Using force feedback to provide attractive forces that pull the user toward a target, or tactile feedback to provide additional feedback for the boundaries of the target, has been found to yield modest speed improvements in some target acquisition experiments, although error rates may also increase (Akamatsu and MacKenzie, 1996; MacKenzie, 1995). However, there have been almost no published studies for tasks where multiple targets are present, as on a computer screen with many icons and menus. Haptic feedback for one target may interfere with the selection of another, unless one uses techniques such as reducing the haptic forces during rapid motion (Oakley et al., 2001). Finally, one should also consider whether software constraints, such as snap to grids, are sufficient to support the user’s tasks.

The construction of force output devices is extremely technically demanding. They must be stiff in order to be able to create the sensation of solid contact, yet light so that they have little inertia themselves, and there must be a tight loop between input (position) and output (force). Sigoma (1993) has suggested that having this loop iterated at 5 kHz may be necessary for optimal fine motor control. It has been shown that force feedback improves performance in certain telerobotic applications when, for example, inserting a peg into a hole (Sheridan, 1992). The most promising applications of force output seem to appear in domains where simulation of force is essential, such as surgical simulation and telerobotics (Burdea, 1996).

Another fundamental challenge for haptic feedback techniques results from the interaction between the haptic and visual channels. Visual dominance deals with phenomena resulting from the tendency for vision to dominate other modalities (Wickens, 1992). Campbell et al. (1999) show that tactile feedback improves steering through a narrow tunnel, but only if the visual texture matches the tactile texture; otherwise, tactile feedback harms performance.

21.15 Auditory Displays

Here, we consider computer-generated auditory feedback. Speech audio can consist of synthesized or recorded speech. All other audio feedback is known as nonspeech audio. With stereo speakers or a stereo headset, either type of audio can be presented such that it seems to come from a specific 3D location

around the user, known as spatialized audio. For speech input and technology-mediated human–human communication applications that treat stored voice as data, see Section 21.8.1.

21.15.1 Nonspeech Audio

Nonspeech auditory feedback is prevalent in video games but largely absent from other interaction with computing devices. Providing an auditory echo of the visual interface has little or no practical utility and may annoy users. Audio should be reserved to communicate simple, short messages that complement visual feedback (if any). Furthermore, one or more of the following conditions should hold: the message should (1) deal with events in time, (2) call for immediate action, or (3) take place when the user’s visual attention may be overburdened or directed elsewhere (Buxton, 1995b; Deathrage, 1972). For example, researchers have attempted to enhance scrollbars using audio feedback (Brewster et al., 1994). However, the meaning of such sounds may not be clear. Gaver advocates ecological sounds that resemble real-world events with an analogous meaning. For example, an empty disc drive might sound like a hollow metal container (Gaver, 1989). If a long or complex message must be delivered using audio, it will likely be quicker and clearer to deliver it using speech output. Audio feedback may be crucial to support tasks or functionality on mobile devices that must take place when the user is not looking at the display (for some examples, see Hinckley et al., 2000).

Nonspeech sounds can be especially useful for attracting the attention of the user. Auditory alerting cues have been shown to work well, but only in environments where there is low auditory clutter. However, the number of simple nonspeech alerting signals is limited, and this can easily result in misidentification or cause signals to mask one another. An analysis of sound signals in fighter aircraft (Doll and Folds, 1985) found that the ground proximity warning and the angle-of-attack warning on an F16 were both an 800 Hz tone, a dangerous confound since these conditions require opposite responses from the pilot. It can also be difficult to devise nonspeech audio events that convey information without provoking an alerting response that unnecessarily interrupts the user. For example, this design tension arises when considering nonspeech audio cues that convey various properties of an incoming e-mail message (Hudson and Smith, 1996; Sawhney and Schmandt, 2000).

21.15.2 Speech Output

Speech auditory output is generally delivered through either recorded speech segments or completely synthetic speech (also known as text-to-speech technology). There has been considerable interest, especially for military applications, in the use of speech in providing warnings to the operators of complex systems. Speech can provide information to direct the operator’s attention in a way that alarms cannot (since an unfamiliar alarm simply indicates a problem, without telling the user the nature or context of the problem). Synthetic speech is most useful where visual information is not available, for example, in touch-tone phone menu systems or in screen reader software for blind or low-vision users. Although progress is being made, synthetic voices still sound somewhat unnatural and may be more difficult for users to understand. Recorded speech is often used to give applications, particularly games, a more personal feel, but can only be used for a limited number of responses known in advance.

The rate at which words must be produced to sound natural is a narrow range. For warning messages, 178 words per minute is intelligible but hurried, 123 words per minute is distracting and irritatingly slow, and a more natural rate of 156 words per minute is preferred (Simpson and Marchionda-Frost, 1984). The playback rate of speech can be increased by overlapping samples in time such that one sample is presented to one ear and another sample to the other ear. Technologies to correct for pitch distortions and remove pauses have also been developed (Arons, 1993; Sawhney and Schmandt, 2000; Stifelman, 1996). It is recommended by the US Air Force that synthetic speech be 10 dB above ambient noise levels (Stokes et al., 1990).

21.15.3 Spatialized Audio Displays

It is possible to synthesize spatially localized sounds with a quality such that spatial localization in the virtual space is almost as good as localization of sounds in the natural environment (Wenzel, 1992). Auditory localization appears to be primarily a 2D phenomenon, that is, observers can localize in horizontal position (azimuth) and elevation angle to some degree of accuracy. Azimuth and elevation accuracies are of the order of 15°. As a practical consequence this means that sound localization is of little use in identifying sources in conventional screen displays. Where localized sounds are really useful is in providing an orienting cue or warning about events occurring behind the user, outside of the field of vision.

