subfields. An interesting aspect of these developments is that LP's original body of knowledge actually branched into subareas, which joined previously existing research areas. For example, CLP is being merged with the area of CSPs; LP researchers are interested in modal, temporal, intuitionistic, and linear logic; relational database research now includes constraints; and OR and CLP have found previously unexplored similarities.

The several subfields of LP now include research on CLP in various domains, typing, nonmonotonic reasoning, inductive LP, semantics, concurrency, nonstandard logic, abstract interpretation, partial evaluation, and blending with functional and with object-oriented language paradigms. It will not be surprising if each of these subfields will become fairly independent from their LP roots, and the various specialized groups will organize autonomous journals and conferences. The available literature on LP is abundant, and it is likely to be followed by a plentiful number of publications in its autonomous subfields.

Key Terms

Backtracking: A manner to handle (*don't know*) nondeterministic situations by considering *one* choice at a time and storing information that is necessary to restore a given state of the computation. PROLOG interpreters often use backtracking to implement nondeterministic situations.

Breadth first: A method for traversing trees in which all of the children of a node are considered simultaneously. OR parallel PROLOG interpreters use breadth-first traversal.

Clause: A general normal form for expressing predicate calculus formulas. It is a disjunction of literals ($P_1 \vee P_2 \vee \dots$) whose arguments are terms. The terms are usually introduced by eliminating existential quantifiers.

Constraint logic programming languages: PROLOG-like languages in which unification is replaced or complemented by constraint solving in various domains.

Constraints: Special predicates whose satisfiability can be established for various domains. Unification can be viewed as equality constraints in the domain of trees.

Cut: An annotation used in PROLOG programs to bypass certain nondeterministic computations.

Depth first: A method for traversing trees in which the leftmost branches are considered first. Most sequential PROLOG interpreters use depth-first traversal.

Don't care nondeterminism: The arbitrary choice of one among multiple possible continuations for a computation.

Don't know nondeterminism: Situations in which there are equally valid choices in pursuing a computation.

Herbrand universe: The set of all terms that can be constructed by combining the terms and constants that appear in a logic formula.

Horn clause: A clause containing (at most) one positive literal. The term *definite clause* is used to denote a clause with exactly one positive literal. PROLOG programs can be viewed as a set of definite clauses in which the positive literal is the head of the rule and the negative literals constitute the body or tail of the rule.

Infinite trees: Trees that can be unified by special unification algorithms, which bypass the occur check. These trees constitute a new domain, different from that of usual PROLOG trees.

Metalevel interpreter: An interpreter written in L for the language L .

Occur check: A test performed during unification to ensure that a given variable is not defined in terms of itself (e.g., $X = f(X)$ is detected by an occur check, and unification fails).

Predicate calculus: A calculus for expressing logic statements. Its formulas involve the following:

- *Atoms:* $P(T_1, T_2, \dots)$ where P is a predicate symbol and the T_i are terms.
- *Boolean connectives:* Conjunction (\wedge), disjunction (\vee), implication (\rightarrow), and negation (\neg).
- *Literals:* Atoms or their negations.
- *Quantifiers:* For all (\forall), there exists (\exists).
- *Terms* (also called *trees*): Constructed from constants, variables, and function symbols.

Resolution: A single inference step used to prove the validity of predicate calculus formulas expressed as clauses. In its simplest version: $P \vee Q$ and $\neg P \vee R$ imply $Q \vee R$, which is called the resolvent.

SLD resolution: Selective linear resolution for definite clauses inference step used in proving the validity of Horn clauses.

Unification: Matching of terms used in a resolution step. It basically consists of testing the satisfiability or the equality of trees whose leaves may contain variables. Unification can also be viewed as a general parameter matching mechanism.

Warren abstract machine (WAM): An intermediate (low-level) language that is often used as an object language for compiling PROLOG programs. Its objective is to allow the compilation of efficient PROLOG code.

Further Information

There are several journals specializing in LP and CLP. Among them we mention the *Journal of Logic Programming* (North-Holland), *New Generation Computing* (Springer-Verlag), and *Constraint* (Kluwer). Most of the conference proceedings have been published by MIT Press. Recent proceedings on constraints have been published in the Lecture Notes in Computer Science (LNCS) series published by Springer-Verlag.

A newsletter is also available (Logic Programming Newsletter, alp@doc.ic.ac.uk). Among the references provided, the following relate to CLP languages: PROLOG III (Colmerauer 1990), CLP(R) (Jaffar et al. 1992), CHIP (Dincbas et al. 1988), CAL (Sato and Aiba 1993), finite domains (Van Hentenryck 1989), and intervals (Older and Vellino 1993). The recommended textbooks include Clocksin and Mellish (1984) and Sterling and Shapiro (1994). The theoretical aspects of LP are well covered in Apt (1990) and Lloyd (1987) and implementation in Ait-Kaci (1991), Kergommeaux and Codognet (1994), Van Roy (1994), and Warren (1983).

66.1 Introduction

High-level programming languages can be classified according to their style of programming, that is, the intended techniques to construct programs from basic elements and composing them to larger units. This is also called a *programming paradigm*. For instance, *imperative programming* is centered around named memory cells (variables) whose contents could be modified by assignments, and assignments are grouped to larger programs using control structures and procedural abstraction. *Functional programming* is based on the concept of defining functions in a mathematical sense and composing them to more complex functions. *Logic and constraint programming* focuses on defining relations between entities and solving goals containing free variables. These are the main programming paradigms.

Other paradigms often occur in combination with these main paradigms. For instance, *object-oriented programming* focuses on objects containing data and operations as basic units and inheritance to structure them. This method of organization can be combined with each of the main paradigms. For instance, Java combines object orientation with imperative programming and OCaml provides object orientation in a functional (and imperative) context. Similarly, *concurrent programming* focuses on threads or processes, which can be composed in a concurrent or sequential manner, and methods for communication and synchronization. Depending on the style of implementing the behavior of threads and processes, concurrent programming is combined with one or more of the main paradigms so that there are imperative concurrent (e.g., Java), functional concurrent (e.g., Alice, Erlang, and Concurrent Haskell), and logic concurrent (e.g., Oz) languages.

When developing software, one should select a programming language that is most appropriate for the specific task to do. If the software system is complex, it is also quite natural to use various programming languages belonging to different paradigms. For instance, database access and manipulation could be done by logic-oriented languages, transformational tasks (like XML transformations) are reasonably implemented by functional languages, and state-oriented user interaction is implemented in imperative (object-oriented) languages. However, the use of different programming languages in one application

could be cumbersome since one has to use different programming environments and implement the exchange of data between different parts of the programs. Moreover, a textual data exchange between different systems is a well-known security risk [22].

In order to improve this situation, *multiparadigm languages* have been proposed. They offer more than one programming paradigm in a single language so that “the well-educated computer programmer...should then be able to select a solution technique that best matches the characteristics of the problem to be solved” [10]. Ideally, paradigms are amalgamated in an orthogonal manner so that the programmer could freely mix the different programming techniques. In practice, however, some restrictions, depending on the amalgamated paradigms, are required to keep the advantages of the individual paradigms. For instance, in an imperative functional language, one might not freely use imperative features inside functional parts, otherwise one loses the freedom to choose optimal evaluation strategies for functional computations. Thus, the challenge in designing multiparadigm languages is to provide the features of the individual paradigms in a single language without too many restrictions.

66.2 Principles of Programming Paradigms

To understand the features of multiparadigm languages, we review in this section the basic ideas and features of the main programming paradigms. More details about these paradigms can be found in other chapters of this handbook.

66.2.1 Imperative Languages

Imperative programming is based on the mutation of variables in order to compute an intended result. Thus, they strongly reflect the computer architecture pioneered by John von Neumann where data stored in memory can be updated. In order to abstract from memory addresses, variables have names and the current computation environment maps these names to memory cells. The environment can change in imperative languages with block structures or procedures. The basic operation of an imperative language is the assignment statement where the value of a memory cell associated to a variable is changed. Collections of memory cells can be composed to data structures and collections of assignments can be composed to larger units by control structures. Procedural abstraction is used to organize larger programs. A procedure assigns a name and parameters to some computation unit so that algorithmic entities can be reused as simple statements. Procedures can also have result values (then they are called *functions*) in order to use them inside expressions. There might be a problem if the function has a *side effect*, that is, if it changes some values of nonlocal variables. In this case, the order of evaluating subexpressions might influence the result of an expression. Since this is difficult to comprehend by a programmer and inhibits or invalidates some compiler optimizations, functions with side effects are considered as a bad programming style. However, this is not forbidden in typical imperative languages.

66.2.2 Functional Languages

Functional programming is based on defining functions and composing them in expressions to more complex functions. A functional computation corresponds to the evaluation of a given expression. Purely functional languages, such as Haskell [26], do not allow side effects so that they are *referentially transparent*: the value of an expression does only depend on the values of the subexpressions and not on the order or time of evaluation. Thus, expressions can be replaced by their values without changing the result of an evaluation, and a functional computation consists of replacing equals by equals w.r.t. the function definitions.

We use the syntax of Haskell in concrete examples, that is, variables and names of defined functions start with lowercase letters and the names of type and data constructors start with an uppercase letter. The application of f to e is denoted by juxtaposition (“ fe ”). For instance, consider the function

```
square x = x*x
```

This equation expresses that `(square 3)` is equal to `(3*3)` so that the expression `5+(square 3)` can be replaced by `5+(3*3)` without changing its value. The replacement of the left-hand side of a function’s rule by its right-hand side in an expression, where the rule’s formal parameters (like `x`) are replaced by actual values, is the basic computation step in a functional program and called a *reduction step*.

Referential transparency is important to enable powerful compiler optimizations and to use advanced evaluation strategies. An *evaluation strategy* determines the next subexpression to be reduced in order to evaluate some expression. For instance, subexpressions can be evaluated in parallel or on demand. As an example, consider the function

```
f x y = if x==0 then f y (f x y) else x
```

and the main expression `(f 0 1)`, which is reduced to `f 1 (f 0 1)` (after evaluating the conditional). An *eager strategy* evaluates all arguments before a function application so that the subexpression `(f 0 1)` is reduced next. This leads to an infinite number of computation steps. On the other hand, a *demand-driven strategy* evaluates a subexpression only if its value is demanded (e.g., by a conditional or primitive operation) to proceed the computation. Since the value of the subexpression `(f 0 1)` is not demanded (since it does not occur in the condition), a demand-driven strategy reduces `f 1 (f 0 1)` to `1` (after evaluating the conditional). Hence, demand-driven (also called *lazy*) strategies are computationally more powerful than eager strategies. Demand-driven strategies also support programming with streams and infinite data structures and increase modularity [21]. Moreover, they are the basis of optimal strategies that evaluate expressions with a minimum amount of reduction steps [20].

Functional languages support the definition of data types by enumerating all constructors. For instance, the type of Boolean values is defined in Haskell as

```
data Bool = False | True
```

where `Bool` is the type name and `False` and `True` are the constructors of the type `Bool`. Functions operating on such types can elegantly be defined by *pattern matching*, that is, by several equations, also called *rules*, for different argument values:

```
and False x = False
and True x  = x
```

Thus, if the first argument of a call to `and` has the value `False`, only the first rule is applicable so that such a call reduces to `False` (without evaluating the second argument, if the strategy is demand-driven).

Another important feature of functional languages are *higher-order functions*, that is, functions that have functions as arguments or yield functions as results. Thus, functions are first-class objects that can be passed as any other data structure. The use of higher-order functions provides better code reuse since programming patterns can often be expressed as higher-order functions [21]. To support a safe use of functions, advanced type systems have been developed for functional languages. Although languages like Standard ML [25] or Haskell [26] are strongly typed, the programmer does not have to specify the type of all functions and variables since compilers can *infer* their types.

66.2.3 Logic Languages

Logic programming is based on defining relations between entities by clauses, that is, by facts or implications. For instance, in the logic programming language Prolog [12], `[]` denotes the empty list and `[X|Xs]` a nonempty list with a first element `X` and a tail list `Xs`. Then we can define the relation `member(E,Xs)` with the intended meaning “`E` is a member of the list `Xs`” as follows in Prolog:

```
member(E, [E|_]).
member(E, [_|_]) :- member(E, _).
```

Similarly to functional languages, pattern matching is also supported in logic languages. The first clause states the fact that `E` is a member if it is the first element. The second clause expresses that the membership in the tail list `Ys` implies the membership in the complete list. Logic programming allows to compute with partially known data expressed by free (unbound) variables. For instance, one can compute some members of the list `[1,2]` by solving the query `member(E,[1,2])`, which yields the two *solutions* (i.e., variable bindings for the free variable `E`) `E=1` and `E=2`. Hence, logic programming is based on a (“don’t know”) nondeterministic computation model where different computation paths are explored in order to find solutions. This principle allows to use free variables at arbitrary argument positions. For instance, the query `member(1,[X,Y])` returns the solutions `X=1` and `Y=1`.

Free variables are also useful inside program clauses. For instance, one can define a predicate that is satisfied if two lists have a common element by

```
overlapping(Xs, Ys) :- member(E, Xs), member(E, Ys).
```

Hence, logic programming supports a more abstract programming style where the programmer is not forced to implement all algorithmic details of a problem. For instance, the predicate `overlapping` is implemented without specifying a strategy to find a common element.

In order to compute solutions to a given query, logic language implementations apply program clauses to the query, similarly to functional programming, but use *unification* to equate the query and the clause’s left-hand side by binding variables to terms. For instance, the first clause of the definition of `member` can be applied to the query `member(1, [X,Y])` if the variables are bound as $\{E \mapsto 1, X \mapsto 1, Ys \mapsto [Y]\}$.

66.3 Multiparadigm Languages in Practice

In the following, we discuss a selection of various programming languages that amalgamate different programming paradigms. Due to numerous approaches to combine different paradigms, we will only discuss a few typical languages in each area.

66.3.1 Imperative Functional Languages

One could consider every modern imperative language as a combination of imperative and functional programming since they support the definition of functional abstractions. However, this viewpoint changes when advanced functional programming concepts are taken into account. For instance, not every imperative language supports higher-order functions, that is, passing defined functions as argument or result values. Since such higher-order features demand for advanced type systems, they are often supported by imperative languages without a static type system. For instance, the languages Smalltalk [15] and Ruby* allow to pass code blocks as first-class objects, and many other imperative languages, like Python† or JavaScript [14], support expressions to denote functional values.

* <http://www.ruby-lang.org/>.

† <http://www.python.org/>.

Although the presence of such features appears as a reasonable combination of imperative and functional programming, imperative languages allow the definition of functions with side effects so that the order of evaluation becomes relevant. This is in contrast to functional languages where one wants to abstract from the order of evaluation, for example, in order to optimize the evaluation of expressions. Thus, it is desirable to keep functional evaluation free of side effects, if possible, or to distinguish purely functional computations from imperative computations. In many languages combining imperative and functional programming styles, however, this distinction is not strictly enforced. For instance, the language Scala* extends a typical imperative object-oriented language with functional programming features, like type inference, pattern matching, and anonymous and higher-order functions. Scala supports the separation of imperative and functional programming styles by distinguishing mutable variables and immutable values. Nevertheless, a defined function might depend on or manipulate mutable data so that it is not free of side effects.

Instead of extending imperative languages with functional features, one could also extend functional languages with imperative features. For instance, Lisp and its dialect Scheme† support multiparadigm programming by an assignment operation that allows the mutation of any parameter or locally declared value. The language Standard ML [25] uses the type system to distinguish between mutable values, which are pointers to memory cells, and immutable values. Nevertheless, computations with side effects can be “hidden” inside functional computations. This is different in the purely functional language Haskell [26], which does not allow hiding of side effects. Operations with side effects, also called *I/O actions*, like reading or printing a character, have the result type “IO τ ”, where τ is the type of the value returned by the side effect of the operation. For instance, the operation `getChar`, which reads a character (of type `Char`) from the keyboard as a side effect, has the type signature

```
getChar :: IO Char
```

Similarly, the operation `putChar` to print a character has the type signature

```
putChar :: Char → IO ()
```

that is, it takes a character as argument but the side effect does not return a value, as indicated by the void type “()”. There are operators like “>>” to compose I/O actions sequentially. Thus, the expression

```
putChar 'a' >> putChar 'a' >> putChar 'a'
```

prints three ‘a’s as a side effect. Since I/O actions are first-class citizens as any other operation, one can also write operations to compose I/O actions. For instance, an operation to print `n` times a character `c` can be defined as follows (`return` is an I/O action that just returns its argument without an additional side effect):

```
putChars c n = if n==0 then return ()
               else putChar c >> putChars c (n-1)
```

Thus, the effect of the previous expression can also be obtained by the expression `(putChars 'a' 3)`.

It has been shown [28] that typical imperative programming techniques can be implemented using this style of composing basic I/O actions to larger units. The important point is that there are no operations of type `IO $\tau \rightarrow \tau'$` where τ' is not an IO type. Thus, it is not possible to hide an operation with side effects inside another operation, in contrast to most other programming languages with imperative features. As a consequence, the type system of Haskell ensures a clear separation between purely

* <http://www.scala-lang.org>.

† <http://www.schemers.org/>.

functional parts and program sections with side effects. Any operation having some side effect has the result type “ $\text{IO } \tau$ ”. Therefore, purely functional expressions can be evaluated in any “good” order. Actually, Haskell uses a lazy evaluation strategy for expressions. However, I/O actions have to follow the sequential evaluation order as specified by applications of the operator “ $>>$ ”. More details about this kind of integrating imperative features in a purely functional language, also called *monadic I/O*, can be found in [37].

66.3.2 Imperative Logic Languages

The amalgamation of imperative and logic programming paradigms does not seem reasonable due to the very different computation models. Thus, there are only few approaches in this direction. On the one hand, logic programming languages like Prolog offer primitive predicates with side effects to perform I/O or manipulate some global state. Although such impure predicates are often used in application programming, this is a rather ad hoc use of imperative features in logic programming. A conceptually cleaner integration is present in logic languages that offer also functional features, like Mercury [35] or Curry [18], since such languages can use the monadic I/O approach from functional languages sketched earlier. This will be discussed later on.