There is also a well-known phenomenon called visual capture of sound. Given a sound and an apparent visual source for the sound, for example, a talking face on a cinema screen, the sound is perceived to come from the source despite the fact that the actual source may be off to one side. Thus, visual localization tends to dominate auditory localization when both kinds of cues are present.

21.16 Future Directions

The future of interaction with computers will both be very different and very much like it is today. Some of our current tools, such as mice and keyboards, have evolved to suit interaction with desktop GUIs and rapid text entry. As long as users' work continues to involve tasks such as calculating budgets, writing reports, looking up citations, exchanging memos, and other knowledge worker tasks that seem to lend themselves to solution using desktop computers, we will continue to see mice and keyboards in use, not only because they are familiar but also because they closely match human skills and the requirements of the tasks. Devising new techniques that provide more efficient pointing at a desktop display than a mouse, for example, is difficult to achieve (Card et al., 1978). Speech recognition will allow new types of interaction and may enable interaction where it previously has been difficult or infeasible. However, even as technical limitations are removed, speech interaction will not replace all forms of interaction: we will continue to interact with computers using our hands and physical intermediaries, not necessarily because our technology requires us to do so but because touching, holding, and moving physical objects is the foundation of the long evolution of tool use in the human species (Wilson, 1998).

But our computers and the tasks they serve are rapidly evolving. Current handheld devices have the display and computational capabilities of common desktop machines from several years ago. What is lacking are new methods of interacting with such devices that uniquely suit mobile interaction, rather than derivatives of the desktop interface. Researchers are still actively exploring and debating the best ways to achieve this. Meanwhile, technology advances and economic trends continue to drive the cost of commodity displays lower and lower, while the limits of the technology continue to increase. Thus, we will continue to see new innovations in both very small and very large displays, and as these become commonplace, new forms of interaction will become prevalent. Very small displays invariably seem to be incorporated into input/output appliances such as watches, pagers, and handheld devices, so interaction techniques for very small form factors will become increasingly important.

The Internet and wireless networking seem to be the main disruptive technologies of the current era. Indeed, it seems likely that 100 years from now the phrase "wireless network" will seem every bit as antiquated as the phrase "horseless carriage" does today. Nobody really understands yet what it will mean for everything and everyone to be connected, but many researchers are working to explore the vision of ubiquitous computing originally laid out by Weiser (1991). Techniques that allow users to communicate and share information will become increasingly important. Biometric sensors or other convenient means for establishing identity will make services such as personalization of the interface and sharing data much simpler (Rekimoto, 1997; Sugiura and Koseki, 1998; Westeyn et al., 2005). Techniques that combine dissimilar input devices and displays in interesting ways also will be important to realize the full potential of these technologies (e.g., Myers et al., 2001; Streit et al.,

1999). Electronic tagging techniques for identifying objects (Want et al., 1999) may also become commonplace. Such a diversity of locations, users, and task contexts points to the increasing importance of sensors to acquire contextual information, as well as machine learning techniques to interpret them and infer meaningful actions (Bellotti et al., 2002; Buxton, 1995a; Hinckley et al., 2003). This may well lead to an age of ubiquitous sensors (Saffo, 1997) with devices that can see, feel, and hear through digital perceptual mechanisms.

Key Terms

Absolute input device: An input device that reports its actual position, rather than relative movement.

A tablet or touch screen typically operates this way (see also relative input device).

Acquisition time: The average time to pick up or put down an input device. It is sometimes known as homing time.

Anti-aliasing: The specification of pixel color values so that they reflect the correct proportions of the colored regions that contribute to that pixel. In temporal anti-aliasing the amount of time a region of a simulated scene contributes to a pixel is also taken into account.

Augmented reality: The superimposition of artificially generated graphical elements on objects in the environment. It is achieved with a see-through head-mounted display.

Background sensing techniques: Implicitly sensed interaction takes place in the background, behind the fore of the user's attention. Background sensing techniques use sensor technology or intelligent algorithms to glean additional, typically neglected, information from the existing input stream, with the goal of supporting the user with semiautomatic or implicit actions and services.

Cognitive chunk: A series of elemental tasks that seems like a single concept to the user. For example, users think of pointing at something as a single chunk, but from a technical perspective it may consist of selecting an (X, Y, Z) coordinate in a 3D environment. By using technologies and interaction metaphors that parallel the way the user thinks about a task as closely as possible, the designer can phrase together a series of elemental tasks into a single cognitive chunk.

Compound tasks: A compound task is a hierarchy of elemental subtasks. For example, the navigate/select compound task consists of scrolling to view an item in a list and then clicking on it to select it. When interacting with a graphical scrollbar, scrolling itself may be a compound task with multiple selection or positioning tasks.

C:D ratio: The ratio between the movement a user must make with an input device and the resulting movement obtained on the display. With a large C:D ratio, a large movement is required to effect a small change on the display, affording greater precision. A low ratio allows more rapid operation and takes less desk space. The C:D ratio is sometimes expressed as a single number, in which case it is referred to as the device gain. Note that many experts have criticized gain as a fundamental concept; one must take great care when manipulating gain in experiments, since it confounds display size and control size in one arbitrary metric.

Direct input device: A device that the user operates directly on the screen or other display to be controlled, such as a touch screen (see also indirect input device).