As an alternative, one could also add logic programming features to an imperative language. This approach has been explored in the multiparadigm language Leda [10] and later in Alma-0 [8], an imperative language with logic programming features. The language Alma-0 is based on a subset of Modula-2 and allows Boolean expressions as statements whose computation can succeed or fail depending on the truth value of the expression. Furthermore, statements have also truth values depending on their successful evaluation, that is, a successful computation has value TRUE and a failing one value FALSE. Hence, the following statement sequence returns TRUE if the (integer) array *a* is smaller than array *b* (where both arrays have *n* elements) w.r.t. the lexicographic ordering [8]:

```
NOT FOR i:=1 TO n DO a[i] = b[i] END;
a[i] < b[i]
```

Since statements, like the FOR loop, have also truth values, they can also be used as arguments to Boolean operations like NOT. Operationally, the execution of the FOR loop fails (and terminates) when it reaches two different elements *a*[*i*] and *b*[*i*]. Due to negation (NOT), the execution of the first line yields TRUE in this case so that the second line is executed that checks the ordering of the different elements.

In order to support the backtracking search mechanism of Prolog, Alma-0 offers an EITHER-ORELSE statement to combine alternative computations to be explored by backtracking. Furthermore, there are control structures to commit to one successful alternative or to explore all alternatives (FORALL). Imperative features can be used to collect information about all alternatives by mutable variables. For instance, the following program fragment uses a mutable variable *num* to count how many of the variables *a, b, c, d* have the value *x*:

```
num:=0;
FORALL
  EITHER a=x ORELSE b=x ORELSE c=x ORELSE d=x END
DO
  num:=num+1;
END;
```

Furthermore, Alma-0 supports a limited form of unification by distinguishing between uninitialized and initialized variables. The integrated imperative and logic programming features support a compact and comprehensible implementation of typical search problems (e.g., see [8]).

66.3.3 Functional Logic Languages

Functional and logic programming are the main *declarative programming* paradigms. Both are based on the idea to describe logical relationships of a problem rather than the individual steps to compute a solution to a problem. Furthermore, functional as well as logic languages have strong mathematical foundations, namely, the lambda calculus and predicate logic. Thus, one might expect that integrating these paradigms is easily possible. However, there are many different options so that the integration of these paradigms have a long history, starting with the extension of Lisp with logic programming features [30]. Detailed surveys about these developments can be found in [16,17].

A lightweight integration of both paradigms can be obtained by small extensions that implement some programming features of one paradigm in the other. For instance, one can extend a logic programming language by some syntax for functional notations. Since any function can also be considered as a relation between the arguments and the result, functional notations can easily be translated into logic programming constructs [11]. Alternatively, one can use lists and list comprehensions to implement search problems in functional languages [36]. However, such approaches do not exploit the potential offered by the amalgamation of both paradigms. List comprehensions do not offer computation with partial information and constraints, as in logic programming, and the translation of functions into predicates do not exploit functional dependencies to obtain good or optimal evaluation strategies. The main objective of multiparadigm languages is to provide the advantages of the different paradigms in a single language. Thus, a functional logic language should combine efficient, demand-driven evaluation strategies from functional programming with nondeterministic search and computing with partial information from logic programming. If this is carefully done, one gets additional advantages like a demand-driven exploration of the search space. The language Curry [18] is a recent example for such a language and, therefore, discussed in the following in more detail.

Similarly to the nonstrict functional language Haskell, the functional logic language Curry* has been developed by an international initiative to create a standard functional logic language that can be used in research, teaching, and applications of such languages. The syntax of Curry is close to Haskell, as introduced in Section 66.2.2. Hence, operations can be defined by pattern matching:

```
not False = True
not True  = False
```

As in functional programming, computation or evaluation of an expression consists of replacing subexpressions by equal (w.r.t. the rules defining the operations) subexpressions until no more reductions are possible. For instance, `not (not True)` can be evaluated as follows (the subexpression to be replaced is underlined):

```
not (not True) → not False → True
```

So far, these features are identical to functional programming. Logic programming features are supported by allowing computations with partially known values. For instance, in Curry it is allowed to apply an operation to a *free variable* (i.e., a variable not bound to any value). In this case, the free variable will be bound to some value such that the computation can proceed. Consequently, the result of such a computation consists of a binding *and* a value. For instance, the evaluation of `(not x)` yields two results:

```
{x = False} True
{x = True}  False
```

* <http://www.curry-language.org>.

The first result line can be read as “the result of `(not x)` is `True` provided that the variable `x` is bound to `False`.” Similarly to logic programming, an expression might have more than one result.

Free variables can also occur inside data structures. Consider the following definition of an infix operator “`++`” to concatenate two lists (as in Haskell, “[]” denotes the empty list and “`x:xs`” a nonempty list with a first element `x` and a tail list `xs`):

```
[ ] ++ ys = ys
(x:xs) ++ ys = x : (xs++ys)
```

Then the condition `(zs++[3]) == [1,2,3]`, also called an *equational constraint*, is satisfied if the free variable `zs` is bound to the list `[1,2]`, since the concatenation `[1,2]++[3]` evaluates to `[1,2,3]`. Several equational constraints can be combined to one constraint by the infix operation “`&`” (“and”). For instance, the only solution to the constraint

```
(xs++ys) == [1,2,1] & ([2]++xs) == ys
```

is `{xs = [1], ys = [2,1]}`. We can use such conditions in the definition of operations to constrain the values to which free variables can be bound. For instance, an operation `last` to compute the last element of a list can be defined as follows (note that free variables must be explicitly declared in program rules):

```
last xs | (zs++[e]) == xs
      = e                where zs, e free
```

The equational constraint `(zs++[e]) == xs` is satisfied if `e` is bound to the last element of the list `xs`. Such a *conditional rule* can be applied in a computation if the condition is satisfied, for example, by binding free variables. We will later explain how such bindings can be effectively computed.

Note that logic programming features increases the reuse of code. Instead of defining the operation `last` by some recursive rules, we reused the code of “`++`” to define `last` by a condition on its input list. This condition states that the actual argument `xs` must match a result of evaluating `(zs++[e])`. This can be expressed in Curry by the following alternative definition of `last`:

```
last (zs++[e]) = e
```

Purely functional languages, like Haskell, do not allow such rules since the pattern contains a defined operation rather than constructors and variables. Such *functional patterns* [7] are a powerful feature to match deeply nested subexpressions. Since the evaluation of `(zs++[e])` has infinitely many results (e.g., `{zs=[]} [e]`, `{zs=[x1]} [x1,e]`, ...), this single rule conceptually abbreviates an infinite number of rules with ordinary patterns. Nevertheless, the overall demand-driven evaluation strategy ensures that the required patterns are evaluated on demand so that a computation space of “`last [1,2]`” is finite.

This example demonstrates the advantage of combining functional and logic programming. By using already defined operations and unknown values, one can define operations as concise specifications. Since these specifications are functional logic *programs*, they are executable (in contrast to formal specifications written in some specification language). The challenge in the design of functional languages is the development of a computation model that avoids an inefficient blind guessing of values for unknowns. Before we discuss such strategies, we proceed with an important further feature.

Logic languages support the search for solutions (they are “don’t know nondeterministic”) which simplifies many programming tasks. The same is true for functional logic languages but they offer another interesting feature, namely, the definition of *nondeterministic operations*. Such operations deliver more than one result on a given input with the intended meaning that all the results are appropriate. The archetype of a nondeterministic operation is the infix operation “`?`” that returns one of its arguments:

```
x ? y = x
x ? y = y
```

Since any rule can be used to evaluate an expression (in contrast to functional languages where only the first matching rule is applied), the expression `0?1` has two results: 0 and 1. Similarly, we can define an operation to insert an element into a list at some indeterminate position:

```
insert x ys      = x : ys
insert x (y:ys) = y : insert x ys
```

Thus, the expression `insert 0 [1,2]` evaluates to any of the results `[0,1,2]`, `[1,0,2]`, and `[1,2,0]`. One can use this operation to define a permutation of some list by inserting the first element at some position of a permutation of the tail list:

```
perm []      = []
perm (x:xs) = insert x (perm xs)
```

Permutations can be used to specify properties of operations. For instance, an operation to sort the elements of a list in ascending order can be defined as a permutation which is sorted. The latter property can be expressed as an identity operation on sorted lists (which fails on lists that are not sorted):

```
sorted []      = []
sorted [x]     = [x]
sorted (x:y:ys) | x<=y = x : sorted (y:ys)
```

Hence, the expression `sorted (perm xs)` evaluates to a sorted version of the input list `xs`. Clearly, the operational behavior of this specification of sorting is inefficient and cannot compete with sophisticated sorting algorithms. However, it should be noted that its behavior is not as bad as it seems at first glance, since the demand-driven strategy has the effect that not all permutations are computed. The evaluation of the argument `(perm xs)` is triggered by the demand of the outer operation `sorted` (which demands at most two elements for the first reduction step). If a computed permutation starts with the first two elements in a wrong order, as in `2:1:(perm ys)`, the operation `sorted` fails on this argument so that the remaining part `(perm ys)` will not be evaluated.

66.3.3.1 Evaluation Strategies

Logic programming frees the programmer from considering the individual computation steps since it is based on strong soundness and completeness results w.r.t. the underlying logic: each computed result is a logical consequence of the program (*soundness*) and each logical consequence is covered by some computed result (*completeness*) [23]. The latter property requires the exploration of all possible computation steps (also called *search space*), in particular, all rules (and not only the first matching one) need to be considered to reduce some subgoal. Similarly, functional logic computations require also the consideration of all rules. For instance, in the definition of the operation `insert` shown above, the second rule must also be considered although the first rule is always applicable. Even worse, it is not obvious to select a subexpression to start a functional logic computation. Therefore, there are many attempts to develop appropriate evaluation strategies for functional logic programming.

In order to enable the evaluation of expressions with free variables, like `not x`, reduction steps from functional programming must be combined with variable instantiation steps used in logic programming. The combination of variable instantiation and reduction is called *narrowing*. It was originally introduced in automated theorem proving [33] and later proposed for using it in programming languages [29]. To ensure completeness in general, all possible rules must be applied to all subexpressions, which results in a huge search space. However, the research in this area has developed much better strategies to restrict the number of possible computation steps without loosing completeness.

Similarly to functional languages, there are strict as well as nonstrict narrowing strategies. Due to the additional instantiation of free variables, strict strategies require sophisticated techniques to restrict the

search space. Therefore, contemporary functional logic languages are based on *nonstrict demand-driven narrowing strategies*. In contrast to purely functional languages, the selection of a demanded argument might be influenced by the instantiation of some free variable. For instance, consider an operation to return a prefix of a given length of a list, where we represent the length as a natural number constructed by zero (Z) and successor (S):

```
take Z      xs      = []
take (S n) []      = []
take (S n) (x:xs) = x : take n xs
```

If we evaluate the expression `take x e`, where `x` is a free variable, the demand to evaluate the subexpression `e` depends on the instantiation of `x`: if `x` is bound to `Z`, the value of `e` is not demanded, but it is demanded if `x` is bound to `(S v)`. Thus, it is reasonable to instantiate free variables *before* the selection of the demanded subexpression. To avoid unnecessary instantiations, free variables are instantiated only with those constructors that are necessary to determine the demanded subexpression. For instance, the variable `x` in the expression `take x e` is either instantiated to `Z`, which yields the result `[]`, or it is instantiated to `(S y)`, where `y` is a fresh free variable, so that in the next step the subexpression `e` is further evaluated.

This *needed narrowing* strategy [6] is guided by a hierarchical structure called *definitional tree* [2]. A definitional tree of an operation encodes the decisions to be performed in order to select a demanded subexpression. Its structure is determined by the patterns of the rules defining this operation. For instance, all rules defining `take` require the value of the first argument. The value of the second argument is required only if the first argument is rooted by the constructor `S`. Hence, the needed narrowing strategy evaluates an expression like `take e1 e2` by an initial case distinction on `e1`:

1. If `e1` is `Z`, the first rule is applied.
2. If `e1` is rooted by `S`, the second argument `e2` is examined (resulting in a similar case distinction).
3. If `e1` is a free variable, it is nondeterministically bound to `Z` or `(S y)` so that one can proceed with case 1 or 2.
4. If `e1` is a function call, it is evaluated by a needed narrowing step so that we start again with this case distinction.

Definitional trees exist for operations defined by case distinctions on data constructors, as in purely functional programs. In this case, needed narrowing has very strong properties. As other narrowing strategies, it is sound and complete. Moreover, it computes only needed steps, so that each computation has minimal length, and it computes only disjoint solutions, that is, no solution is repeated [6]. These properties also demonstrate the advantages of combining functional and logic programming since similar properties are not known for purely logic programs.

Operations defined by overlapping rules, like `insert` or “?” earlier, do not have definitional trees in this strong sense. However, if we consider the choice operation “?” as primitive, one can transform any operation into one with a definitional tree and possible occurrences of “?” in the right-hand side. Such programs are also called *overlapping inductively sequential* [3]. For instance, the definition of `insert` can be transformed into

```
insert x ys = (x:ys) ? (insertTail x ys)
insertTail x (y:ys) = y : insert x ys
```

One can easily extend needed narrowing to this class of programs by introducing a nondeterministic reduction step for the operation “?”. This extended strategy enjoys similar optimality properties as needed narrowing [3]. Due to these properties, contemporary implementations of functional logic languages are based on this strategy. Thus, source programs are transformed into overlapping inductively sequential programs that can be implemented by combining functional implementation techniques

(pattern matching, graph reduction) with logic implementation techniques (variable bindings, choice points). A good survey on evaluation strategies and classes of functional logic programs can be found in [4].

Backtracking is a technique used in the logic programming language Prolog to explore the search space. If the nondeterministic choices of a logic computation are organized in a tree-like structure (*search tree*), backtracking corresponds to a depth-first search in the search tree. The backtracking strategy is important in Prolog since predicates with side effects require a precisely known evaluation order. A disadvantage of backtracking is its incompleteness, that is, a computation might loop without reporting any solution although solutions exist from a declarative point of view. Since functional logic languages avoid side effects in operations (since they can use the monadic I/O approach from purely functional programming), they do not fix a particular strategy for dealing with nondeterministic computations. Although backtracking is used in some implementations, the definition of Curry [18] does not enforce it so that there are also implementations of Curry supporting complete search strategies, like iterative deepening or breadth-first search. Moreover, functional logic languages also support the encapsulation of nondeterministic computations where the programmer can implement his own search strategies (see later sections).

66.3.3.2 Extensions

The definition of data types, operations, and expressions that are evaluated by narrowing constitutes the kernel of functional logic languages. In order to support features useful for various programming tasks and application areas, functional logic languages offer a variety of extensions. The most important ones are reviewed in the following.

Constraints are an important extension to logic programming. Constraints are based on a specific domain (e.g., truth values, real numbers, or finite sets) and operations and predicates on this domain. Although this could also be expressed as a functional logic program, constraints come also with dedicated constraint solvers, that is, specific algorithms for the considered domain. For instance, an equation like “ $3+x ::= 5$ ” can be naively solved by enumerating values for x such that the equation is valid. However, one can solve this equation without any guessing by applying Gaussian elimination and transform the equation into “ $x ::= 5-3$,” which further evaluates to “ $x ::= 2$ ”. Thus, constraints over real numbers and linear equations and inequations can be supported by a constraint solver based on Gaussian elimination and the simplex algorithm. Hence, the integration of constraints is merely a matter of implementing constraint solvers but does not require an extension of the base language. Similarly to equational constraints, further type of constraints can be added. For instance, constraint solvers for finite domains usually offer a constraint `allDifferent`, which has a list of integer values as an argument. It is satisfied if all values are pairwise different. This can be used to compute solutions to SuDoku puzzles in a straightforward way. If we use some higher-order functions that are standard in functional programming, like `map` (applying an operation to each element of a list) or `foldr1` (accumulating a list by applying a binary operation to all elements), we can solve SuDoku puzzles by the following constraint, where `m` is a matrix (list of elements) containing digits and free variables for unknown elements (`transpose` is the standard matrix transposition and `squaresOfNine` computes the list of 3×3 sub-matrices):

```
foldr1 (&) (map allDifferent m) &
foldr1 (&) (map allDifferent (transpose m)) &
foldr1 (&) (map allDifferent (squaresOfNine m))
```

The first line constrains all rows to contain different digits, the second and the third line constrains the same for all columns and submatrices, where all individual constraints are combined by the conjunction operator `&`. Although the number of potential solutions is quite high, the constraint solver `allDifferent` restricts them so that solutions are found in a few milliseconds. More details about the use of finite domain constraints in functional logic languages are discussed in [13], whereas [31] reviews the general approaches to integrate constraints into functional logic languages.

Encapsulated search is a technique to process the different results of a nondeterministic computation inside a functional logic program. This is often necessary to print all solutions or to select a “best” solution according to some ordering. Whereas logic programming languages like Prolog offer built-in predicates like `findall` with a fixed (backtracking) strategy, functional logic languages generalize this in order to support the possibility to define arbitrary search strategies. For instance, the primitive operation (`getSearchTree e`) returns the search tree corresponding to the evaluation of e , where a search tree is some computed value, a failure, or a choice between two trees:

```
data SearchTree a = Value a | Fail
                  | Or (SearchTree a) (SearchTree a)
```

Thus, concrete values can be extracted from this structure by operations implementing standard tree traversals. Due to the overall demand-driven strategy, search trees are also constructed on demand so that infinitely many values do not cause the nontermination of the operator `getSearchTree` if one selects only a single value. More details about encapsulated search and a review of different approaches can be found in [9].

Input/output is often neglected or integrated in an ad hoc manner in logic languages. Due to the functional component, functional logic languages often use the monadic I/O concept from purely functional programming (see Section 66.3.1). However, functional logic computations may be nondeterministic so that it might be unclear which I/O action should be finally applied. Therefore, it is required that nondeterministic computations between I/O actions must be encapsulated. This can be done by the methods described above. Using I/O actions, one can access and manipulate global data like databases, networks, etc., so that imperative programming features are also available for programming. However, the type system ensures, as in Haskell, a strict separation of the imperative and declarative programming features, which is essential to support flexible and optimal evaluation strategies.

Concurrency features are available in functional logic languages in various shapes. One approach is based on concurrent logic programming [32] where different predicates are concurrently evaluated and synchronized on a common constraint store. In Curry, the conjunction operator “&” on constraints is actually a concurrent operator: if the evaluation of one argument suspends, the other argument is evaluated. An evaluation might suspend if some information is missing to continue it. For instance, if there is some external operation that should be used in a functional logic program, for example, a multiplication operation implemented in some foreign language like C or Java, then this external operation might not be able to deal with free variables. Instead of raising a run-time failure, one can suspend this computation until the variable is bound in another part of the program. The principle to delay the evaluation of operations applied to free variables is also called *residuation*. This alternative to narrowing is used in some languages integrating functional and logic programming, like Le Fun [1] or Oz [34]. In residuation-based languages, free variables are instantiated only by predicates or disjunctive expressions. Although residuation is a high-level method for concurrent evaluation (no side effects, synchronization on binding constraints), strong results as for needed narrowing are not known.

Another alternative for concurrency features can be found in concurrent functional programming. For instance, Concurrent Haskell [27] uses I/O actions to start concurrent processes. Synchronization and communication is implemented by I/O actions that create, read, and write mutable variables. Since I/O actions are also available in functional logic languages, this concept can also be integrated in such languages.

66.3.3.3 Further Languages

Although Curry is the only functional logic language based on strong foundations (e.g., soundness, completeness, and optimal evaluation) and used to develop larger applications, there are many other languages with similar goals. We briefly discuss some of them and relate them to Curry.

The functional logic language TOY [24] has a different syntax but executes programs also with a demand-driven narrowing strategy. In contrast to Curry, it is purely narrowing-based and does not

cover residuation or concurrency. Therefore, the connection with external operations is rather ad hoc in TOY. The language TOY also supports constraints over finite domains or real numbers but does not provide a concept to encapsulate search. In addition to Curry, TOY allows higher-order patterns on the left-hand sides of program rules.

The functional logic language Mercury [35] restricts logic programming features in order to provide a highly efficient implementation. In particular, predicates and functions must have distinct modes so that their arguments are either ground or unbound at call time. This inhibits the application of typical logic programming techniques, like computation with partially instantiated structures. This restriction is dropped in Ciao [19], which is a Prolog implementation but offers various syntactic extensions, in particular, for functional programming. Since Mercury as well as Ciao provide only functional syntax to a logic kernel language, they do not exploit the strong foundations of functional logic programming.

The language Oz [34] is based on a computation model that extends the concurrent constraint programming paradigm [32] with features for distributed programming and stateful computations. Nondeterministic computations must be explicitly represented as disjunctions so that operations used to solve equations require different definitions than operations to rewrite expressions. In contrast to Curry, the base semantics is strict so that optimal evaluations are not directly supported.

66.4 Research Issues

The integration of paradigms has made much progress from early ad hoc integrations to more systematic approaches. In particular, the integration of the functional and logic programming paradigms resulted in languages with advanced programming concepts that are based on strong theoretical foundations developed in the last years. These developments are ongoing and there are many topics for future work. Some of them are exemplified below.

Language concepts: The approaches to combine declarative programming concepts with imperative features ranges from clear separations between both concepts, for example, by type systems as in Haskell, to relaxed combinations, for example, as in Standard ML or Scala. The latter might cause problems when operations have side effects whose evaluation order is important. For instance, languages with functional features allow the implementation of demand-driven or lazy strategies using higher-order functions. Since the detailed evaluation order of a demand-driven strategy is difficult to grasp, operations with side effects should be avoided. Thus, multiparadigm languages with a relaxed combination of declarative and imperative features require techniques to support the programmer to control side effects, for instance, by advanced type and effect systems or program analysis techniques.

Although we have not considered concurrent programming as an own paradigm, the integration of concurrency and distribution features is important for current and future applications. Thus, there are many approaches for this in all main paradigms. However, multiparadigm languages might offer new concepts for concurrent and distributed programming.

Software techniques: Multiparadigm languages allow new programming techniques so that new design patterns need to be developed for such languages. The integration of declarative features allows new ways to develop reliable software. One can start with a declarative formulation and improve its efficiency if necessary. Specific program verification and transformation techniques are required to support such developments, as well as new refactoring methods.

Implementation: Multiparadigm languages can be implemented using known concepts from the individual paradigms, but it might be reasonable to develop new techniques. Sometimes, the support of several paradigms could cause an overhead compared to implementations of the individual paradigms. Thus, program analysis techniques can help to determine the required run-time support at compile time in order to optimize the target programs. New techniques to analyze and optimize multiparadigm programs are required for this purpose.

Debugging: Research in functional programming has shown that traditional trace-oriented debugging tools are often not helpful due to the more complex evaluation strategies, for example, demand-driven evaluation. This provoked the development of declarative debugging methods that visualize the program execution in a different order that is better comprehensible for the programmer. As multiparadigm languages combine features from different paradigms, debugging techniques from different paradigms need to be combined, for example, declarative debugging, trace-oriented debugging, or run-time assertions.

66.5 Summary

This chapter has discussed the main programming paradigms and the approaches to amalgamate them in a single programming language. In principle, all combinations are possible but some combinations do not preserve the properties of the individual paradigms. For instance, the combination of imperative and functional programming can lead to functions with side effects so that referential transparency is destroyed, but there are also approaches to keep the functional parts free of side effects. The most advanced and strongest combination of paradigms are functional logic languages which is due to the fact that both paradigms are based on strong formal foundations. Nevertheless, sophisticated evaluation strategies are necessary in order to combine the efficiency of functional evaluation with the flexibility of logic evaluation in an optimal manner. This combination does not only help to use the nice programming concepts of functional and logic programming in a single language, but it is also useful to improve logic programming by avoiding its impure features (like “cut”, arithmetic, I/O) since they can be replaced by functional concepts. Since purely functional languages like Haskell provide clean approaches to deal with imperative computations, they can also be used in functional logic languages leading to a combination of all three main paradigms. The programming language Curry is an example to demonstrate this in practice.

The combination of paradigms is not only useful to provide a variety of programming styles, but they are also helpful to support a smooth software development. For instance, logic programming styles are appropriate to avoid fixing algorithmic details at an early stage of the development. The examples for computing the last element of a list or to sort a list have shown that it is easier to specify what an operation should compute rather than developing an algorithm for it. In a functional logic language, such specifications are executable so that one can test them in order to become confident that they capture the intent. If they are too inefficient, one can use some algorithmic knowledge to improve the implementation, for example, by sophisticated data structures. In this case, the initial specification is valuable since it can be used as an oracle to test the new implementation or to check its execution via run-time assertions.

Finally, side effects cause many complications when parallelizing programs so that they must be carefully analyzed or mainly avoided for parallel programming. Thus, declarative programs have a big potential for parallelization in order to exploit the computational power available by current and future computer hardware. The implementation of these ideas is one of the challenges for the future.

Key Terms

Constraints: Relations on specific domains (real numbers, finite sets) together with specialized constraint solvers for these relations.

Declarative language: A language where the logical relationships of a problem are described rather than the individual steps to compute a solution. Functional and logic languages are the main classes of declarative languages. Declarative languages also occur in dedicated applications, like SQL in database programming.

Demand-driven evaluation: An evaluation strategy that reduces a subexpression only if it is strictly demanded to compute an overall result, also called *lazy evaluation* when subexpressions are evaluated at most once.

Encapsulated search: Collect the results of a nondeterministic computation in some data structure so that they can be processed inside a program.

- Evaluation strategy:** A technique to determine the next subexpression to be reduced in order to evaluate some expression.
- Functional language:** A language that is based on the definition of functions without side effects, that is, no mutable variables.
- Imperative language:** A language that is based on mutable variables and variable assignments as its basic operation.
- Logic language:** A language that is based on the definition of relations between entities and supports nondeterministic solving of goals containing unknown values.
- Multiparadigm language:** A programming language that supports more than one of the basic programming paradigms.
- Narrowing:** The combination of unification and reduction to evaluate expressions containing unknown values.
- Pattern matching:** The definition of operations by rules having data constructors as formal parameters. A programming style useful to provide specific definitions for the different cases of applying an operation.
- Programming paradigm:** Style to construct programs from basic elements and composing them to larger units. The basic paradigms are the imperative, functional, and logic programming paradigms.
- Reduction:** A computation step where the left-hand side of a defining rule is replaced by the corresponding right-hand side after instantiating formal parameters by appropriate expressions.
- Referential transparency:** A property stating that expressions can be replaced by their values without changing the result of the program. A language allowing functions with side effects is not referentially transparent.
- Residuation:** Delaying functions calls until all values are known in order to perform a reduction step.
- Side effect:** A change in the value of some variable when an expression is evaluated, for example, due to assignments in function calls of the expression.
- Unification:** A method to replace free variables in two expressions so that they become equal.

Further Information

An introduction into multi-paradigm programming together with many programming examples for the language Leda can be found in [10]. A survey on early developments and implementations of functional logic languages can be found in [16]. Later developments are reviewed in [17]. Evaluation strategies for functional logic programs are surveyed in [4]. Reference [5] contains an introduction into functional logic programming techniques.

Research papers on recent developments in the area of multi-paradigm languages can be found in various journals and conferences related to programming languages, in particular, those that are specialized in functional or logic programming, like the *Journal of Functional Programming*, *Theory and Practice of Logic Programming*, the *International Conference on Functional Programming*, or the *International Conference on Logic Programming*. There are also conference series which covers functional and logic programming research, like the *International Symposium on Principles and Practice of Declarative Programming*, the *International Symposium on Functional and Logic Programming*, or the *International Symposium on Practical Aspects of Declarative Languages*.

67.1 Introduction

According to WebMonkey [15]:

A scripting language is a simple programming language used to write an executable list of commands, called a script. A scripting language is a high-level command language that is interpreted rather than compiled, and is translated on the fly rather than first translated entirely. JavaScript, Perl, VBScript, and AppleScript are scripting languages rather than general-purpose programming languages.

A major characteristic of scripting languages is that they can serve as *glue* for connecting existing components or applications together. Scripting languages usually have powerful string processing operations since text strings are a fairly universal communication medium.

67.2 History

Scripting languages originated in the early 1960s. At that time, they were used as a device for defining the control sequence for running a series of programs one after the other. Such a series was often known as *batch processing*, and it was the predominant means for accomplishing computing tasks in commercial data processing environments at that time.

67.2.1 Shell Languages

The earliest scripting languages were the job control languages of the 1960s. Their primary use was to instruct the operating system on the sequence of steps required to run a job.

For example, a job to develop a summary sales report for the past month might have the following steps:

1. A program to select all sales records for the previous month from a larger file and copy them to a temporary file
2. A program to sort the temporary file into sequence by sales district, usually using a general-purpose utility
3. A program to calculate subtotals and present the information in a way that is easy for the end-users to read
4. A program to format and display selected pages of the end-user information on a printer or terminal.

However, these languages lacked almost all of the features you might expect, including variables, if and loop statements, expression evaluation, etc. The first true job control languages capable of scripting appeared with the emergence of Unix in the 1970s. The command interpreter in Unix was known as a *command shell*; a file of such shell commands was termed a *shell script*.

The earliest shell was known as the Bourne shell, named after its creator, Steve Bourne. Although later shells, such as the C shell created by Bill Joy, became more popular as a command interpreter, the Bourne shell maintained its popularity for writing shell scripts.

Figure 67.1 shows a typical grading script. This application assumes that all the files needed to grade a class assignment have been collected into a single directory. Each student has his/her own subdirectory. The files in the directory include input test data files, various log files, various shell scripts, etc.

The purpose of the script is to compile each student's program files, and, if successful, execute the resulting program on all of the test cases, producing an output file for each input test case.

Assuming the name of the script was `testem.sh`, it would be invoked as

```
testem.sh Freecell *
```

The first command line argument is the name of the file that contains the main program, minus its suffix.

```

1  #! /bin/sh
2  if [ $# -lt 2 ]; then
3      echo Usage: testem. sh mainprog dir1 ...
4      exit
5  fi
6
7  main=$1; shift
8  # for each student
9  for d in $*; do
10     if [ -d $d -a ! -f $d/DONE. log ]; then
11         cd $d
12         echo $d
13
14         if [ ! -f $main.class ]; then
15             cp ../*.java .
16             echo "compiling $d"
17             javac $main.java &> compile.log
18         fi
19         touch DONE.log
20         cp ../*. $data.
21         for f in ../*. $data; do
22             java $main $f < $f & > $f.log
23         done
24         cd ..
25     fi
26 done
```

FIGURE 67.1 A student test script.

When the script is invoked, it determines whether it has fewer than two arguments: the first is the file-name of the file containing the main program. The script must also be invoked with at least one student subdirectory name. If the test fails, the script prints a usage message and then quits.

Otherwise, the first command argument is stored in the variable `$main`, and then deleted from the command line. A for loop is then executed on the remaining command line arguments.

Since each student corresponds to a subdirectory, line 10 tests to see if the argument is a directory and if it is not done. If both conditions are met, then the argument represents an untested student. The next two lines change directories into the student's directory (note the `cd` back to the parent on line??) and echos the student id to the screen.

The script next checks if a class file exists for the java source; if not, it copies any instructor supplied code into the student directory and compiles the result with output diverted to the file `compile.log`.

Next we record the fact that this student has been tested by creating the file `DONE.log` in the student directory. The next four lines test the student program on a set of test data supplied by the instructor, with the output diverted to a separate file for each input test case.

For many class assignments, this is the only script we need to test the student-written programs. It handles a wide variety of cases, including the following:

- Assignments that consist of a single source file, as well as those that include both student and instructor written source code. No assumption is made about who supplied the main program file.
- The student program can obtain the command line argument and then open and read that file. Alternatively, the program can read its input from the keyboard.

Note the use of variables in the script representing the current student and the current test.

67.2.2 Text Processing Languages

As part of the development of Unix, a number of text processing utilities were developed, as well as the troff word processor for writing documentation. The next step in the evolution of scripting languages was the development of specialized languages for processing text, specifically, *grep*, *sed*, and *awk*. The latter was an acronym made up of the first letters of the languages developers: Aho, Weinberger, and Kernighan. *awk* appeared around 1978.

In this section, we present two *awk* scripts: the first is a very small, typical script, while the second is considerably more complex. The first is so small and useful that such scripts are still common today. Scripts like the second served as the impetus for the development of general purpose scripting languages.

The first script was written back in the late 1980s when one of the authors was the systems manager for a network of Unix computers. In the fall semester of each academic year, there were many new students and a few new professors who needed computer accounts. At that time, creating a new user account was a multistep, manual process carried out by student help.

One fall day a new student came to see me because they were unable to login to their new Unix account. My investigation quickly revealed that their record in the user table had one too few fields. It was a simple matter to edit the user table and add the missing field. This quick resolution made the user happy, but not I.

One solution to prevent this problem from recurring was to create a written procedure with a checklist to create a new user account. Although this approach had a certain appeal. I decided to take the extra step of implementing the procedure as a combination of a *Makefile*, a few shell scripts, and a few simple *awk* scripts.

Since editing the user table was a manual process, I decide to implement the checks on this step as a sequence of (largely *awk* scripts). The first of these was to check that each line had the same number of fields:

```
#!/usr/bin/awk -f
NR == 1 { ct = NF }
NF != ct { print NR, $0 }
```

An *awk* program consists of a *guard* followed by a block of statements, repeated as many times as desired; the first line is a pseudo comment used in Unix/Linux computers that identifies the interpreter to use. The *awk* processing cycle consists of reading an input line, then testing each guard in the program. For any guard that is true, its corresponding block is executed, after which the testing of guards resumes. Only after all the guards have been tested and their blocks executed, if applicable, is the next input line read and processed.

Based on a field separator (the default is whitespace), the input line is broken up into fields. The *awk* variable *NR* is the current line (record) number and *NF* the number of fields on the current input line. The variables *\$1*, *\$2*, ... hold the contents of each field, whereas the variable *\$0* refers to the entire line.

So the aforementioned program consists of two guarded blocks. The first guard is true only for the first line read; its block stores the number of fields on the first input line into the variable *ct*. The last guarded block prints any lines whose number of fields disagrees with *ct*.

Although the author is no longer a systems manager, this first *awk* script still finds occasional use even today.

The second script is considerably more complex. It was developed to solve the following problem. The authors were writing a text book. In addition to the text, a number of nontrivial programs were developed. The authors needed to include portions of these programs as examples. Most importantly, they wanted the code in the textbook to be identical to the code used in the programs.

So they used a *Makefile* and a set of text filters for extracting the code of interest into a file, which was then automatically included in the book. The *awk* script presented here was given the task of extracting a single function or method in Java. A typical script parameter was the return type and name of the method, which made the starting point easy to find. Having located the starting point, the end point was determined by basically counting braces, based on the authors' coding style:

```
#!/bin/sh
awk "BEGIN { ct = 0; prt = 0 }
/$1/ { prt = 1 }
prt > 0 { print \$0 }
prt > 0 && /\{/ { ct++ }
prt > 0 && /\}/ { ct-- }
prt >0 && ct == 0 { prt = 0 }
"
```

Before the first input line is read, the script sets a *prt* switch to off (0). It then searches through the input file until it finds the function it is looking for, namely, the second guard, whose block turns the switch on. The third guard prints the input line if the *prt* switch is on. The next two statements increment/decrement the brace count whenever the *prt* switch is on and they detect a left/right brace. The final guarded block turns the switch off when the brace count goes to zero.

There is a very subtle point in this script. The observant reader will have noted that, unlike the previous script, this one is a shell script which then invokes the *awk* interpreter. The parameter to the script is substituted into the second guarded block, while in the statement of the third guarded block, the dollar sign is escaped so that to the *awk* interpreter the statement appears as

```
print $0
```

Quirks like this, together with the limited processing ability of text processing languages, led to the development of more general purpose scripting languages, which are discussed in the next section.

67.2.3 Glue Languages

Larry Wall ... created Perl when he was trying to produce some reports from a Usenet-news-like hierarchy of files for a bug-reporting system, and *awk* ran out of steam. Larry, being the lazy programmer that he is, decided to over-kill the problem with a general purpose tool that he could use in at least one other place. The result was the first version of Perl. [12]

In the 1980s, scripting languages began to move away from simple text processing to more complex tasks with the development of the languages Perl and Tcl/Tk. A hallmark of a *glue* language is its ability to take data output from one application and reformat it so that it could be input to another application. Initially, scripting languages were considered much too slow and inefficient to implement an entire application. With the development of faster interpreters and faster computers, this assumption disappeared.