Fish tank virtual reality: A form of virtual reality display that confines the virtual scene to the vicinity of a monitor screen.

Fitts' law: A model that relates the movement time to point at a target, the amplitude of the movement (the distance to the target), and the width of the target (i.e., the precision requirement of the pointing movement). The movement time is proportional to the logarithm of the distance divided by the target width, with constant terms that vary from one device to another. Fitts' law has found wide application in HCI to evaluating and comparing input devices and transfer functions for pointing at targets.

Flicker fusion frequency: The frequency at which a flickering light is perceived as a steady illumination.

It is useful in determining the requirements for a visual display.

Footprint: The physical movement space (area) required to operate an input device.

Fovea: The central part of the retina at which vision is the sharpest, about 2° of visual angle in diameter.

Gamma correction: The correction of nonlinearities of a monitor so that it is possible to specify a color in linear coordinates.

Indirect input device: A device that the user operates by moving a control that is located away from the screen or other display to be controlled, such as a mouse or trackball (see also direct input device).

Input device: A hardware computer peripheral through which the user interacts with the computer.

Interaction task: A low-level primitive input to be obtained from the user, such as entering a text string or choosing a command.

Interaction technique: The fusion of input and output, consisting of all hardware and software elements, that provides a particular way for the user to accomplish a low-level task with a physical input device. For example, the pop-up menu is an interaction technique for choosing a command or other item from a small set, using a mouse and a graphical display.

Lambertian diffuser: A diffuser that spreads incoming light equally in all directions.

Latency: The end-to-end delay between the user's physical movement and the system's ultimate feedback to the user. Latency of more than 75–100 ms significantly impairs user performance for many interactive tasks.

Luminance: The standard way of defining an amount of light. This measure takes into account the relative sensitivities of the human eye to light of different wavelengths.

Preattentive processing: Visual stimuli that are processed at an early stage in the visual system in parallel. This processing is done prior to processing by the mechanisms of visual attention.

Refresh rate: The rate at which a computer monitor is redrawn. It is sometimes different from the update rate.

Relative input device: An input device that reports its distance and direction of movement each time it is moved, but cannot report its absolute position. A mouse operates this way (see absolute input device).

Screen gain: A measure of the amount by which a projection video screen reflects light in a preferred direction. The purpose is to give brighter images if viewed from certain positions. There is a corresponding loss in brightness from other viewing positions.

Supercuities: The ability to perceive visual effects with a resolution that is finer than can be predicted from the spacing of receptors in the human eye.

Three-state model: A model for the discrete states of input devices that models transitions between three states: tracking, dragging, and out of range. Most input devices only sense two of these three states (e.g., a mouse senses tracking and dragging, whereas a touchpad senses tracking and the out-of-range state).

Transfer function. A mathematical transformation that scales the data from an input device to ideally provide smooth, efficient, and intuitive operation. Appropriate mappings are transfer functions that match the physical properties sensed by the input device and include force-to-velocity, position-to-position, and velocity-to-velocity functions.

Uniform color space: A transformation of a color specification such that equal metric differences between colors more closely correspond to equal perceptual differences.

Update rate: The rate at which the image on a computer monitor is changed.

Virtual reality: A method of monitoring a user's head position and creating a perceptible view of an artificial world that changes as the user moves, in such a way as to simulate an illusory 3D scene.

Visual acuity: The ability of the human visual system to resolve fine targets.

22.1 Introduction

In previous chapters, the reader should have become familiar with the basics of instruction set architecture and datapath and control unit design. Knowledge of these principles is sufficient to understand the essentials of central processing unit (CPU) architecture and implementation and, given some effort, to generate the logical design for a complete, usable CPU. Decades ago, purely sequential, von Neumann architecture processors were commercially viable. To succeed in today's marketplace, however, a processor (and the system containing it) must not only work correctly but must perform extremely well on the application(s) of interest. This chapter is devoted to exploring various implementation techniques that computer manufacturers have adopted in order to achieve the goal of making their CPU process information as rapidly as possible. The basis of virtually all of these techniques, which we shall shortly introduce, is known as *pipelining*. Essentially all high-performance computers utilize some form of pipelining.

Implementation technologies used to manufacture computer components change rapidly over time. For decades, transistors (which make up the most basic binary switching elements) have become smaller and faster; circuits that were considered blindingly fast 4 or 5 years ago are hopelessly slow today and will be completely obsolete that far, or less, in the future. Over the history of computing devices, technology has always improved and continues to improve—though at some point, Moore's law must expire as we approach the ultimate physical limits [1]. Where will more speed come from when we have switching elements close to the size of individual atoms, with signal propagation over such tiny distances still

limited by the velocity of light? Perhaps the unique approach of quantum computing will allow us to do much more than is currently thought possible within the limits of conventional physics. Only time will tell where new innovations in technology will take us, as designers and users of computer systems.

What is always true is that at any given time, be it 1955 or 1981 or 2013, computer manufacturers could, and can, only make a given piece of hardware so fast using available technology. What if that is not fast enough to suit our purposes? Then we must augment technology with clever design. If a given hardware component is not fast enough to do the work we need to do in the time we have to allow, we build faster hardware if we can, but if we cannot, we build *more* hardware and divide the problem. This approach is known as *parallelism* or *concurrency*. We can achieve concurrency within a single processor core and/or by using multiple processors in a system (either in the form of a multicore chip, multiple CPU chips in a system, or both). The former approach—concurrency within one core—is the subject of the rest of this chapter; the latter will be addressed in Chapters 23 and 24 on multiprocessing.