Although Perl and Tcl/Tk had their roots as a Unix scripting languages, all major scripting languages are now available for all major platforms including Unix, Linux, Macintosh, and Windows. These languages include Perl, Tcl/Tk, Python, and Ruby.

For example, the first author has used these scripting languages for the following tasks:

- Systems administration tasks on a network of computers including: setting up new user accounts, running backups, reconfiguring servers, and installing software.
- Class management, including converting electronic class rolls from one form to another, managing email for each course, grading support, and an interactive, GUI-based grading system.
- A textbook support system, which consisted primarily of scripts for including source code in a book.
- Newer versions of programs previously written in conventional programming languages such as C++ and Java. Such programs fall into a variety of subject domains including simple utility programs, computer science research, etc.

To illustrate the robustness of scripting languages, let us consider the academic task of maintaining a grade book of numeric grades earned by students in a class for their assignments, quizzes, tests, and exams. Each grade may have a different weight; for example, an exam may be more heavily weighted than a quiz. The script presented here provides a secure way to deliver grades to students.*

A spreadsheet is used to do the grade management itself, one spreadsheet per class. An example spreadsheet is given in Figure 67.2. In this example, column one is used for student names and column two is used for email addresses. The rightmost two columns used are weighted totals and averages. The intervening columns are used for grades on assignments and tests; at any point in time, any number of grade columns may be blank (empty).

Also, note that the first row is a descriptive title for each grade, and the second row for the maximum points possible for each grade. The last row is used for the average for each assignment or test. The intervening rows contain the students records, one row per student.

The scripting problem here is to move the grade values from the spreadsheet to the email system. This process consists of exporting the data in textual form from the spreadsheet and then using a Python script to generate the email. The spreadsheet output used is comma-separated-values. We have found over the years that each spreadsheet application has its own, often unique definition of the format of

* Specialized web software developed for education, such as Blackboard and WebCt, provide equivalent functionality to instructors through secure login to a dedicated Web server. However, the system described here was developed long before such software became available; it relied on the use of email for conveying grades back to students.

	A	B	C	D	E	F	G	H
1			Quiz1	Test1			Total	Ave
2			25	100			125	
3	Snoopy	snoopy@tribe.edu	24	90			114	91%
4	Lucy	lucy@tribe.edu	21	80			101	81%
5	Linus	linus@tribe.edu	25	100			125	100%
6	Ave		23	90			113	90%
7								
8								
9								
10								

FIGURE 67.2 A spreadsheet gradebook.

comma-separated-values. Fortunately, Python provides a module (or library) which deals with that. For our current spreadsheet the third row would appear as

```
"Snoopy" , "snoopy@wm.edu" , 24,90 , , 114,91.2
```

In the remainder of this section, we describe the Python script given in Figure 67.3 as a means of examining some of the features of glue languages in general, and Python in particular.

As noted in the previous section, line 1 of the script is a pseudo comment that gives the full path name of the language interpreter. Line 2 imports any needed modules (or libraries).

In lines 4–6, we set any global constants that are likely to change. For this script, these are kept in an dictionary or associative array as a key-value pair. This allows each grade spreadsheet to have its own set of values, which can be read from a file, overriding the defaults. These parameters include the column number of the student's name, his/her email address, etc. For the sake of simplicity, the routine for reading (and checking) these parameters (amounting to 11 lines of code) is omitted here.

The main logic of the program is shown in lines 8–10. First, the CSV input file is read and stored in an array of students. All the student entries must be read because the averages (which are included in each mail message) are last. Then an email is constructed and sent to each student:

All that remains is to examine the functions `readGrades` and `emailGrades`. The first function is passed the name of the file to be read as the first command line argument; a simple GUI alternative would use a dialog box to ask for the file name. The first line of the function sets the variable `student` to be an empty, indexed array. The `filename` is opened and passed to a reader which deals with comma-separated format files. The `for` loop reads one row per iteration, which is appended to the end of the `student` array.

The function named `emailGrades` is passed the `student` array. Next, leading nonstudent entries are copied and trailing ones removed. Then a simple `for` loop that generates an email message per student entry.

Basically, this function iterates over the students, generating a string that contains the student's grades and then mailing them. It counts the lines as it goes so that it can skip the initial lines which contain header information. On a row containing an actual student, the function formats the student's grades in a manner familiar to any programmer, storing the message in the string `outline`.

The function `emailGrades` then creates a subprocess that executes a system command; the `mailx` command works here if you have a static IP address, otherwise it is somewhat more complicated. Note that the subprocess's file `stdin` is set to be a pipe, which is then filled by the `proc.communicate` method call. The function then waits for the subprocess to finish. One essential feature of a *glue* language is the ability to execute system commands (like `mailx`) and send them input or read their output or both.

```

1  #!/usr/bin/python
2  import sys, csv, process
3
4  param = {"name":0, "email":1, "gradecol":2, "studentrow":2,
5          "titles":0, "maxgrade":1}
6  readPrefs("ugrades.pref")
7
8  student = readGrades(sys.argv[1])
9  ct = emailGrades(student)
10 print ct, "messages sent"
11
12 def readGrades(filename):
13     student = [ ]
14     for row in csv.reader(open(filename, "rU")):
15         student.append(row)
16     return student
17
18 def emailGrades(student):
19     titles = student[prefs["titles"]]
20     maxgrade = student[prefs["email"]]
21     ave = student.pop()
22     ct = 0
23     for s in student:
24         ct += 1
25         if ct <= prefs["studentrow"]:
26             continue
27         outline = formatGrades(s, titles, maxgrade, ave[s])
28         proc = subprocess.Popen("mailx -sgrades %s@cs.wm.edu"
29                                 %(student[prefs["name"]],
30                                   student[prefs["email"]]),
31                                 shell=True, stdin=subprocess.PIPE)
32         out = proc.communicate(outline)
33         proc.wait( )
34     return len(student) - prefs["studentrow"]

```

FIGURE 67.3 A glue script for emailing grades.

The function `formatGrades` (not shown here) generates a multiline email message; it amounts to 11 lines of code.

Python has some interesting features that are worth noting here. First, it uses the plus symbol as the string concatenation operator. Second, it provides no automatic conversion from a number to a string, even in string concatenation. Third, the percent operator with a string as the left operand and a tuple as the right operand is basically the `sprintf` function of C; the left operand serves as a formatting code for each operand in the tuple. After setting up some column headers, the `for` loop generates one grade per output line, each containing a grade name, a maximum grade, and the grade earned by the student.

As presented here, the entire program has fewer than 40 lines of code. It was written and debugged in less than a day to replace a similar, cryptic, less flexible Perl script. The script accommodates spreadsheet output generated by Excel, OpenOffice Calc, and GoogleDocs using a variety of conventions used by the author and his graders. It has proven to be a very valuable glue script, since it is used about 10 times per semester per class.

This typical Python glue script linking two disparate applications exposes many commonly used features of glue languages such as Python:

- Scripting languages do not require declaration of variables and supports dynamic typing.
- Scripting languages support a wide variety of string operations, including pattern matching.

- Scripting languages provide both dynamic arrays (lists) and dictionaries (also known as associative arrays or hash tables).
- Scripting languages provide a means of executing system commands with the ability to supply input to those commands or to read their output.
- Unlike many languages, Python has a simple syntax. A compound statement such as a function definition (`def`), a `for`, or an `if` end with a colon. The statements forming the loop body (for example) being indented. In Python if a statement looks like it is part of a function definition, loop body, or a then/else body, then it is interpreted as one.
- Python supports a large number of modules, which are very useful language extensions. In this program, we used the `sys` module to access command line arguments, the `csv` module to simplify reading CSV format files, and the `subprocess` module to create a subprocess capable of executing system commands and communicating with its parent.

Finally, we note that many universities now teach Python in their CS1 courses (the first course in a computer science major). One reason for this is that the course is rapidly becoming a service course, taken primarily by physical science and social science majors. Its popularity is partly due to its simple syntax and partly because of this value as a tool for solving computing problems in other fields of study.

67.2.4 Web Languages

According to its developer, Rasmus Lerdorf, the motivation for developing PHP [4] was the following:

As the Web caught on, the number of non-coders creating Web content grew exponentially. ... But soon they were asked to add dynamic content to their sites. ... This is where PHP found its niche. ... I had written all sorts of CGI [Common Gateway Interface] programs in C, and found that I was writing the same code over and over. What I needed was a simple wrapper that would enable me to separate the HTML portion of my CGI scripts from my C code ... This concept became PHP.

Lerdorf initially developed PHP in 1994, but because its usage quickly grew beyond the abilities of a single developer, it became an open-source product. PHP is a server-side scripting language whose scripts can be directly embedded within the HTML code that defines the page layout. In this way, PHP is ideal for use with Web pages that have dynamic content, including forms processing and database access.

A major advance in the development of PHP was the release of PHP 5 in 2004, which added the following major features:

- A new OOP model
- Improved database support for MySQL and SQLite
- A host of new functions to simplify coding of common features, such as date and array handling

These features, along with its basic syntactic similarity with Java, C, and C++, tend to obscure the distinction between PHP and other general purpose languages. They also make PHP easier to learn for programmers who have prior experience with these other languages.

At many sites, PHP is installed on the main Web server. It is often installed together with MySQL, an open source database management language. A popular package used across many server varieties is known as *xAMP*, which combines PHP, MySQL, and an Apache server in an easily installed server configuration that can be run either locally or remotely.*

* The Windows variety is called WAMP, the Mac OS variety is called MAMP, and the Linux variety is called LAMP, appropriately. All three varieties of xAMP are open source and so can be freely downloaded and used by any software developers.

Typical examples of PHP usage on a Web page include

- Dynamic content such as today's date or a news item of the day
- Forms processing, including forms validation
- Database access

The PHP processor takes a document file as input and produces HTML as output. Like JavaScript, the input file consists of a mixture of HTML and PHP, which are marked by special HTML-like tags. The major difference from JavaScript is that a PHP script is executed on the server, not on the client. This provides a level of security that is unachievable with JavaScript, since the PHP script is never downloaded to the client's Web browser.

The PHP processor has two modes of operation. It begins in copy mode in which HTML tags and text are copied directly to the output. When it encounters the special tags:

```
<?php
// one or more lines of PHP code
?>
```

the PHP processor switches to script mode and interprets the script on the fly. The output from the script, whatever is written to stdout, is inserted directly into the HTML page. The double slashes (//) denote a PHP comment, which continues until the end of the line.

Figure 67.4 contains a simple example that illustrates some of the features of PHP. Familiarity with both HTML tags and C programming is presumed. In this example, we use a PHP script in conjunction with a database to produce department directories, one each for the faculty, the staff, and the graduate teaching assistants. The directory desired is specified as a parameter in the URL; for example, <http://www.cs.wm.edu/people/index.php?id=Faculty> will list the faculty directory.

```

1 <?php
2 $title = $_GET['id'];
3 include "header.inc";
4 if (! eregi("Faculty:Staff:GradTA:", ":$title:"))
5     errorPage($title);
6 include "dbaccess.inc";
7 $result = mysql_query ("select * from $title");
8 print '<center> <table cellspacing=5 cellpadding=5 border=2>
9     <tr align=left><th>Name</th><th>Office</th>
10    <th>Phone</th><th>Email</th></tr>
11 ' ;
12 while (list($name, $url, $office, $phone, $email) =
13     mysql_fetch_array ($result)) {
14     print "<tr align=left>\n";
15     $lname = $name;
16     if ($url != "")
17         $lname = "<a href=$url>$name</a>";
18     print "<td>$lname</td>\n";
19     print "<td>$office</td>\n";
20     print "<td>$phone</td>\n";
21     print "<td><a href=mailto:$email>email</a></td>\n";
22     print "</tr>\n";
23 }
24 print '</table> </center> ' ;
25 include "trailer.inc";
26 ? >
```

FIGURE 67.4 A PHP script for a directory listing.

With this parameter, the script accesses the appropriate database table, in this case the faculty table, and generates the appropriate HTML output. Because these directories are fairly static, it is fair to ask the question: Why not maintain the information as static HTML pages? Here are three reasons:

1. The staff people who maintain this information need only interact with a form that interfaces with the database—they do not need to learn HTML.
2. Using PHP allows the webmaster to more easily maintain a consistent look and feel to the web pages.
3. The information can be accessed from other portions of the web site.

A PHP page begins in HTML mode; this would be used to set up the page in a site-specific standard format, including the title, background color, navigation buttons, etc. Because HTML lacks an include facility, a common use of PHP is to set up the page via parameterized header (line 3) and trailer (line 25) files.

The global `$_GET` is an associative array of variable-value pairs that are passed to the script via the URL parameters. In this case, the parameter `id`, whose value is the string `FACULTY`, is passed to the PHP variable `$title`. The `header.inc` script expects the title variable to be set.

Before we begin setting up the body of the page, we want to check to see that the `id` parameter has a valid value. Because this value is used to access a database table, a malicious user could attempt to attack the database by providing an unexpected value. In this case, we test the value supplied for the `id` parameter using a pattern match against the three legal values. If the pattern match fails, an error routine is called, which generates an error page and exits with no further processing.

Otherwise, database access code is included, which sets the name of the database along with security information such as `userid` and `password`. The `select SQL` statement is shown, which in this example accesses the faculty table in the database. At the current time, each of the three tables contains the following information for each person:

- The person's name
- A URL, if they have a homepage
- Their office address
- Their phone number
- Their email address

The information is to be generated as an HTML table with one row per person. Each column should have an appropriate heading (lines 7–10).

Next comes the main logic of the script. A `while` loop (line 11 ff.) is used to fetch the rows of the result of the SQL query one person at a time. That result is returned as an array, so the `list` function is used to assign the array values to conveniently named variables. The body of the loop consists mostly of print statements to write the appropriate columns: As with Perl, variable references may be freely embedded in double-quoted strings. The `name` field is made into a link if the person has a non-empty URL field.

All that remains is to close the table and center HTML tags and invoke the standard web site trailer:

This script is a typical example of server-side scripting and exposes some of the commonly used features of PHP:

PHP scripts freely alternate between pure HTML and PHP.

PHP does not require the declaration of variables and supports dynamic typing. The same value can be treated both as a string and as a number (provided it can be interpreted as a valid number).

PHP supports a wide variety of string operations. It also supports pattern matching as found in the Unix utilities `grep` and `sed`.

PHP provides both dynamically sized arrays and associative arrays (hashtables).

PHP directly supports accessing information from a database.

Besides PHP, all of the glue scripting languages can be used for dynamic web programming, including Perl, Python, and Ruby.

67.2.5 Embedded Languages

Embedded languages provide functionality that can be activated by the user by the user to perform specific tasks, like text editing. One of the earliest examples of an embedded language is GNU Emacs, developed in the 1980s.

Like other versions of Emacs available at the time, GNU Emacs had an embedded Lisp interpreter. Everything from setting startup options to the development of modes was done in Lisp. This made Gnu Emacs customizable by the end user. Most of the customizations themselves were developed by end users writing in Lisp.

For example, a typical customization of Emacs was developed for editing Python programs. This customization automatically indents the program as it is typed, colorizes reserved words, identifiers, strings and other literals, etc. By selecting a region, the user can comment it out, indent it left or right, wrap lines as needed, etc.

The development of computer games, whether on a dedicated console or on a personal computer, has rekindled interest in embedded languages. Many books on writing game programs discuss the use of an embedded scripting language. The choice of language can vary from Lisp/Scheme to Lua to languages similar to Javascript. Factors that are considered in choosing an embedded scripting language include its suitability to the task, familiarity of the development team with the language, and the size and speed of the interpreter for the language.

Tasks performed by the embedded language may include loading options and configuration files at startup, saving and reloading state information, implementing and interpreting finite-state machines, moving objects in the game, etc.

An important consideration in choosing an embedded scripting language is the size and speed of the interpreter. Consider Lua as an example. Compared to Python, Lua has a paucity of data structures and types. Python offers both infinite precision integers, as well as floating point numbers, while Lua offers only the latter.

67.3 Principles

Until recently, scripting languages were designed primarily for programming in the small, as opposed to application programming languages, which were designed for programming in the large. The languages used dynamic typing and were interpreted rather than compiled. The primary application for scripting languages was to glue existing applications and utilities together to make a new application.

The advent of languages like Java and C# began to muddy these waters. Like scripting languages, they were compiled to byte code for a virtual machine and then interpreted. Other than the fact that they used static rather than dynamic typing, there seems little to distinguish them from scripting languages such as Perl and Python.

Entire applications, such as content management systems for web applications, are now being written in scripting languages. Indeed, except for embedded languages, such as Lua, the distinction between scripting languages and application programming languages may soon disappear. In such a case, scripting languages should be held to the same principles as application programming languages. Such principles include

1. A well-defined syntax, expressible in a content-free grammar
2. A clear, well-defined semantics, which is expressible in an efficient implementation
3. A well-defined type system
4. The syntax, semantics and type systems should work together to minimize programming errors

5. The language should support its intended application area with a rich set of constructs that encompass needed functions and idioms
6. The language should be as simple as possible, both to learn and to use
7. The language should support future extensions while maintaining backward compatibility

In the remainder of this section, we will consider each of these in turn. In cases where principles are in conflict with one another, the language designer must make appropriate tradeoffs to achieve a workable implementation for the language.

Further complicating the issue is that, with the exception of Ruby and Lua, most scripting languages began as imperative languages, to which object-oriented features were later added. In some cases this addition resulted in breaking earlier features.

67.3.1 Syntax

A well-designed language starts with a simple syntax that is expressible by a grammar. Most application language definitions present their syntax as a context-free grammar; the size and complexity can vary among languages. For example, see Table 67.1 [13], which shows the number of pages of text required to present the complete grammar for each of four prominent programming languages.

From this table, it can be inferred that the languages Pascal and C are syntactically simpler than Java and C++.

However, a review of the websites for Perl, for example, reveals that Perl may not have a syntactic grammar in the traditional sense.

Moreover, its informal syntactic definition reveals that Perl distinguishes between constant strings using either single or double quotes [14]:

Besides the backslash escapes listed above, double-quoted strings are subject to *variable interpolation* of scalar and list values. ... Variable interpolation may only be done for scalar variables, entire arrays (but not hashes), single elements from an array or hash, or slices (multiple subscripts) of an array or hash.