22.2 Underlying Principles

22.2.1 Limitations of Purely Sequential Processors

The original digital computers, and their successors for a number of years, were all serial (sequential) processors not only in their architecture but also in their implementation. Not only did they *appear* to execute only one instruction at a time, as the von Neumann model suggests, but they actually *did* execute only one instruction at a time. Each machine instruction was processed completely before the next one was started. This sequential execution property allowed the processor's control unit, whether hardwired or microprogrammed, to be kept relatively simple as it only has to generate the control signals for one instruction at a time.

The sequential execution approach that forms the basis of the von Neumann machine cycle is very effective as well as simple, but it has one obvious flaw: it does not make very efficient use of the hardware. In a typical architecture, executing a single machine instruction requires several steps: fetch the instruction from memory, decode it, retrieve its operands, perform the operation it specifies, and store its result. (Somewhat different breakdowns of the machine cycle are possible, but this will suffice for discussion.) If the machine processes one instruction at a time, what is the arithmetic/logic unit (ALU) doing while the instruction (or an operand) is being fetched? Probably nothing. What work are the instruction decoder, memory address register, memory data register, and various other parts of the CPU accomplishing while the ALU is busy performing a computation? Probably none.

For the most efficient use of all the system components in which we have invested design time, chip area, electrical power, and other valuable resources, we would ideally like to keep all of these components as busy as possible as much of the time as possible. A component that is unused part of the time is not giving us our money's worth; designers should search for a way to make more use of it. Conversely, a component that is overused (needed more often than it is available) creates a *structural hazard*; it will often have other components waiting on it and will thus become a bottleneck, slowing down the entire system [2]. Designers may need to replicate such a component to improve throughput. The art of designing a modern processor involves balancing the workload on all the parts of the CPU such that they are kept busy doing useful work as much of the time as possible without any of them “clogging up the works” and making the other parts wait. As the reader might expect, this “balancing act” is not a trivial exercise. Pipelining, which we are about to investigate, is an essential technique for helping bring about this needed balance.

22.2.2 Basic Concepts of Pipelining

Pipelining, in its most basic form, means breaking up a task into smaller subtasks and overlapping the performance of those subtasks for different instances of the task. (The same concept, when applied to

FIGURE 22.1 Subdividing a task into sequential subtasks. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.1.)

the manufacture of automobiles or other objects, is called an assembly line.) Or, to use terms more specifically related to computing, pipelining means dividing a computational operation into steps and overlapping those steps over successive computations. This approach, while much more common in today's computers than it was 20 or 30 years ago, is hardly new. The first use of pipelining in computers dates back to the International Business Machines (IBM) Stretch and Univac LARC machines of the late 1950s [3]. Pipelining, as we shall see, improves the performance of a processor in much the same way that low-order interleaving can improve the performance of main memory while being subject to many of the same considerations and limitations.

To understand how pipelining works, consider a task that can be broken down into three parts, performed sequentially. Let us refer to these parts as step 1, step 2, and step 3 (see Figure 22.1). The time taken to perform step 1 is represented as t_1 , while t_2 and t_3 represent the times required to perform steps 2 and 3. Since the three steps (subtasks) are performed sequentially, the total time to perform the task is of course given by

$$t_{\text{TASK}} = t_1 + t_2 + t_3$$

Without pipelining, the time to perform three iterations of this task is $3 * t_{\text{TASK}}$, while the time to perform fifty iterations is $50 * t_{\text{TASK}}$. The time required is directly proportional to the number of iterations to be performed; there is no advantage to be gained by repeated performance of the task.

Now, suppose that we separate the hardware that performs steps 1, 2, and 3 in such a way that it is possible for them to work independently of each other. (We shall shortly see how this can be accomplished in computer hardware.) Figure 22.2 illustrates this concept. We begin the first iteration of the task by providing its inputs to the hardware that performs step 1 (call this stage 1). After t_1 seconds, step 1 (for the first iteration of the task) is done, and the results are passed along to stage 2 for the performance of step 2. Meanwhile, we provide the second set of inputs to stage 1 and begin the second iteration of the task *before the first iteration is finished*. When stage 2 is finished processing the first iteration and stage 1 is finished processing the second iteration, the outputs from stage 2 are passed to stage 3, and the outputs from stage 1 are passed to stage 2. Stage 1 is then provided a new, third set of inputs—again, before the first and second iterations are finished. At this point, the pipeline is full; all three stages are busy working on something. When all are done this time, iteration 1 is complete, iteration 2 moves to stage 3, iteration 3 moves to stage 2, and the fourth iteration is initiated in stage 1. This process can continue as long as we have more iterations of the task to perform. All stages will remain busy until the last task iteration leaves stage 1 and eventually “drains” from the pipeline (completes through all the remaining stages).

Obviously, this approach works best if the three stage times t_1 , t_2 , and t_3 are all equal to $t_{\text{TASK}}/3$. Let us refer to this as the stage time t_{STAGE} . If t_1 , t_2 , and t_3 are not all equal, then t_{STAGE} must be set equal to the greatest of the three values; in other words, we cannot advance the results of one stage to the next until the *slowest* stage completes its work. If we try to make t_{STAGE} smaller than that, at least one of the stages will be given new inputs before it finishes processing its current inputs and the process will break down (generate incorrect results).

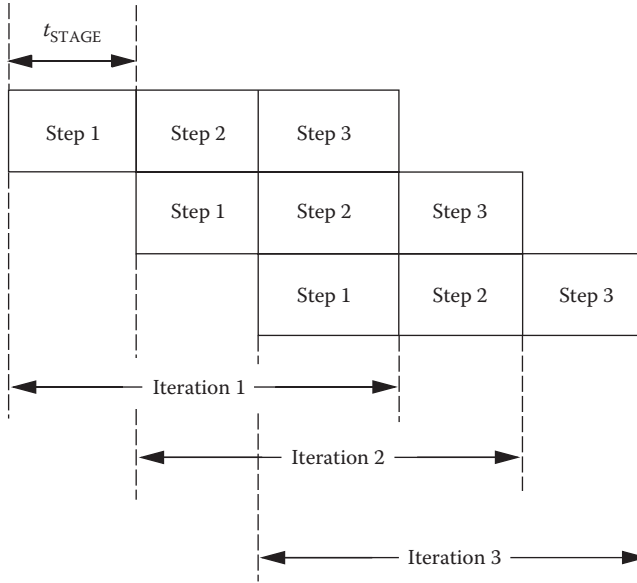

FIGURE 22.2 Basic pipelining concept. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.2.)

22.2.3 Performance Implications of Pipelining

What are the performance implications of this pipelined (or assembly line) approach? It should be obvious that pipelining does nothing to enhance the performance of a *single* computation. A single iteration of the task still requires at least t_{TASK} seconds. In fact, it may take somewhat longer if the stage times are mismatched (we know that $3 * t_{STAGE} \geq t_1 + t_2 + t_3$). The performance advantage occurs only if we perform two or more successive iterations of the task. While the first iteration takes just as long as ever (or perhaps slightly longer), the second and all subsequent iterations are completed in one additional t_{STAGE} each, rather than the $3 * t_{STAGE}$ taken by the first iteration. Two iterations can be completed in $4 * t_{STAGE}$, three iterations in $5 * t_{STAGE}$, four in $6 * t_{STAGE}$, and so on. In general, we can define the time taken to perform n iterations of the task using this three-stage pipeline as

$$t_{TOTAL} = [3 * t_{STAGE}] + [(n - 1) * t_{STAGE}] = [(n + 2) * t_{STAGE}]$$

If t_{STAGE} is equal (or even reasonably close) to $t_{TASK}/3$, then a substantial speedup is possible versus the nonpipelined case; larger values of n lead to a greater advantage for the pipelined implementation. Let us suppose for the sake of simplicity that there is no hardware overhead (we will address this topic later) and that t_{STAGE} equals 1 ns and t_{TASK} equals 3 ns. Five iterations of the task would take $(5 * 3) = 15$ ns without pipelining but only $(7 * 1) = 7$ ns using the pipelined approach. The speed ratio in this case is 2.143 to 1 in favor of pipelining. If we consider ten consecutive iterations, the total times required are 30 ns (nonpipelined) versus 12 ns (pipelined), with pipelining yielding a speedup factor of 2.5. For fifty iterations, the numbers are 150 and 52 ns, respectively, for a speedup of 2.885. In the limit, as n grows very large, the speedup factor of the pipelined implementation versus the nonpipelined implementation approaches 3, which is—not coincidentally—the number of stages in the pipe.

Most generally, for a pipeline of s stages processing n iterations of a task, the time taken to complete all the iterations may be expressed as

$$t_{TOTAL} = [s * t_{STAGE}] + [(n - 1) * t_{STAGE}] = [(s + n - 1) * t_{STAGE}]$$

The $[s * t_{\text{STAGE}}]$ term represents the *flow-through time*, which is the time for the first result to be completed; the $[(n - 1) * t_{\text{STAGE}}]$ term is the time required for the remaining results to emerge from the pipe. The time taken for the same number of iterations without pipelining is $n * t_{\text{TASK}}$. In the ideal case of a perfectly balanced pipeline (in which all stages take the same time), $t_{\text{TASK}} = s * t_{\text{STAGE}}$ and so the total time for the nonpipelined implementation would be $n * s * t_{\text{STAGE}}$. The best-case speedup obtainable by using an s -stage pipeline would thus be $(n * s)/(n + s - 1)$, which, as n becomes large, approaches s as a limit.

From this analysis, it would appear that the more stages into which we subdivide a task, the better. This does not turn out to be the case for several reasons. First of all, it is generally only possible to break down a given task so far. (In other words, there is only so much *granularity* inherent in the task.) When each stage of the pipeline represents only a single level of logic gates, how can one further subdivide operations? The amount of logic required to perform a given task thus places a fundamental limitation on the *depth* of (number of stages in) a pipelined implementation of that task.

Another limiting factor is the number of consecutive, uninterrupted iterations of the task that are likely to occur. For example, it makes little sense to build a ten-stage multiplication pipeline if the number of multiplications to be done in sequence rarely exceeds 10. One would spend most of the time filling and draining the pipeline—in other words, with less than the total number of stages doing useful work. Pipelines only improve performance significantly if they can be kept full for a reasonable length of time. Or, mathematically speaking, achieving a speedup factor approaching s (the number of pipeline stages) depends on n (the number of consecutive iterations being processed) being large, where “large” is defined relative to s . “Deep” pipelines, which implement a *fine-grained* decomposition of a task, only perform well on long, uninterrupted sequences of task iterations.