But “variable interpolation” as described earlier is never given a precise syntax, so beginners often avoid its use altogether.

Secondly, in order to distinguish among scalar variables, arrays, and hashes, Perl requires that each of these start with a unique character. Omitting this character leads to the so-called bare word compile error, which (in our experience) is the most common error in Perl. Languages that have copied this convention, namely, PHP and Ruby, inherit the same weakness.

Since Python does not support variable interpretation of arbitrary strings, variables are not required to start with a special character. This supports Python’s reputation as a simpler language than Perl.

Since these languages support the `printf` function of C, as well as string concatenation, *variable interpretation* of double quoted strings leads to more problems than it solves.

TABLE 67.1 Grammars for Various Languages

Language	Approximate Pages
Pascal	5
C	6
C++	22
Java	14

67.3.2 Semantics

Languages should have a well-defined semantics based on a formal semantic definition to the extent possible. However, if formal semantic definitions of scripting languages exist, we could not find them. A formal semantic definition allows alternative implementations of language, since it can be proved that the abstract models of various implementations are equivalent. These formal definitions can be based on either operational semantics or denotational semantics.

Again using Perl as an example, the implied subject of most operations is the special variable `$_`. A common error in Perl is to assume that each function has its own copy of this variable but, in fact, there is only a single copy in the entire program. One implication of this rule is that modules or library functions that a programmer develops must avoid using the same special variable.

67.3.3 Type System

Scripting languages are all dynamically typed. A language is defined to be *dynamically typed* if types are associated with values rather than variables; thus, a variable can have a different type at any time during program execution, depending on the value currently assigned to the variable at that time.

Since scripting languages were originally intended for programming in the small, it was felt that a script with only a screenful of code (or two) did not need the extra complexity of having to declare all its variables.

The question then becomes what do you do if one or more operands of an operator has the wrong type. With respect to automatic coercion from one type to another, a permissive language attempts to convert a value from one type to another. A language is more strict with respect to automatic coercions if it allows only those which are guaranteed to be safe.

Permissive languages such as Perl and PHP try to keep the program running if possible. Because of this they tend to allow automatic coercions of values, even when such conversions are more likely to be incorrect rather than correct. In the case of PHP, this attitude eliminates many error messages being written to the browser window. Such a practice can be defended on security grounds.

Because of this permissiveness, scripting languages try to avoid overloading operators based on the types of their operands. Perl and PHP use the dot to denote string concatenation, whereas Python overloads the plus operator for concatenation. Perl even has unique operators for string comparisons, instead of using the mathematical operators already used for numeric types.

Strict languages such as Python do not permit automatic coercions unless they are safe. For example, converting an integer to a string is guaranteed to work, although Python does not permit an automatic conversion. Converting a string to a number would be disallowed, since the string may contain arbitrary text not representing a number. For a glue language, reporting errors tends to be preferable to generating incorrect output.

67.3.4 Other Properties

A good scripting language should support the needed functions, data structures, and idioms of its intended applications. We have seen how PHP supports an HTML mode, which is quite useful in web applications.

Most of the languages we have examined support unbounded indexed lists and dictionaries. They also support iterators for traversing these structures. Whether these features lead to dramatically simpler applications is a subject of debate.

The one area where all of these languages have had problems is in maintaining backward compatibility. As the size and number of scripts written in these languages continues to grow, breaking existing scripts is likely to cause programmers to seek a more stable language.

Consider the language Python as an example. Through versions 1 and 2, Python remained largely backward compatible. However, the design goals for version 3 was that “there should be one—and preferably only one—obvious way to do it.” The backward-compatibility problems relative to earlier versions are as follows:

- The `print` statement became a function, necessitating parentheses surrounding the arguments. This broke almost all scripts written for earlier versions of Python.
- The division operator was redefined to always produce a floating point number. A new operator was introduced which produced an integer when one integer was divided by another.
- Removing previous backward-compatibility features, including old-style classes, integer-truncating division, string exceptions, and implicit relative imports.
- Many changes were made to key libraries. For example, the glue script in Figure 67.3 will not run under version 3 due to changes in the `process` module. Many user libraries would not work under version 3.

Although Python version 3 came out in December 2008, only in late 2011 and early 2012 have Python textbooks started to appear in large numbers.

To summarize, as the distinction between traditional application programming languages and scripting languages continues to shrink, the principles and qualities of traditional languages should be applied more carefully to scripting languages as well.

67.4 Conclusions

Scripting languages began in the 1960s as a simple device for connecting individual tasks in a sequence of programs that ran in batches.

Throughout the 1970s and 1980s, especially with the rapid emergence of Unix and time sharing systems, scripting languages grew in richness and versatility to accommodate the needs of these systems.

With the widespread emergence of the Internet in the 1990s and recent years, newer scripting languages embodied still more features and functionality to support web-based programming requirements.

In fact, scripting languages of today, like PHP and Python, are not easily distinguishable from other modern programming languages like Java and C++. For that reason, it appears that tomorrow’s scripting languages will need to adhere to a more rigorous definitional standard, in order that they maintain such important characteristics as backward compatibility, interoperability, and type safety.

68.1 Introduction

Compilers and interpreters are language translators that have many functions in common, in that both must read and analyze source code. A compiler, however, produces a program equivalent to the source program in a target language, usually in object or assembly code but also sometimes abstract machine code such as Java virtual machine (JVM) code or even C code, whereas an interpreter directly executes the source program. Any programming language may be either compiled or interpreted, but languages with significant static properties (e.g., FORTRAN, Ada, and C++) are almost always compiled, whereas languages that are more dynamic in nature (e.g., LISP and Smalltalk) are more likely to be interpreted. Languages that differ substantially from the standard von Neumann model of most architectures (e.g., PROLOG) may also be interpreted rather than compiled. A performance penalty is incurred by interpretation over compilation, so in cases where speed is critical, compilation is to be preferred. By mixing compilation and interpretation, this performance penalty can be reduced, usually to well within an order of magnitude. The advantage to interpretation is that the compilation step is avoided (useful during program development), and an interpreter offers greater control over the execution environment (useful for complex run-time environments) and greater flexibility in adapting to different architectures.

The first translators were developed in the 1950s. Prior to the development of high-level languages, a compiler was essentially what is known as a linker today: it “compiled” a collection of machine-language routines from a library to form a single program. A team at IBM under the direction of John Backus is generally credited with developing the first commercial compiler for a high-level language,

during the period 1954–1957 (Backus et al., 1957). The language translated by this first compiler was FORTRAN, which was designed simultaneously with the compiler (and is also credited with being the first high-level language). Modern translation techniques were first used in Algol60 compilers a few years later (see, e.g., Randell and Russell, 1964), when the relationship of language translation to the theory of finite automata and context-free grammars became better understood. The study of these subjects was further stimulated by this relationship, and by the early 1970s, many of the standard techniques in use today were known. Since then, general improvements in translators have come in the following areas:

- The automation of a significant portion of the construction of a translator
- Improvements in the speed of the target code, due to the increased application of code-improving (or *optimizing*) algorithms

A greater ability for compilers to be relatively easily *retargeted*, or rewritten for a new target machine language, due in part to automation and in part to a better understanding of the required compiler structure.

Improvements have also come in the implementation of special language features, such as exception handling, generics (parametric polymorphism), object-oriented features (such as dynamic binding), and parallelization, due to increasing understanding of these mechanisms. One area in which significant theoretical advances have taken place in the past few decades is in the translation of functional languages, with new algorithms for type checking, type classes, and interpretation by tree reduction (see, e.g., Peyton Jones, 1987). So far, however, these techniques have remained outside of the mainstream of languages and translators.

An important aspect of the technology of translators is its strong interaction with language design. For example, the introduction of block structure in the Algol language family gave impetus to the development of stack-based translation algorithms. In turn, the stack-based algorithms influenced the development of language semantics specifically designed to take advantage of the algorithms, such as the lexical scope rule and the principle of syntax-directed translation, in which the semantics of a program (i.e., its execution behavior) is directly reflected in its syntax, or structure, so that translation can be guided by this structure. (This rule could equally well have been formulated as *semantics-based syntax*.) Because of its early appearance, FORTRAN was not designed with these principles in mind, and it remains a somewhat more difficult language to translate with the standard techniques than later languages of the Algol family.

Another aspect to the development of language translators has been the tendency of the computing community to constantly rediscover or recreate translation techniques (other than the basic, well-known ones outlined in many texts). Primarily, this is due to the lack of detailed documentation of specific translators in the computer science literature. This, in turn, is largely due to the commercial and/or proprietary nature of most translators. Two translators that historically were reasonably well documented and exerted a corresponding influence on subsequent translator construction were the portable C compiler (Johnson, 1978) and the PASCAL P-compiler (Wirth, 1971; Nori et al., 1981). Lately, the availability of public-domain software from the Internet has greatly improved the opportunity to study existing translators. Particularly well-documented and of high quality are the compilers distributed as part of the GNU software project of the Free Software Foundation (<http://gcc.gnu.org>).

Common to almost all modern compilers is a conceptual structure in which the tasks performed are divided into *phases*, or logically complete processing steps. The standard phase structure is shown in outline in Figure 68.1.

The first phase, called the scanner or lexical analyzer, is the only phase directly involved in reading the source program. It converts the characters of the source program into tokens, sequences of characters that represent the basic units of program structure. Typical tokens are keywords such as *while*, numeric literals such as 3.14159, and identifiers.

The second phase in a compiler is the parser, or syntactic analyzer, which collects sequences of tokens into complete units, such as expressions, statements, and declarations. The output of the parser (either explicitly or implicitly) is a tree or other equivalent data structure representing the structure of the programming unit just recognized. This tree is called the *syntax tree*.

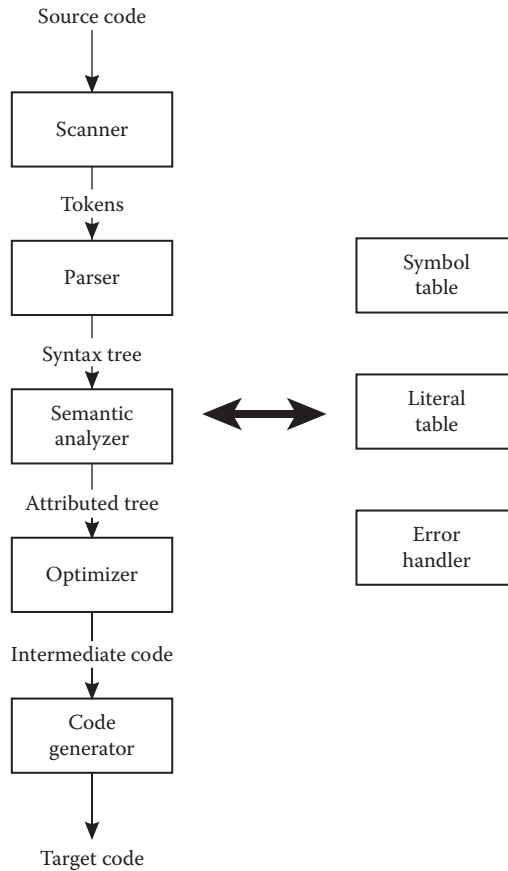

FIGURE 68.1 The phases of a compiler.

The third phase in a compiler is the semantic analyzer, which computes attributes, or properties of each programming construct, as well as its effect on the attributes of other constructs. Typical attributes include data types of expressions and identifiers, memory sizes, and actual or potential memory locations. The semantic analyzer also determines if the construct makes sense according to these attributes. That is, it performs consistency checks, such as type checking or range checking. The output of the semantic analyzer can be represented by an attributed tree representing the original tree modified by the computed attributes. The fourth phase in a compiler is called the optimizer in Figure 68.1. This phase usually generates some form of linear code, called *intermediate code*, from the representation passed to it by the semantic analyzer. It also applies some forms of code-improving algorithms, either before or after generating intermediate code (or both). This phase of compilation is the most variable in different compilers; it may even be absent altogether.

The fifth and final compiler phase shown in Figure 68.1 is the code generator. This phase generates the final target code and may also perform some additional improvements to the code.

All of the phases of a compiler interact with various tables and handlers within the compiler. Figure 68.1 shows three important examples of these other components: the symbol table, the literal table, and the error handler. The figure indicates their interaction with the phases by a large double-headed arrow. The symbol table maintains the names defined by the program under translation, as well as possible predefined names in the language, and associates the names with their attributes, which may include scope, memory location, data type, and memory size. The symbol table may be monolithic, or it may be separated into a tree or graph of smaller tables, representing different scopes in the program. A similar

table is needed for literal values that appear in the program, such as strings and numeric literals. The third component, shown in Figure 68.1, is the error handler, whose job is to generate different kinds of error messages but, more importantly, to provide error recovery, so that translation may continue (at least as far as is practical) in the presence of errors.

It must be emphasized that the compiler phases are logical units only and may not correspond to any actual grouping of operations within the compiler itself, or to any temporal sequencing of these operations. Indeed, it is customary for scanning, parsing, and some semantic analysis to be completely integrated in a single pass over the source code. A compiler may even be one-pass, in that all phases, including code generation, are performed simultaneously (assuming that the language itself permits it). More likely is that there are separate passes for parsing (including scanning), optimization, and code generation (with later passes using the intermediate code generated by the first pass). If the language does not require names to be declared before use, then a pass is also necessary to resolve name references.

A useful division of the tasks performed by a compiler is into an analysis part and a synthesis part, sometimes also referred to as the *front end* and *back end*. The analysis part is concerned with analyzing the source program, whereas the synthesis part is concerned with generating the target program. The analysis part depends primarily on the source language, whereas the synthesis part depends primarily on the target language or target machine. Scanning, parsing, and semantic analysis are part of the front end, whereas code generation is part of the back end. Optimization and the generation of intermediate code usually require information about both the source and the target; these are more difficult to divide into a front-end component and a back-end component. The more successfully this is done, the easier it is to retarget the compiler. In the best case, a group of compilers can share front ends and back ends interchangeably. A popular and effective design for an interpreter consists of a compiler front end and a back end that is an interpreter for the intermediate code produced by the front end. This results in a reasonably efficient interpreter that is also easily retargetable.

68.2 Underlying Principles

Algorithms used in translators are based heavily on computation theory and, to a lesser extent, on formal semantics. Scanners are direct implementations of finite automata that solve string recognition problems through nonrecursive pattern matching. Parsers depend on the theory of context-free grammars and pushdown automata, which solve recursive recognition problems through stack-based pattern matching. Semantic analysis depends on solving sets of tree equations called *attribute grammars*. Code generation and interpretation can also be seen as applications of attribute grammars. It is possible to use even more formal semantic specifications, particularly denotational specifications, of the source and target languages to construct semantic analyzers and code generators (see, e.g., Polak, 1981 and Lee, 1989). The advantage to doing so is that the compiler can be proved correct (i.e., the semantics of the source and target programs are guaranteed to be the same). However, these techniques have not become popular, and we do not discuss them further. In the remainder of this section, we will discuss each of the areas mentioned in a little greater detail.

68.2.1 Finite Automata

A finite automaton is an abstract computational machine consisting of a finite number of states and transitions between states based on input symbols. The machine runs by beginning in the starting state and consuming input symbols while entering new states via corresponding transitions, until either an error state or an accepting state is reached. At that point, it may declare success or failure, or possibly continue executing. Each state represents stored knowledge about the computation up to that point. A finite automaton can handle arbitrary repetition by a fixed, finite set of input symbols, but it cannot handle recursive processes, because that would involve an unpredictable number of states.

Finite automata are the basis for the recognition of tokens within a scanner. Based on the well-known correspondence from computation theory between finite automata and regular expressions, tokens are usually given initially by regular expressions, which are specifications for the string patterns, or *lexemes*, that a token represents. The mathematical theory of regular expressions limits itself to the consideration of three matching operations: the choice between two alternatives, indicated by the vertical bar | (similar to the logical OR operation); the concatenation or sequencing of two strings (with no operator symbol); and the repetition of a pattern, indicated by a postfix asterisk* (sometimes called the closure or Kleene closure operation). Parentheses are also used to group subexpressions together. As an example of the use of regular expressions to represent tokens, the following regular expression for a token represents simple, unsigned numbers consisting of a sequence of one or more decimal digits:

```
(0|1|2|3|4|5|6|7|8|9) (0|1|2|3|4|5|6|7|8|9)*
```

Such a regular expression can be converted into a finite automaton by one of several standard algorithms. The basic method is to use Thompson's construction (Aho et al., 2007, p. 159) to derive a nondeterministic automaton (i.e., one with an unpredictable next state) from the regular expression, and then to use the subset construction (Aho et al., 2007, p. 153) to derive an equivalent deterministic automaton from the nondeterministic one. Other algorithms exist that perform this conversion in one step and also construct an automaton with a minimal number of states. Although these algorithms can sometimes be useful for the design of scanners, their primary use is in the construction of scanner generators such as Lex (discussed in Section 68.3.2).

68.2.2 Context-Free Grammars

The theory of context-free grammars extends the ideas of finite automata and regular expressions to recursive situations. A context-free grammar is a collection of named recursive rules of the form $A \rightarrow \alpha_1 | \dots | \alpha_n$, where A is the name of the rule and the α are strings of tokens and names (including possibly A itself) representing the different possible choices for the structure of A . The names are called *nonterminals* and the tokens are called *terminals*, for technical reasons explained shortly. Grammar rules are also sometimes referred to in the theory as *productions*. Each such rule represents the fact that a structure represented by A may become any one of the structures represented by an α . The absence of context for these potential replacements of A is what makes these grammars context free. It is possible to define grammars that are more general than context-free grammars; these can be arranged according to increasing generality in what is known as the Chomsky hierarchy. However, context-free grammars are the most useful within the computational constraints of language translation.

Every nonterminal in a context-free grammar defines a set of token strings: the strings of tokens that can be legally parsed by the grammar rule for that nonterminal (and associated rules). The most general structure that is defined by the grammar is usually singled out as the structure representing the entire language, and its associated nonterminal is called the *start symbol*. A legal parse is represented by a sequence of replacements of nonterminals by choices of right-hand sides of their associated grammar rules. This sequence of replacements is called a *derivation*. In a derivation, every nonterminal must eventually be eliminated by replacing it with another string, whereas a terminal, once it appears, is never replaced; this may be seen as a justification for the names *terminal* and *nonterminal*. In general, there are many possible derivations for the same string, which can be constructed by varying the order in which the replacements are made. Two kinds of derivations that are important for parsing use fixed orders for the replacements. In the first, called a leftmost derivation, the leftmost nonterminal in the current string is always the one to be replaced at the next step.

Although derivations are useful for expressing exactly which steps are taken in a parse, they do not express the structure of the parsed string very well. A more useful representation of this structure is the parse tree, which represents each terminal and nonterminal by labeled nodes, and each replacement step in a derivation by the construction of a set of children of the node label being replaced. In a parse tree, each leaf node is labeled by a terminal, and each interior node is labeled by a nonterminal. Even parse

FIGURE 68.2 A parse tree for the string 3 + 4 + 5.

FIGURE 68.3 A syntax tree for the string 3 + 4 + 5.

trees have more detail than is actually needed to determine the meaning of a structure; and a condensed form of a parse tree, called a syntax tree, is the most useful data structure for translation. In a syntax tree, nodes may have a more diverse structure than in a parse tree: they may have more than one label, and both terminals and nonterminals may be used as labels of interior nodes.

As a brief example of the grammar concepts we have summarized, consider the grammar

$$expr \rightarrow expr + num \mid num$$

which has one nonterminal *expr*, two terminals *+* and *num*, and a single production with two choices. (Here, *num* represents a number token with lexemes such as 42 or 7.) An example of a legal string for this grammar is 3 + 4 + 5. A leftmost derivation is

$$expr \quad expr + num \quad expr + num + num \quad num + num + num$$

(Note that, because there is only one nonterminal to be replaced at each step, this is also a rightmost derivation.) A parse tree for the same string is given in Figure 68.2. A syntax tree is given in Figure 68.3.

68.2.3 Parsing Algorithms

Algorithms designed to match an input string of tokens based on a grammar and, either implicitly or explicitly, to construct a parse or syntax tree, are called *parsing algorithms*. Parsing algorithms come in two general varieties: *top-down* and *bottom-up*. Top-down algorithms construct a parse tree from the root to the leaves by guessing which structures are about to appear, based on the next part of the input string and the structure expected to be seen. Bottom-up algorithms construct a parse tree from the leaves to the root by consuming the input and forming a set of subtrees until the next structural element can be guessed from the structures seen so far and the next part of the input string. Because of the recursive nature of context-free grammars, both kinds of algorithms must use a stack, either explicitly or implicitly, to hold partial results. When it is constructed explicitly, this stack is referred to as the *parsing stack*, and it will possibly contain terminals, nonterminals, or other symbols representing the state of the parser. Because of the nature of their operation,

top-down parsers trace out the steps of a leftmost derivation, and bottom-up parsers trace out in reverse the steps of a rightmost derivation.

There are algorithms of both varieties that will parse any context-free grammar. Early's algorithm (Early, 1970) is the most well-known bottom-up algorithm. A general top-down algorithm may be found in (Graham et al., 1980). General algorithms may run in significantly slower than linear time (Early's algorithm requires cubic time in general), so they are rarely used in practice. Standard algorithms for top-down parsing are the LL(k) algorithms (parsing the input from left to right, giving a leftmost derivation, using k symbols of lookahead) and the LR(k) algorithms for bottom-up parsing (parsing the input from left to right, giving a rightmost derivation, using k symbols of lookahead). Both kinds of algorithms require that a grammar satisfy extra conditions to be parsable. The LL(k) algorithms, in particular, are quite restrictive, although easy to use. The LR(k) algorithms, although less restrictive, are more complex. One top-down parsing method that is more flexible than the LL(k) methods is called *recursive-descent*. A bottom-up algorithm that is simpler than the LR(k) algorithms is called LookAhead LR(1) (LALR(1)) (DeRemer, 1971; DeRemer and Pennello, 1982) and is normally restricted to one symbol of lookahead. Because these algorithms have proved themselves to be the most effective and easiest to use in practice, we discuss them in a little more detail.

In recursive-descent parsing, the grammar rules are viewed as prescriptions for the code of a set of mutually recursive procedures, one for each nonterminal. Recursive-descent, although suffering from some of the same problems as LL(k) parsing, is more flexible and can use simple ad hoc techniques to solve many of the problems of LL(k) parsing (Wirth, 1976). For instance, simple left recursion, which cannot be handled directly by an LL(k) parser, can be handled in recursive-descent by noting that a left-recursive rule $A \rightarrow A\alpha \mid \beta$ is equivalent to a parsing procedure that first recognizes β and then a sequence of zero or more α 's (because the grammar rule generates strings of the form $\beta\alpha\alpha\dots$). Thus, a recursive-descent procedure for the grammar $expr \rightarrow expr + num \mid num$ can be written using a while loop, as follows:

```
void expr(void)
{ match(NUM);
  while (nextToken == PLUS)
  { match(PLUS);
    match(NUM);
  }
}
```

An LALR(1) parser uses an explicit parsing stack instead of recursion. The state of a parse can be expressed by a finite automaton whose states consist of sets of so-called *items*, each item consisting of a production choice, a distinguished position indicated by a period (representing the point of progress in recognizing the rule), and an associated set of lookahead tokens legal at that point in the parse. (In the following discussion, we will use the so-called LR(0) items that lack a lookahead component; although LALR(1) items are more complex, the basics of the LALR(1) algorithm can be understood using these simpler items.)

Consider, for instance, the grammar $expr \rightarrow expr + num \mid num$, which we will write for convenience in the form $E \rightarrow E + n \mid n$. There are six LR(0) items: $E \rightarrow .E + n$, $E \rightarrow E.+ n$, $E \rightarrow E + .n$, $E \rightarrow E + n.$, $E \rightarrow .n$, and $E \rightarrow n.$. The start of a parse is indicated by beginning in a state represented by a new rule representing a start symbol that cannot appear elsewhere, and which we will write as $E' \rightarrow E$ in the example. The corresponding initial item is $E' \rightarrow .E$. Because this rule represents the fact that we may be about to recognize an E , we must also include the items $E \rightarrow .E + n$ and $E \rightarrow .n$ in this state. Transitions to new states are then given by moving the period past the symbols that follow it. For instance, there is a transition on the symbol E from the start state to the state containing the item $E \rightarrow E.+ n$, and a transition on the symbol n from the start state to the state containing the item $E \rightarrow n.$. The complete finite automaton of items is given in Figure 68.4.

FIGURE 68.4 A DFA of sets of LR(0) items.

This finite automaton has no accepting states and is only used to keep track of the state of the parser. It is used in conjunction with a parser stack that holds the state numbers that the parser has passed through while parsing the input. It is used as follows. First, the initial state is pushed onto the stack. Then, the next input token is consulted. If there is a transition on this token from the current state (on top of the stack), then the token is removed from the input and the new state is pushed onto the stack; this is called a *shift operation*. If, however, there is an item in the current state of the form $A \rightarrow \alpha$ (a so-called final item), then this indicates that the string α has already been recognized, and it can be replaced by A ; this is called a *reduce operation*.

A reduce operation is performed as follows. The states on the stack corresponding to α are popped from the stack (one state for each symbol in α). The state remaining at the top of the stack must have a transition on A , which is then taken, and the new state is pushed onto the stack.

As an example of this process, consider the automaton of Figure 68.4 and suppose that the input string is $n + n$. We depict the initial state of the parse as follows:

Parsing Stack	Input
\$0	$n + n$ \$

The \$ in this representation is used to indicate both the bottom of the stack and the end of the input. The first step in the parse is a shift on n from state 0 to state 2. Then a reduction by $E \rightarrow n$ takes place, and the parser moves to state 1. At that point, the $+$ and n are shifted, and the parser is in state 4. Then a reduction by $E \rightarrow E + n$ is made, popping states 4, 3, and 1, revealing again state 0. Again, the E transition is followed into state 1. At this point, the end of the input is encountered, and a reduction by $E' \rightarrow E$ is made, which corresponds to accepting the input.

The complete set of actions of the parser is given in Table 68.1, in which shift actions also include the new state number. Table 68.2 shows the LALR(1) parsing table for this simple grammar, which is used by the parser to select the actions indicated in Table 68.1. This table is two-dimensional, indexed by state, and lookahead token. Each table entry contains an action; shift entries are indicated by an s and the new state number; reduce entries are indicated by an r and the rule to be reduced; empty entries are errors. While this table is closely related to the automaton of Figure 68.4, the exact entries can only be inferred from a lookahead component, which we did not compute here.

TABLE 68.1 Actions of an LALR(1) Parser

Parsing Stack	Input	Action
\$0	$n + n$ \$	Shift 2
\$02	$+n$ \$	Reduce $E \rightarrow n$
\$01	$+n$ \$	Shift 3
\$013	n \$	Shift 4
\$0134	\$	Reduce $E \rightarrow E + n$
\$01	\$	Accept

TABLE 68.2 LALR(1) Parsing Table

State	Input			Goto
	n	$+$	$\$$	
0	s2			1
1		s3	Accept	
2		$r(E \rightarrow n)$	$r(E \rightarrow n)$	
3	s4			
4		$r(E \rightarrow E + n)$	$r(E \rightarrow E + n)$	

An additional area in Table 68.2 is called the goto area. In this area are the transitions on nonterminals that are performed during reductions. These are essentially the same as shift operations, except that no input is consumed. A parser may also choose to condense this table by the use of default entries. For example, because state 2 only has reduce entries by the same rule, this could be made the default, in which case even on input token n , the parser will perform the given reduction. This has the effect of postponing the declaration of error, but it cannot result in an incorrect parse. A similar default can be used for state 4.

68.2.4 Attribute Grammars

Although context-free grammars are generally accepted as the standard way to describe the syntax of a programming language, there is no equivalently accepted method for describing semantics. Formal methods for describing semantics, such as operational semantics or denotational semantics, have not met with universal acceptance, and though translators can be derived from such specifications, this is rarely done. Instead, various *ad hoc* mechanisms are used in translators to perform semantic analysis and code generation or interpretation.

One method that has proven useful for the translator writer is to use a so-called attribute grammar to describe the semantics of a programming language (Knuth, 1968). An attribute grammar associates to each grammar rule a set of equations describing the computational relationships among a set of attributes attached to the symbols in the rule. These attributes can be anything from the data type of a variable to the value of an expression; even the target code generated by a compiler can be represented as a string attribute in an attribute grammar. Most often, attributes are used to represent the static, rather than the dynamic properties of programs, and they are viewed as being fixed values attached to the nodes of a syntax tree. Indeed, attribute values are usually written using a dot notation similar to that of record fields, so that $X.a$ means the value of attribute a of symbol X . Attributes may in fact be implemented as fields in syntax tree nodes, or they may be stored in the symbol table or other data structures elsewhere in the translator.

Given a set of attributes a_1, \dots, a_k and a grammar rule choice $X_0 \rightarrow X_1 X_2 \dots X_n$, the j th attribute at the i th symbol is given in an attribute grammar by an equation of the general form

$$X_i.a_j = f_{ij}(X_0.a_1, \dots, X_0.a_k, X_1.a_1, \dots, X_1.a_k, \dots, X_n.a_1, \dots, X_n.a_k) \quad (68.1)$$

where f_{ij} is a mathematical function. An attribute grammar is thus written in purely functional style without side effects.

As an example, consider the grammar $expr \rightarrow expr + num \mid num$, which we may assume expresses the summation of a series of numbers. An attribute grammar for the numeric value of an expression defined by this grammar is given in Table 68.3. Note that the two instances of the nonterminal $expr$ in the first grammar rule must be distinguished by subscripting, and that the terminal num is assumed to have its numeric value (called *lexval* in Table 68.3) precomputed, possibly by the scanner.

Of particular importance to the translator writer are the kinds of dependencies that the attribute equations create among the attributes of different symbols in a parse tree, because these dependencies

TABLE 68.3 Attribute Grammar for a Simple Expression Grammar

Grammar Rule	Attribute Equations
$expr_1 \rightarrow expr_2 + num$	$expr_1.val = expr_2.val + num.lexval$
$expr \rightarrow num$	$expr.val = num.lexval$

determine when and how—or even if—the attributes can be computed during translation. A primary requirement is that the attribute grammar does not have any circular dependencies. In practical situations, this requirement is virtually guaranteed unless an error has been made. Attributes whose dependencies flow from right to left in the grammar rules (i.e., those whose Equation 68.1 all have only the symbol X_0 on the left) are called *synthesized* attributes; any other attributes are called *inherited*. Synthesized attributes can be computed bottom-up during a parse, or by postorder traversal of the syntax tree, while inherited attributes require a more complex computation scheme. Indeed, as the name implies, inherited attributes are often passed down the syntax tree from parent to child, or from sibling to sibling, and so can be computed by some form of modified preorder traversal of the syntax tree.

A great deal of effort can be expended to ensure that all attribute values are computable during the parsing phase to avoid having to construct the entire syntax tree and to avoid having to make additional passes over the input. The requirements that this places on the attribute grammar vary, depending on the parsing method employed. First, because virtually all parsers read the input from left to right, the attributes must be computable from left to right, and this means that all inherited attributes must depend only on the attribute values of their left siblings. In terms of the Equation 68.1, this means that each equation for an inherited attribute ($X_i.a_j$ is on the left and $i > 0$) must have the form

$$X_i.a_j = f_{ij}(X_0.a_1, \dots, X_0.a_k, X_1.a_1, \dots, X_1.a_k, \dots, X_{i-1}.a_1, \dots, X_{i-1}.a_k) \quad (68.2)$$

An attribute grammar in which all equations for inherited attributes are of this form is called *L-attributed*.

A further requirement for attribute evaluation during parsing is a form of strong noncircularity, in which an order for attribute evaluation can be fixed in advance without incurring any cycles (naturally occurring attribute grammars satisfy this non-circularity requirement, too).

The particulars of the parsing algorithm can also have a significant effect on which attributes are computable during parsing. Recursive-descent parsers are the most flexible; in the recursive routines, inherited attributes can be implemented as passed parameters, while synthesized attributes become returned values (Katayama, 1984). Bottom-up parsers most naturally compute synthesized attributes. They do this by maintaining a stack of attribute values in parallel with the parsing stack. New synthesized attributes are computed on this stack at each reduction step. It is also possible to evaluate certain inherited attributes during a bottom-up parse, but this often requires that the grammar be rewritten, so that the attribute equations can be converted to a manageable form. Indeed, it is theoretically possible to rewrite a grammar so that all attributes become synthesized (Knuth, 1968). However, the grammar thus produced bears little resemblance to the original. Thus, in difficult situations, it may be preferable to delay an attribute computation until after the parse and avoid rewriting the grammar into an unrecognizable form.

68.3 Best Practices

The theory of scanning, parsing, and attribute analysis implies that, in principle, a compiler or interpreter can be generated automatically from descriptions of the source language, attributes, and target machine. While a number of compilers have been generated in this way (Farrow, 1984), it is not common. This is partially because the necessary tools (particularly for optimization and code generation) are complex and have not become standard, and partially because of the need for efficiency, both in translation and in terms of the generated code, which is more difficult to achieve using general tools. At this writing, it is common to automate only the construction of the front end (i.e., the scanner, parser,

and semantic analyzer), although at least partial automation of code generation has become more common with the increasing importance of retargetability.

Although a large number of scanner and parser generators have been written, only a few have gained broad acceptance. We describe here two sets of tools that have been used in many compilers: the Unix tools, Lex and yet another compiler-compiler (Yacc), and their more modern public domain versions, Flex and Bison, and the Java tool, JavaCC. Yacc produces an LALR(1) parser in the C language, whereas Bison can produce a parser using more general algorithms (Denny and Malloy, 2010). JavaCC (Kodaganallur, 2004) produces a recursive-descent parser in the Java language that can be extended to multisymbol lookahead. Another popular tool not discussed here is ANother Tool for Language Recognition ([http://www.antlr.org/](http://wwwantlr.org/)), which also produces more general recursive-descent parsers (Parr and Fisher, 2011) and can generate source code in a number of different languages. It should be noted that many commercial compilers and interpreters have been written by hand without the use of any tools at all; in such cases, the parsers are usually written using recursive-descent.

68.3.1 Specifying Syntax Using Regular Expressions and Grammars

In order to automate the task of generating a scanner and a parser, the first step is to specify the tokens using regular expressions and the syntax using context-free grammar rules. Although it is essential to understand the mathematical theory of both of these mechanisms, the theory ignores extensions and features of practical importance. We mention a few of these here.

The theory of regular expression relies on only three operations: concatenation, choice, and repetition. While these are enough to match any string recognizable by a finite automaton, most pattern matching systems extend this set of operators in many ways. As a typical example, consider the regular expression

$$[0-9]+(\.[0-9]+)?$$

which is written using standard conventions for the Unix tools Lex and Grep. This expression specifies a pattern for a simple floating point constant without exponential part: the expression $[0-9]$ refers to a choice from the range of characters 0 to 9 (i.e., a digit), the $+$ indicates a repetition of one or more ($a+$ is equivalent to aa^*), the backslash in front of the period *escapes* the metacharacter meaning of the period (otherwise, it would match any character), and the question mark indicates an optional component.

Even with these extensions, it is sometimes difficult to write regular expressions for certain patterns, even when such patterns do exist, and one may choose to apply an *ad hoc* recognition process instead of using a regular expression. A notorious case in point is that of C comments, which can be loosely described as $/*$ (not $*/$) $*/$. The trouble is expressing (not $*/$) as a regular expression. More generally, the non-existence of sequences of more than one character in a string is a difficult property to express as a regular expression. Fortunately, these situations do not occur very often in real languages.

It is also necessary to be aware that the theory of regular expressions can be easily extended to cover simple non-regular situations. For instance, nested comments require recursion, and so cannot be directly expressed as a regular expression. Nevertheless, adding a simple counter variable to a scanner permits it to recognize potentially nested comments.

Similar considerations arise in defining syntax using context-free grammars. Consider the following grammar that specifies a simple four-function floating-point calculator program with a single memory:

```

session → asgn n1 session | n1
asgn → = expr | expr
expr → expr addop term | term
addop → + | -
term → term mulop factor | factor
mulop → * | /
factor → - factor | ( expr ) | NUMBER | m

```

A `session` consists of a sequence of assignments (`asgn`) followed by newlines (indicated in the grammar by `nl`), or just a newline (this is used to end the session). The arithmetic operations have their usual meanings. The optional `=` sign at the beginning of an `asgn` indicates assignment of the value of the following expression to the memory. The single letter `m` in a factor fetches the value of this memory. The token **NUMBER** is the only token with more than one possible lexeme, and it is assumed to be given by the regular expression given earlier in this section.