Yet another factor that limits the speedup that can be achieved by subdividing a task into smaller sub-tasks is the reality of hardware implementation, which always incurs some overhead. Specifically, constructing a pipeline with actual hardware requires the use of a *pipeline register* (a parallel-in, parallel-out storage register comprised of a set of flip-flops or latches) to separate the combinational logic used in each stage from that of the following stage (see Figure 22.3 for an illustration). The pipeline registers effectively isolate the outputs of one stage from the inputs of the next, advancing them only when a clock pulse is received; this prevents one stage from interfering with the operation of those preceding and/or following it. The same clock signal is connected to all the pipeline registers so that the outputs of each stage are transferred to the inputs of the next simultaneously.

Of course, each pipeline register has a cost of implementation: it consumes a certain amount of power, takes up a certain amount of chip area, etc. Also, the pipeline registers have finite propagation delays that add to the propagation delay of each stage; this reduces the performance of the pipeline somewhat, compared to the ideal, theoretical case. The clock cycle time t_C of the pipeline can be no smaller than t_{STAGE} (the longest of the individual stage logic delays) plus t_R (the delay of a pipeline register). The register delays represent an extra cost or “overhead factor” that takes away somewhat from the advantage of a pipelined implementation. If t_R is small compared to t_{STAGE} , as is usually the case, the pipeline will perform close to theoretical limits and certainly much better than a single-stage (purely combinational) implementation of the same task. If we try to divide the task into very small steps, though, t_{STAGE} may become comparable to, or even smaller than, t_R , significantly reducing the advantage of pipelining. We cannot make t_C smaller than t_R no matter how finely we subdivide the task. (Put another way, the maximum clock frequency of the pipeline is limited to $1/t_R$ even if the stages do no work at all!) Thus, there is a point of diminishing returns beyond which it makes little sense to deepen the pipeline. The “best” design would probably be one with a number of stages that maximizes the ratio of performance to cost, where cost may be measured not so much in dollars as in terms of chip area, transistor count, wire length, power dissipation, and/or other factors.

CPU pipelines generally fall into one of two categories: *arithmetic pipelines* or *instruction-unit pipelines*. Arithmetic pipelines are generally found in vector supercomputers, where the same numerical (usually floating-point) computation(s) must be done to many values in succession. Vector machines

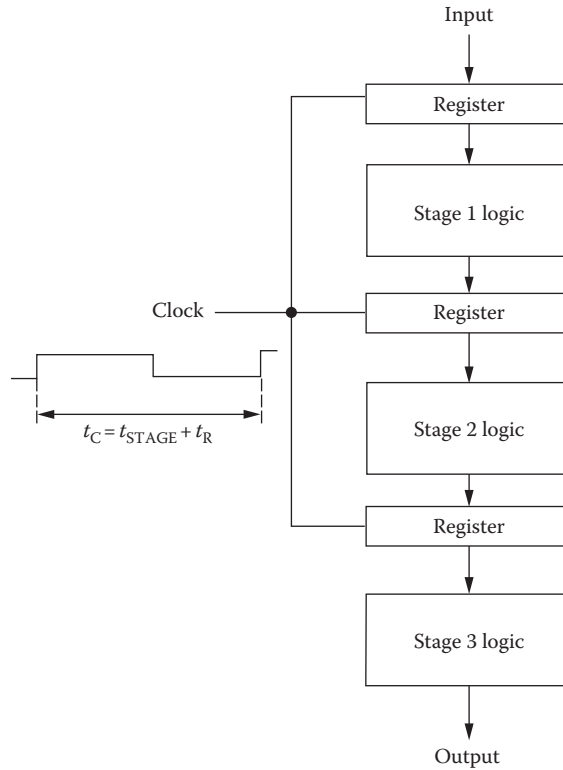

FIGURE 22.3 Pipeline construction showing pipeline registers. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.3.)

are a dying breed, though; while in June 1993, approximately 65% of the world's top 500 supercomputers used a vector architecture, by November 2007, that figure had dropped to less than 1%, where it remains. (The highest-ranked vector supercomputer remaining on the list is Japan's Earth Simulator 2, an NEC SX-9/E system that debuted at number 22 in June 2009 but had dropped to 94th place by November 2011 and all the way to 217th by November 2012 [4].) By contrast, instruction-unit pipelines, which are used to execute a variety of scalar instructions at high speed, are found in practically all modern general-purpose processors—including those used in most high-performance, massively parallel systems. Thus, the following sections will concentrate on techniques used in pipelined instruction execution units.

22.3 Impact on Practice

22.3.1 Instruction-Unit Pipelines

Instruction-unit pipelines are pipelines that are used to execute a machine's scalar instruction set (the instructions that operate on only one or two individual operands to produce a single result—these make up most, if not all, of the instruction set of a typical general-purpose machine). As we discussed in Section 22.2.1, the execution of each machine instruction can be broken into several steps. Often, particularly in a machine that has simple instructions, most of these steps are the same for many (possibly most or all) of the instructions. For example, all of the computational instructions may be done with the same sequence of steps, with the only difference being the operation requested of the ALU once the operands are present. With some effort, the data transfer and control transfer instructions may also be implemented with the same or a very similar sequence of steps. If most or all of the machine's

instructions can be accomplished with a similar number and type of steps, it is relatively easy to pipeline the execution of those steps and thus improve the machine's performance considerably versus a completely sequential design.