A sample session with an interpreter for this grammar might look as follows:

```
= 3.14 - 2
      1.14
= m*3.14 + 3
      6.5796
m*3.14 - 4
      16.6599
```

This represents a computation of the value of the polynomial $x^3 - 2x^2 + 3x - 4$ at the point $x = 3.14$ using Horner's Rule ($x^3 - 2x^2 + 3x - 4 = ((x - 2)x + 3)x - 4$).

This grammar is written in a style called Backus Normal Form or Backus-Naur Form (*BNF*). In it, the only metasympols are the arrow and the vertical bar (sometimes `::=` or `=` is used instead of the arrow, and sometimes nonterminals are distinguished more directly from terminals by surrounding them with angle brackets `<...>`). Repetition is expressed by recursion, and optional features are expressed by writing separate choices. This grammar also expresses the associativity and precedences of the operators: a left-recursive grammar rule such as `expr → expr addop term` indicates left associativity, and the different precedence levels `expr`, `term`, and `factor`, cause the operators at each level to be given precedences in ascending order (lowest precedence first). When recursion is used only to express repetition, it can be written on the right or the left: the rule for a `session` is written right-recursively for more or less arbitrary reasons.

An alternative to this grammar would be to condense it to the following grammar (still in BNF):

```
session → asgn nl session | nl
asgn → = expr | expr
expr → expr op expr
      | - expr
      | ( expr )
      | NUMBER
      | m
op → + | - | * | /
```

This grammar is ambiguous, however, in that the order in which the operations are applied is not specified, and a legal string may have many different parse trees. This grammar can still be used as the basis for the calculator, as long as separate *disambiguating rules* are stated giving the associativities and precedences of the operators. The advantage to this is that the grammar itself becomes shorter and easier to understand.

A different variety of context-free grammar is obtained by adding metasympols representing optional and repeated constructs. One standard version of this is called *extended BNF* (*EBNF*), which uses square brackets [...] to surround optional constructs and braces {...} to surround repeated constructs (one could just as well use parentheses, ?, and * as in regular expressions). The calculator grammar in EBNF becomes

```
session → { asgn nl } nl
asgn → [=] expr
expr → term { addop term }
addop → + | -
term → factor { mulop factor }
mulop → * | /
factor → - factor | ( expr ) | NUMBER | m
```

In such a grammar, the associativity of the operators is now suppressed in favor of showing the repetition directly. A standard convention is to assume left associativity of operators in any rule using the braces (since a session has no operators, the associativity of its rule is of no consequence).

68.3.2 Lex/Flex and Yacc/Bison

Lex (Lesk, 1975) and Yacc (Johnson, 1975) are scanner and parser generators that are a part of most Unix distributions. Both have modern public domain versions, Flex (Fast Lex; Paxson, 1990, <http://flex.sourceforge.net/>, based on ideas of Jacobson, 1987) and Bison (<http://www.gnu.org/software/bison/>) that run under a variety of operating systems. Each of these programs reads a definition file and produces as output a C source code file containing a scanning/parsing procedure. The definition file for each has the same basic format:

```
{definitions}
%%
{rules}
%%
{auxiliary routines}
```

We discuss the contents of the definition files first for Flex and then for Bison, using our running example of a simple calculator program whose tokens and grammar were described previously.

The Flex definition file for the calculator scanner is given in Table 68.4. In this example, the definitions section contains an `#include` directive inside the brackets `%{and %}`, and the definitions of the three tokens `digit`, `number`, and `whitespace`, using regular expressions written with previously described metasympols (e.g., `whitespace` is defined to be a sequence of one or more blanks or tabs, or “return” characters). All code inside the special brackets is inserted directly at the beginning of the C output file, thus allowing the user to provide declarations/definitions that may be used by the rest of the C code. In this case, the only insertion is to indicate the inclusion of the file `calc.tab.h`. This file can be generated by Bison, and it contains the definitions of tokens and other globals that permit communication between the Flex-generated scanner and the Bison-generated

TABLE 68.4 Flex Definition File

```

/*****
  CALC.L
  *****/
%{
#include "calc.tab.h"
%}
digit      [0-9]
number     {digit}+(\.{digit}+)?
whitespace [ \t\r]+
%%
{whitespace} { /* skip */ }
{number}     { sscanf(yytext, "%lf", &yyval);
              return NUMBER; }
\n          { return '\n'; }
.           { return yytext[0]; }

```

parser. In our example (and for one particular version of Bison), the essential features contained in this file are as follows:

```
/* file calc.tab.h */
enum yytokentype {
    NUMBER = 258,
    UNARY = 259
};
extern YYSTYPE yylval;
```

The subsequent Flex code uses only the definition of `NUMBER` and `yylval` from this file.

The rules section specifies the actions that the Flex scanner is to take when each token is recognized. These actions are placed inside a C block and are inserted directly at the appropriate places in the scanner. In Table 68.4, the specified actions are as follows. All `whitespace` is skipped (empty action). A `number` causes the scanner to compute the floating point value from the `yytext` string and place it in `yylval`, and then return the `NUMBER` token. (The `yytext` string contains the lexeme matched from the input.) The newline character `\n` is singled out for special handling, because it is not placed in the `yytext` string; it is returned directly. Finally, the period indicates a default action (it matches any character), and this causes the character value itself to be returned (`yytext[0]`).

This concludes the description of the calculator Flex file in Table 68.4. Note that this file contains no auxiliary routines section, and the `%%` symbol separating this section from the previous rules section is also omitted.

We turn now to a description of the Bison definition file, which is in Table 68.5. The definitions section contains four lines of C code to be inserted in the output file. The first two are library inclusion commands that include standard I/O and library function definitions for use in the code (`printf` and `exit` are respective examples). The third line of code defines `YYSTYPE` to be `double`; this is the type used to define the Bison value stack, which needs to be `double`, because expressions compute floating point values. The fourth line defines a static variable `mem`, which is to be used as the actual memory location for the single calculator memory. The definitions section also contains the token definitions, indicated by the `%token` directive. In this example, only the `NUMBER` token need be defined; other tokens are single-character and may be referred to directly. Finally, the definitions section contains a description of the associativity and precedence of the arithmetic operators; these are necessary disambiguating rules, because the rules section uses the ambiguous form of the calculator grammar. The order in which the operators are listed determines their precedence (with lowest precedence listed first). The `%left` directive indicates that an operator is left associative. Finally, the `UNARY` token is implicitly defined by the last definition as having the highest precedence. It will be used to give unary minus a higher precedence than any of the binary operators.

The rules section of the Bison specification contains the grammar in a modified BNF format, with actions contained in braces. Since Bison is a bottom-up parser generator, it is easiest to use to compute synthesized attributes. In the calculator grammar, the value attribute is synthesized, and it is this attribute that we use Bison's value stack to compute. The stored memory value, which has an inherited component, is handled directly by using the defined `mem` variable. The action code refers to the attribute values on the value stack by using symbols beginning with `$`. The symbol `$$` refers to the (synthesized) value to be computed for the nonterminal defined by the rule. Each of the symbols `$1`, `$2`, etc., refers to the attribute value computed for each symbol on the right-hand side of the grammar rule. Thus, `$$ = $1 + $3` in the rule `expr: expr + expr` indicates that the value of the first and third symbols (the right hand expressions) are to be added to get the value of the result expression. This convention allows Bison rules to be written in a style very close to the synthesized rules of an attribute grammar.

A few changes have been made to the grammar to make it more usable with Bison. One is that the operators are written directly into the expressions, instead of being listed separately; this eliminates the need for a separate character attribute for an operator rule. Two additional changes have been made to

TABLE 68.5 A Bison Definition File

```

/*****
  CALC.Y
  *****/
%{
#include <stdio.h>
#include <stdlib.h>
#define YYSTYPE double
static double mem;
%}
%token NUMBER
%left '+' '-'
%left '*' '/'
%left UNARY
%%
session : /* empty */
        | session '\n' { exit(0); }
        | session asgn '\n' { printf("\t%g\n", $2); }
        | session error '\n' { yyerrok; }
        ;
asgn    : '=' expr { mem = $2; $$ = $2; }
        | expr { $$ = $1; }
        ;
expr    : expr '+' expr { $$ = $1 + $3; }
        | expr '-' expr { $$ = $1 - $3; }
        | expr '*' expr { $$ = $1 * $3; }
        | expr '/' expr { $$ = $1 / $3; }
        | '-' expr %prec UNARY { $$ = - $2; }
        | '(' expr ')' { $$ = $2; }
        | NUMBER { $$ = $1; }
        | 'm' { $$ = mem; }
        ;
%%
int main()
{ yyparse(); return 0; }

int yyerror( char* t)
{ fprintf(stderr, "%s\n", t);
  return 0; }

```

the grammar rule for a *session*. First, the rule is written in left recursive instead of right recursive form. A right recursive rule causes the parsing stack to grow without limit; this means that a very long session might cause a stack overflow (a similar situation is caused by tail recursive procedure calls). Thus, all right recursive rules that do not reflect an associativity requirement should be rewritten in left recursive form. The remaining change is the addition of the rule

```
session : session error '\n' { yyerrok; }
```

to the choices for a *session*. This is an error-handling production. It matches any line that is not a legal assignment to the internally defined Bison nonterminal error, and the action `yyerrok` resets the parser to accept more input. Bison also automatically calls a `yyerror` procedure that can print an error message or perform some other action.

Finally, the auxiliary routines section of Table 68.5 contains a main procedure that just calls the parsing procedure `yyparse` which is generated by Bison. (The scanning procedure generated by Flex is called `yylex` and is automatically called at the appropriate times by `yyparse`.) The `yyerror` procedure is also defined in this section; it simply prints an error message (supplied by Bison, typically `syntax error`).

Assuming that the Flex definition for the calculator is in the file `calc.l`, and the Bison definition is in the file `calc.y`, then a running calculator program can be built in a Unix-like system with the commands

```
flex -I calc.l
bison -d calc.y
gcc calc.tab.c lex.yy.c -lfl -ly
```

The file `calc.tab.c` is the output file produced by Bison, and the file `lex.yy.c` is the output file produced by Flex. The option `-I` causes flex to produce an interactive scanner (i.e., one with lazy lookahead), the option `-d` causes Bison to produce the file `calc.tab.h` automatically, and the options `-lfl` and `-ly` cause the C compiler (in this case the GNU C compiler `gcc`) to consult the Flex and Bison (or Yacc) libraries when linking (if necessary).

One additional Bison feature is the verbose option `-v`. If we give the command

```
bison -v calc.y
```

then a file `calc.output` is produced that contains a description of the parsing table used by the Bison-generated parser, similar to Table 68.2. This can be useful in tracking down exactly the behavior of the parser.

68.3.3 JavaCC

JavaCC (<http://javacc.java.net/>) is a tool for automatically generating scanners and recursive-descent parsers in Java. While these parsers suffer from some of the same restrictions as other top-down parsers, JavaCC offers some advantages over Flex and Bison. First, the parser and scanner generators are more fully integrated, so that only one definition file needs to be created, and this file contains both the token and grammar definitions. Second, the number of lookahead symbols can be increased and can even vary within a JavaCC-generated parser. (Bison can also handle lookahead problems, but does so by employing multiple parsers, which can substantially decrease execution speeds.) Finally, there are additional tools available for use with JavaCC, such as JJTree, which can assist with the automatic building of syntax trees.

As with Bison and Flex, we give a description of a JavaCC definition file using the calculator grammar as an example. The only file needed for JavaCC is shown in Table 68.6. The general form for this file (in EBNF) is

```
javacc_input → javacc_options
               PARSER_BEGIN ( ID ) java_compilation_unit
               PARSER_END ( ID ) { production } EOF
```

The `javacc_options` section allows for the user to change default properties used by JavaCC to produce the parser, such as lookahead, debug information, and error reporting. The calculator example of Table 68.6 omits this section to accept all defaults; the reader is referred to the JavaCC documentation for further information. The `java_compilation_unit` contains standard Java code to create a runnable program. Note that this code allows the programmer an arbitrary choice of the nonterminal to use as the start symbol (in Table 68.6, it is a `session`). This code also includes the definition of the static variable `mem` to use as the memory for the calculator.

After the definition of the parser code, the file contains definitions of zero or more production elements. Each of these can be one of four kinds: grammar rules (with embedded Java code), regular expressions defining tokens, Java code separate from other rules, and special declarations to include in

TABLE 68.6 JavaCC Definition File

```

/*****
Calc.jj
*****/
PARSER_BEGIN(Calc)
public class Calc
{
    static double mem;
    public static void main(String args[]) throws ParseException
    {
        Calc parser = new Calc(System.in);
        parser.session();
    }
}
PARSER_END(Calc)
SKIP: { " " | "\t" | "\r" }
TOKEN:
{
    < NUMBER: (<DIGIT>)+ ( "." (<DIGIT>)+ )? >
    | < DIGIT: ["0"-9"] >
}
void session(): { double a; }
{
    (
        a=asgn() "\n" { System.out.println(a); }
    )*
    "\n"
}
double asgn(): { double a; }
{
    "=" a = expr() { mem = a; return a; }
    | a = expr() { return a; }
}
double expr(): { double a; double b; }
{
    a=term()
    (
        "+" b=term() { a += b; }
        | "-" b=term() { a -= b; }
    )*
        { return a; }
}
double term(): { double a; double b; }
{
    a=factor()
    (
        "*" b=factor() { a *= b; }
        | "/" b=factor() { a /= b; }
    )*
}

```

(continued)

TABLE 68.6 (continued) JavaCC Definition File

```

                                { return a; }
}
double factor(): { Token t; double a; }
{
    "-" a = factor()      { return -a; }
  | t=<NUMBER>           { return Double.parseDouble(t.image); }
  | "(" a=expr() ")"     { return a; }
  | "m"                  { return mem; }
}

```

the scanner. Table 68.6 has examples only of the first two kinds: grammar rules and token definitions. Typically, token definitions are introduced by the keyword `TOKEN` and a colon. Table 68.6 contains a separate special token definition using the keyword `SKIP`, which defines tokens that are not passed on to the parser (white space characters in the example).

Finally, the grammar rules are given in a modified EBNF form using regular expression-like symbols; for example, in Table 68.6 the notation $(...)^*$ indicates a repetition of 0 or more times. Non-terminal matches are also represented as function calls, with the associated Java code to be executed after the call given in braces immediately afterward, similar to Bison. Unlike Bison, however, there are no automatic variables representing returned values as in Bison. Instead, such variables must be declared and explicitly assigned. Furthermore, in JavaCC these variables must be declared in a separate section surrounded by braces before the production choices are given, and these choices must also be surrounded by braces.

JavaCC, in keeping with Java conventions, requires that the file for the calculator example be named `Calc.jj`. A calculator program can be built and executed using the following command-line commands:

```
javacc Calc.jj
javac *.java
java Calc
```

The first line calls `javacc`, which creates a number of Java code files in the current directory, including a parser in `Calc.java` and a scanner in `CalcTokenManager.java`. The second line compiles these together with the additional Java code files to produce a `Calc.class` file that is executable with the JVM, which is what the last line above performs. The result is an execution similar but not identical to that of the Bison calculator (since different compilers and runtime systems are involved).

It should be noted that no attempt has been made to perform error recovery with this version of the calculator. Indeed, the following execution shows that parse errors end the execution of the calculator with an uncaught Java exception:

```
> java Calc
2 -
Exception in thread "main" ParseException: Encountered " "\n" "\n" " at line
1, column 5.
Was expecting one of:
<NUMBER> ...
"-" ...
"(" ...
"m" ...
at Calc.generateParseException(Calc.java:338)
at Calc.jj_consume_token(Calc.java:276)
at Calc.factor(Calc.java:153)
at Calc.term(Calc.java:95)
at Calc.expr(Calc.java:79)
```

```

at Calc.asgn(Calc.java:45)
at Calc.session(Calc.java:26)
at Calc.main(Calc.java:7)

```

Because of Java's built-in extensive exception handling mechanisms, which JavaCC uses in essential ways, it is possible to perform rigorous error recovery, but doing so involves techniques that are beyond the scope of this chapter.

68.3.4 Dealing with Ambiguity

Although the expectation is that a language grammar should be unambiguous, in that each legal input string will correspond to exactly one syntax tree, there are many practical situations in which it is difficult or impossible to write a grammar unambiguously. In such cases, disambiguating rules must be stated and built into the parser in some way. We have already seen how Yacc/Bison can accommodate precedence and associativity disambiguating rules for operators. We give three additional examples of the use of disambiguating rules.

The dangling-else ambiguity is typical in languages such as C and Java, which allow both simple and compound statements in control structures. In C, the dangling-else ambiguity appears in statements like

```
if(e) if(f) { /*then-part*/ } else { /*else-part*/ }
```

The question is: should the else-part be executed when *f* is false, or when *e* is false? The standard answer is that it should be executed when *f* is false (and when *e* is true). This is called the most closely nested disambiguating rule for the *if* statement, because it implies that the else-part structure is to be associated in the parse tree with the closest previous *if* statement that does not have an else-part. This also corresponds to always preferring the second choice in the BNF rule

```

if_statement → if ( expression ) statement
              | if ( expression ) statement else statement

```

This disambiguating rule could actually be incorporated directly into the BNF, but it is slightly complicated (and not very illuminating), and the rule as stated is easily implemented in a parser. It is worth noting that languages in which the *if* statement has a closing keyword (such as **end** or **endif**) do not have the dangling-else ambiguity; Ada is an example of such a language.

A second kind of ambiguity is represented by the availability in C++ of function-style casts, where one can write `int(x)` to mean the same thing as the C cast `(int)x`. Now consider the code fragment

```

typedef int (*F)();
void **x;
void p(void)
{ F (*x)();
  ...
}

```

Is the first code line inside `p` a cast of global `*x` to type `F`, after which this function value is called, or is it a declaration of a local variable `x` of type “pointer to function returning a value of type `F`?” The C++ standard says it is the latter: any statement that may be interpreted as a declaration *is* a declaration. This means that all grammar rules for declarations are to be preferred to all other grammar rules. Note that this is an ambiguity *between* nonterminals, rather than an ambiguity within a single nonterminal, as with the dangling-else ambiguity. It is also impossible to remove this ambiguity directly within the grammar, because the order of rules in a BNF description is immaterial to the language defined.