22.3.2 Basics of an Instruction Pipeline

The basic concept flows from the principles that were introduced at the beginning of Section 22.2.2. Pipelining as we defined it means breaking up a computational task into smaller subtasks and overlapping the performance of those subtasks for different instances of the task. In this case, the basic task is the execution of a generic, scalar instruction, and the subtasks correspond to subdivisions of the von Neumann execution cycle, which the machine must perform in order to execute it. The von Neumann cycle may be broken into more or fewer steps depending on the designer's preference and the amount of logic required for each step. (Remember that for best pipelined performance, the overall logic delay should be divided as equally as possible among the stages.) As an example, let us consider a simple instruction-unit pipeline with four stages, as follows:

F	—Fetch instruction from memory.
D	—Decode instruction and obtain operand(s).
E	—Execute required operation on operand(s).
W	—Write result of operation to destination.

A sequential (purely von Neumann) processor would perform these four steps, one at a time, for a given instruction, then go back and perform them one at a time for the next instruction, and so on. If each step required one CPU clock cycle, then each machine instruction would require four clock cycles. Two instructions would require 8 cycles, three would require 12 cycles, etc. As we noted previously, this approach is effective but slow and does not make very efficient use of the hardware.

In an instruction-pipelined processor, we break down the required hardware into smaller pieces, separated by pipeline registers as described previously. Our example divides the hardware into four stages as shown in Figure 22.4. By splitting the hardware into four stages, we can overlap the execution of up to four instructions simultaneously. As Table 22.1 shows, we begin by fetching instruction I_1 during the first time step t_0 . During the next time step (t_1), I_1 moves on to the decoding/operand fetch stage, while simultaneously instruction I_2 is being fetched by the first stage. Then during step t_2 , I_1 is in the execute (E) stage, while I_2 is in the D stage, and I_3 is being fetched by the F stage. During step t_3 , I_1 moves to the final stage (W), while I_2 is in E, I_3 is in D, and I_4 is in F. This process continues indefinitely for subsequent instructions.

As in the nonpipelined case, it still takes four clock cycles to execute the first instruction I_1 . However, because of the overlap of operations in the pipeline, I_2 completes one clock cycle later, I_3 completes one cycle after that, and likewise for subsequent instructions. Once the pipeline is full, we achieve a steady-state throughput of one instruction per clock cycle (IPC), rather than one instruction per four cycles as in the nonpipelined case. Thus, in the ideal case, the machine's performance may increase by nearly a factor of four.

Of course, the ideal case is not always the way things work out in the real world. It appears from an initial examination that we can easily achieve a pipeline throughput of one instruction per cycle. (This was the goal of the original reduced instruction set computer [RISC] designers [5] and of course is the goal of any pipelined processor design.) However, a sustained throughput of 1.0 instruction per cycle is never attainable in practice using a single instruction pipeline (although in some cases we can come fairly close). Why not? For the same reason, we can never achieve maximum throughput in an arithmetic or any other type of pipeline: *something* happens to “break the chain” or temporarily interrupt the operation of the pipeline. For a vector arithmetic pipeline, this might result from having to change a dynamic pipeline to another configuration or simply reaching the end of the current vector computation

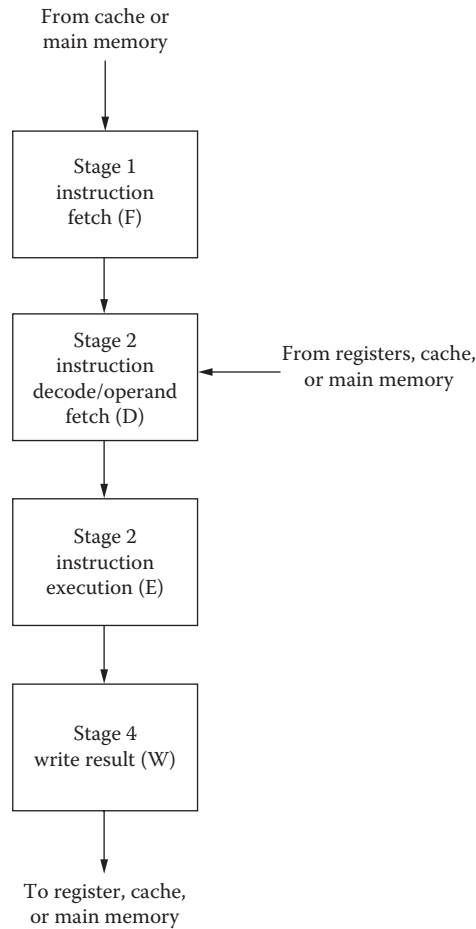

FIGURE 22.4 Stages of a typical instruction pipeline. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.12.)

TABLE 22.1 Execution of Instructions in a Four-Stage Pipeline

	t_0	t_1	t_2	t_3	t_4	t_5	t_6
Stage 1 (F)	I_1	I_2	I_3	I_4	I_5	I_6	I_7
Stage 2 (D)		I_1	I_2	I_3	I_4	I_5	I_6
Stage 3 (E)			I_1	I_2	I_3	I_4	I_5
Stage 4 (W)				I_1	I_2	I_3	I_4

(i.e., running out of operands). Anytime we miss initiating a new operation into the pipe for even a single cycle, we will correspondingly miss completing one operation per cycle at some later time and thus not average performing one operation per cycle.

Neither of the previous scenarios applies directly to an instruction-unit pipeline. Though different instructions are executed, they all use the same sequence of steps; thus, the pipeline structure is not reconfigured. And of course the CPU is always executing *some* instructions! They may be part of a user program or the operating system; they may be computational instructions, data transfers, or even “no operation” (NOP) instructions, but the processor never stops executing instructions as long as it is “up.”