The final example of an ambiguity that we present here is also one that arises with casts, but this time in C. Consider the C statement

```
(t) - x
```

If `t` is a type name declared in a `typedef`, then this is a cast of the value `-x` to type `t`. On the other hand, if `t` is a variable, then this is the value obtained by subtracting `x` from `t`. In order to parse this correctly, it is necessary to consult the symbol table to see whether `t` is defined as a type. Thus, the symbol table (or at least the `typedef` part of it) must be built as parsing proceeds. Unlike the previous examples of ambiguity, this is a context ambiguity that cannot be resolved by purely syntactic means.

In an LR parser, these ambiguities, or parsing conflicts, can be of two different kinds. The first, more common, situation, is when both a shift and a reduction by a grammar rule choice are called for on the same input token; this is a *shift-reduce conflict*. The other case is when reductions by two different rules are called for on the same input token; this is a *reduce-reduce conflict*. Shift-reduce conflicts are usually resolved by selecting the shift over the reduce. This ensures that the longest possible string will be matched by each rule. The typical example is the dangling-else ambiguity, where preferring the shift corresponds exactly to the most closely nested disambiguating rule. Reduce-reduce conflicts, on the other hand, have no natural disambiguating rule. Parsers generally adopt an *ad hoc* rule, in which the reduction by the lowest-numbered rule is preferred (where the rules are numbered in the order they are considered by the parser). The C++ ambiguity between cast expressions and declarations (also described previously) can be resolved in this way in favor of the declarations (as the C++ definition requires) by listing the declaration rules before the expression rules. Yacc/Bison adopts both of these disambiguating rules as stated. Unfortunately, the third ambiguity mentioned previously, a cast vs. an arithmetic expression in C, cannot be resolved by either of these means. Typically, this is handled by having the scanner consult the symbol table when recognizing an identifier and returning a different token for a type name than for a variable. Both Flex and JavaCC have mechanisms for introducing code to achieve this into their scanner specifications.

An alternative to these disambiguating rules is to build manual disambiguation mechanisms directly into the parser generator. Indeed, in a top-down parser like that generated by JavaCC, such a capability is a necessity, because ambiguities such as preferring declarations over expressions in C++ cannot be handled by reordering the grammar rules: a top-down parser would simply commit to the first rule possible and never consider a subsequent rule, generating a parse error instead (there are no shift-reduce or reduce-reduce conflicts in LL parsers, only shift-shift conflicts).

In JavaCC, the primary disambiguation mechanism is that of extending the lookahead tests locally to possibly arbitrary lengths, essentially causing backtracking if a grammar rule choice should fail. For example, in order to prefer a C++ declaration over an expression, one might use code such as the following in a JavaCC specification:

```
void statement(): {}
{
    LOOKAHEAD(declaration()) declaration()
    | expression()
}
```

Since this kind of lookahead can be expensive in terms of execution speed, it is also possible in JavaCC to put a bound on the number of tokens to consider, as well as to add tests for specific tokens that would provide clear decision points. For example, writing `LOOKAHEAD(10, declaration())` in the aforementioned code would limit lookahead/backtracking to 10 tokens.

Finally, the `LOOKAHEAD` construct in JavaCC will also accept user-defined Boolean tests (called *semantic predicates*, as opposed to the syntactic tests of previous examples). Details can be found in the JavaCC `LOOKAHEAD` MiniTutorial at <http://javacc.java.net/doc/lookahead.html>.

68.3.5 Attribute Analysis

Yacc/Bison and JavaCC restrict the kinds of attributes that can be reasonably computed during a parse, because of the requirements of their parsing algorithms. In cases of difficult attribute computations, these limitations are overcome by either providing ad hoc solutions using external data structures, or by constructing an intermediate representation such as a syntax tree during the parse, and then writing specialized procedures that perform semantic analysis by traversing the intermediate form in one or more passes. Tools for automating the computation of general attributes (other than syntax tree construction) have not been widely used, partially due to the many different varieties of intermediate representations and partially due to the variety and complexity of the semantic attributes of different languages. Some notable systems that do permit the automation of this step include Eli (Gray et al., 1992) (see also <http://eli-project.sourceforge.net>), JastAdd (Hedin and Magnusson, 2003), and Gentle (Schröer, 1997) (see also <http://gentle.compilertools.net>). Code generation is a special case of this problem, and special methods for automating the code generation step have been developed, which we describe next.

68.3.6 Intermediate Representations and Code Generation

The abstract syntax tree is a convenient way to represent the source program within a translator, particularly for semantic attribute analysis. However, it is less suited for code generation. Although target code can be generated as a form of attribute analysis, either during parsing or by traversal of the syntax tree, the quality of this code is usually poor, and further processing must be done before an acceptable level of target code is produced. Typically, this is achieved by generating some form of intermediate code that is closer to the code of the target machine but still abstract enough that the compiler can perform code improving transformations on it. Many choices have been used for this intermediate code. Some of the more common are sequences of expression trees, sequences of postfix expressions, an abstract linearized form of syntax tree called *three-address code*, and actual code for a hypothetical target machine, such as P-code for the stack-based P-machine of many Pascal-related compilers (Nori et al., 1981). An example of three-address code corresponding to the source code line $=3.1+m/2$ for the calculator language described previously is

```
t1 := m/2
t2 := 3.1 + t1
m := t2
```

Here, the identifiers `t1` and `t2` are temporaries introduced by the compiler that can be thought of as pseudo-registers, and later assigned either to actual registers or to temporary locations in memory.

The equivalent (annotated) P-code for this same source code is as follows:

```
ldo r,m      ; load real value onto stack from static location m
ldc r,2.0    ; load constant real value 2.0 onto stack
dvr         ; divide two reals on top of stack, push result
ldc r,3.1    ; load constant real value 3.1 onto stack
adr         ; add two reals on top of stack, push result
sro r,m      ; store real from stack to static location m, pop stack
```

The use of the code of a precisely defined, simple machine, such as the P-machine as the intermediate target language, has several benefits. First, the compiler can be run in interpreter mode, in which the P-code functions as the target code, and a P-machine simulator is used to execute the P-code on the actual target machine. The target code is then kept as P-code, which is generally much more compact than actual executable machine code. Furthermore, in order to retarget the compiler to a new machine, it is only necessary to rewrite the P-machine simulator. Second, in order to obtain a native-code compiler from the P-code compiler, one need only write a translator from P-code to the native code of the

target machine. This is usually done by writing individual procedures for each P-code instruction that perform something like a macro expansion of each P-code instruction into target code. By itself, this process will produce very poor code, but it can be combined with a static simulation of the P-machine itself, whose stack can be used to discover opportunities for optimization. An improvement on P-code that adds significant attributes for tracking address calculations and optimizing transformations is U-code (Perkins and Sites, 1979).

An intermediate language that is compact, capable of efficient interpretation, and easily retargeted to different architectures is of special interest for heterogeneous networks, where the platform on which the intermediate code is to be executed or compiled to native code may not be known in advance. If the intermediate code is given a numeric machine code-like encoding (called *bytecode*), and techniques to improve interpretation performance are used (such as on-the-fly compilation or threaded code interpretation [Bell, 1973]), then good performance on a variety of machines across a network can be achieved. This is, for example, the basis for Java implementations (Gosling, 1995). Although one might think that the use of bytecode interpreters in Java implementations should incur a performance penalty, dynamic (*just-in-time* [JIT]) compilation techniques, together with runtime (*hotspot*) monitoring, frequently achieves execution speeds that are the same or even better than those of programs compiled to native code; see Section 68.5 and Lewis and Neumann (2003).

A similar process of macro expansion works for three-address code and its variants, although in this case the underlying abstract machine and its state is not made explicit (as it is for P-code), and the accumulated information during code generation must be stored as attributes in data structures associated with the intermediate code. Typically, these include address descriptors, which record the locations at which named quantities (such as variables) can be found, and register descriptors, which record information about the values that can be statically predicted to be in registers at particular points in the target code. Address descriptors can be kept in the symbol table, while register descriptors can be maintained in an array indexed by the register numbers.

Unfortunately, both of these code generation schemes spread the information about the target machine throughout the code generator. This means that retargeting the compiler is more costly than if the target machine information were collected compactly in one place. Several approaches have been taken towards achieving this.

The first method for improving the retargetability of the code generator involves writing a syntactic description of the macro expansion process for the intermediate code together with code-emitting actions, much as a Yacc/Bison or JavaCC description associates semantic actions with syntactic rules (Glanville and Graham, 1978). This method permits the automatic generation of the code generator from this description, using a tool similar to a parser generator. This method has been expanded in (Ganapathi and Fischer, 1985) to include semantic predicates. As an example, consider generating code for the three-address instruction

```
t1 := m/2
```

A rule that would handle this instruction for a VAX-like architecture might appear as

```
reg(n) → adr(a)/const(i) dead?(n) float?(a) #emit("divd3 #i.,a,rn")
```

This rule establishes that emitting the VAX instruction `divd3 #i.,a,rn` allows the expression consisting of an address `a` divided by a constant `i` to be reduced to a register `n`, provided `n` is *dead* (i.e., contains a value that is no longer needed), and provided that `a` is the address of a real-valued quantity. Matching this rule to the previous three-address instruction causes `t1` to be identified with `reg(n)`, `m` to be identified with `adr(a)` (thus computing `a` as the address of `m`), and identifying `2` with `const(i)` (thus setting `i` to 2). The resulting line of VAX code generated is

```
divd3 #2.,m,r1
```

In the absence of predicates, such a set of rules describing the target machine could be written as a Yacc/Bison input. The difference between this kind of grammar and a grammar describing the syntax of the source language is that the target machine grammar usually comprises thousands rather than hundreds of rules, and the grammar is highly ambiguous, because there are usually many ways to generate target code to achieve a specific effect. Parser generators such as Yacc/Bison are inefficient and cumbersome when dealing with such grammars, and a code generator specifically tuned to this situation is more appropriately used (Henry, 1984).

The second variety of retargeting mechanism we discuss is that used in the portable C compiler (Johnson, 1978). In this mechanism, a special template language is used to describe the process of matching intermediate code to target code. The code generator then consults a table of these templates during code generation in an attempt to find the optimal match.

The third variety of retargeting mechanism is similar to the second, except that both the intermediate code and the target code templates are written in the template language, and the matching routine runs statically, usually during the installation of the compiler, and selects a match between certain sequences of intermediate code and target code, which is then fixed once and for all. This method was used in the Production-Quality Compiler-Compiler project (Cattell, 1980; Leverett et al., 1980). A related method has also been used in the GNU compiler suite (GCC, 2010), based on ideas of Davidson and Fraser (1984). In the GNU compiler, the template language is called the register transfer language, or RTL. This language is written in LISP-like prefix form. An example of an instruction template is as follows:

```
(define_insn "divdf3"
  [(set (match_operand:DF 0 "register_operand" "=f")
        (over:DF (match_operand:DF 1 "register_operand" "f")
                 (match_operand:DF 2 "register_operand" "f")))]
  "! TARGET_SOFT_FLOAT"
  "divd3 %1,%2,%0"
  [(set_attr "type" "arith")])
```

Instruction templates are introduced using the `define_insn` operator. This operator is followed by a symbolic name for the instruction template, a pattern with predicates (such as `register_operand`), constraints (such as `f`, indicating the register may be used for floating point values), and extra conditions (such as `!TARGET_SOFT_FLOAT`, indicating that there must be a hardware floating point arithmetic unit available in the processor). Following this, there is a pattern for the instruction to be generated, with numbers referring to the operands of the pattern (in this example, it is the VAX instruction `divd3%1,%2,%0`). Finally, there is a specification of attributes for the template.

Such instruction templates are used to generate actual target code in RTL format directly from C code during a parse. Optimizing steps are then applied directly to the RTL intermediate code, and then templates are again used to generate assembly output. Specialized RTL attribute descriptions are also used to guide the code generation process.

One possibility for a compiler writer is to avoid the issue of code generation for a target machine altogether and instead generate code in the C language or other language capable of expressing lower-level code, and then use a widely available C compiler such as the GNU C compiler GCC to generate target code. This represents an elegant and simple solution, but has a number of drawbacks. First, the available C compiler must of course be capable of producing target code for the desired target. Second, it forces the compiler writer to rely on the optimizing capabilities of the C compiler, since many optimizations are not able to be expressed directly in the generated C code. Furthermore, because of its relative lack of constraints, C can be a difficult language to optimize for critical performance. One approach to these difficulties is to define a language similar to C that has better capabilities to be used as an intermediate target language for compilers; this is, for example, the goal of the *C-Minus-Minus* development effort (see <http://www.cminusminus.org>).

A different approach has been taken by the *LLVM project* (see <http://llvm.org>; LLVM is now a proper name but earlier was an acronym for *low-level virtual machine*). LLVM consists of a core intermediate language as well as a *compiler infrastructure* consisting of many loosely coupled modules that can be easily manipulated with low coding overhead to achieve desired effects. The core intermediate language itself is an abstract reduced instruction set computer (RISC)-like assembly language, but with calling conventions and register use left unspecified. LLVM has proven to be extremely versatile in reducing coding effort and code size while maintaining high levels of optimization and is the foundation for most of the translation tools in Apple products.

68.3.7 Compiler Output

In general, compilers process source files as input and generate object code files as output. Depending on various compiler directives or command-line options, compilers can also generate metadata about the source program that program development utilities such as debuggers and profilers can use. (See, e.g., <http://gcc.gnu.org/onlinedocs/gcc/Debugging-Options.html> for Gnu gcc, <http://docs.oracle.com/javase/7/docs/technotes/tools/windows/javac.html#options> for Java, and <http://msdn.microsoft.com/en-US/library/19zlt1wy%28v=vs.80%29.aspx> for Microsoft C++.) Compilers can embed this metadata into the object files or they can output the metadata as separate files.

Symbolic, or source-level, debuggers allow developers to interact with their application programs at run time and use identifiers (names of constants, variables, functions, etc.) that appear in the source code and refer to the source program statements by their line numbers. Such symbol table and cross-reference information is often lost by the time a compiler outputs the object files. Compiler directives or command-line options can specify that this information be kept by embedding it into the object code or outputting it as separate files.

Profilers monitor the execution of application programs. Upon completion of the program, the profiler generates a report containing such statistics as how many times each source statement was executed, how many times each variable was accessed and modified, and how much time was spent in each function. Gathering these statistics while an application program is running requires similar metadata to those that debuggers require. Again, compiler directives or command-line options can specify that this information be embedded into the object code or output as separate files.

Another type of output file that some C and C++ compilers can generate is precompiled headers. (See e.g., <http://gcc.gnu.org/onlinedocs/gcc/Precompiled-Headers.html> for Gnu gcc and <http://msdn.microsoft.com/en-us/library/szfdksca%28v=vs.71%29.aspx> for Microsoft C++.) A so-called header file (typically named with a .h suffix) contains constant and macro definitions that multiple source files include at the beginning of each file. To save the time of rescanning and reparsing a header file each time it is included, the compiler can *precompile* a header file the first time it is included and save it in an intermediate form as a precompiled header file. Then each subsequent time the header file is included, the compiler uses the precompiled header file instead. Compiler directives or command-line options specify whether or not to generate and use precompiled headers.

68.3.8 Code Optimization

A code generator that naively expands intermediate code into target code will produce code that is extremely inefficient, both in terms of execution speed and target code size. A production-quality compiler must include processing steps that improve its ability to generate good target code, so that it more nearly resembles the code that would be produced by an assembly language programmer. Such processing steps are usually referred to as *optimization*, though they almost never produce truly optimal code. Indeed, the production of mathematically optimal code, except in the very simplest cases, is known to be computationally intractable (NP-complete), so to attempt this would result in unacceptably slow compilation speed.

Optimization steps can be built into almost all the phases of a compiler, from parsing to final target code generation. If an optimization pass is performed separately, it usually occurs after intermediate code generation, but before target code generation. Such optimizations are generally *source-level* in that they do not depend heavily on the details of the target machine. Some optimizations, however, are *target-level*, and require that the details of the target code be known. Such optimizations are referred to as *peephole optimizations*, because they were originally (and are sometimes still) performed by examining small sequences of target code and replacing them with more efficient code. This term can be misleading, however, because modern compilers sometimes perform considerably more sophisticated analysis of the target code than the name might imply (an example is the GNU C++ compiler). One complex aspect of the scheduling of optimizations during compilation is that some optimizations may uncover opportunities for other optimizations and vice versa (this is sometimes called the *phase problem*). This leads some compilers to repeat certain optimizations in an attempt to catch such cascaded situations. More adaptable optimizers should in principle be able to solve this problem more effectively in the future, and indeed the versatile LLVM compiler infrastructure (see Section 68.3.6) has been used together with genetic algorithms to achieve better optimization results than hand-chosen sequences (see <http://donsbot.wordpress.com/2010/03/01/evolving-faster-haskell-programs-now-with-llvm/>).

Optimizations are classified according to the region of the program about which information is gathered in order to perform the code improvement. Local optimizations consider only straight-line segments of code, that is, those not involving jumps or calls. Global optimizations consider the code of a single procedure. Interprocedural optimizations consider the entire program or compilation unit. Most compilers perform some kinds of local optimizations. A more heavily optimizing compiler will perform global optimizations, typically using an information-collection method called *dataflow analysis*, which passes information around a flow graph representing the flow of control through a procedure. It is a rare compiler that performs interprocedural optimization, and for a very good reason: such optimizations are largely ineffective unless they are postponed to link time, because many procedures will not be available in a single compilation unit. This means that the linker must be closely coupled with the compiler; in particular, the system linker cannot be used. This raises the level of complexity of the compilation environment considerably.

In the remainder of this brief discussion of optimizations, we list the principal sources of code improvement over a naive code-generation strategy. While the focus of this list is on speed optimizations, one needs to be aware that there are other possible goals for optimization steps, such as reducing code size, reducing memory or disk usage, or reducing communication bottlenecks. An important optimization for modern portable devices, such as cell phones, is aimed at reducing power consumption; see the Further Information section for a reference. See also the chapter on Scheduling.