(We are ignoring the special case of some embedded processors that have “sleep” or “standby” modes where they halt execution in order to save power.) So if these types of situations are not the problem, what can—and does—happen to hold up the operation of a pipelined instruction unit and keep it from achieving its theoretical throughput of one instruction per cycle? There are several possibilities that we shall explore later, but the most fundamental difficulty is the fact that execution of instructions is not always sequential.

22.3.3 Control Transfers and the Branch Penalty

It is control transfer instructions, which of course are very important to all practical programs, which cause the most obvious problem with respect to pipelined instruction execution. Pipelining instructions that are sequentially stored and sequentially executed is relatively easy, but sooner or later in any useful program, we must make a decision (based on data input or retrieved from memory or on the results of computations performed on data) as to what to do next. This decision-making process is typically done using a comparison and conditional branching technique. The program performs a comparison (or some other arithmetic or logic operations), and then a conditional branch instruction is executed. This branch tests some condition related to the operation just performed and either *succeeds* or *fails* based on whether or not the specified condition is true. A conditional branch that succeeds means that the next instruction executed is the one at the specified target address, while one that fails means that the next instruction executed is the next one in program sequence.

If it were possible to know in advance which of these events would occur, handling the situation would pose fewer problems for the pipelined instruction execution unit. But of course, if it were possible to always know ahead of time that a given branch would be taken or not, it would not have to be encoded as a branch! And in fact the CPU often (particularly in the case of program loops) encounters a particular branch repeatedly over time, where—depending on the particular data being processed—it may succeed on some occasions and fail on others. Conditional transfers of control are an unavoidable fact of life in the logic of useful programs built on the von Neumann execution model, and as we shall see, these control transfers do pose problems, known as *control hazards*, for pipelined execution of instructions [2].

The problems we encounter with branching stem from the obvious fact that a single pipeline can only process one sequence of instructions. There may indeed be only one sequence of instructions leading up to a given conditional branch, but there are always two possible sequences of instructions following it. There is the sequence of instructions immediately following the branch instruction in memory, to be executed if it fails, but there is also the sequence of instructions beginning at the branch target location in memory, to be executed if it succeeds. The pipeline can only process one of these sequences of instructions at a time—what if it is the wrong one?

If the pipeline control logic assumes that a given conditional branch will fail and begins working on the sequential instructions, and it turns out that the branch actually fails, then there is no problem and the pipeline can continue completing instructions at the rate of one per clock cycle. Likewise, if the pipeline logic successfully predicts that the branch will succeed and begins processing at the target location, the pipeline can be kept full or nearly so. (Depending on the pipeline structure and the memory interface, there may be a slight delay as instructions must be obtained from a different part of memory.) But in either of the other two cases, where a branch succeeds while sequential instructions have already started down the pipe or where a branch fails while the processor assumed it would be taken, there is a definite problem that will interrupt the completion of instructions—possibly for several clock cycles.

When any given conditional branch instruction first enters a pipeline, the hardware has no way of knowing whether it will succeed or fail. Indeed, since the first stage of the pipeline always involves fetching the instruction from memory, the control unit would not even know at this point whether or not this instruction is a control transfer! That information is not available until the instruction is decoded

TABLE 22.2 Pipelined Instruction Execution with Conditional Branching

	t_0	t_1	t_2	t_3	t_4	t_5	t_6	t_7	t_8
Stage 1 (F)	I ₁	I ₂	I ₃	I ₄	I ₅	I ₆	I ₁	I ₂	I ₃
Stage 2 (D)		I ₁	I ₂	I ₃	I ₄	I ₅	—	I ₁	I ₂
Stage 3 (E)			I ₁	I ₂	I ₃	I ₄	—	—	I ₁
Stage 4 (W)				I ₁	I ₂	I ₃	I ₄	—	—

(in our example, this occurs in the second pipeline stage). And even once the instruction is identified as a conditional branch, it takes some time to check the appropriate condition and make the decision of whether or not the branch will succeed (and then to update the program counter with the target location if the branch does succeed). By this time, one, two, or more subsequent instructions, which may or may not be the correct ones, may have entered the pipe.

Table 22.2 illustrates a possible scenario where a branch that was assumed to fail instead happens to succeed. Assume that instruction I₄ is a conditional branch that implements a small program loop; its target is I₁, the top of the loop, while of course the sequential instruction I₅ will be executed on completion of the loop. We do not know ahead of time how many times the loop will iterate before being exited; either I₁ or I₅ may follow I₄ at any time.

Instruction I₄ is fetched by the first pipeline stage during cycle t_3 . During the following cycle, t_4 , it is decoded while the pipeline is busy fetching the following instruction I₅. Sometime before the end of cycle t_4 , the control unit determines that I₄ is indeed a conditional branch, but it still has to test the branch condition. Let us assume that this does not happen until sometime during cycle t_5 , when the fetch of instruction I₆ has begun. At this point, the control unit determines that the branch condition is true and loads the address of I₁ into the program counter to cause the branch to take place. I₁ will thus be fetched during the next clock cycle, t_6 , but by this time, two instructions (I₅ and I₆) are in the pipeline where they should not be. Allowing them to continue to completion would cause the program to generate incorrect results, so they are aborted or *nullified* by the control logic (meaning that the results of these two instructions are not written to their destinations). This cancellation of the incorrectly fetched instructions is known as “flushing” the pipeline [6]. While the correctness of program operation can be retained by nullifying the effects of I₅ and I₆, we can never recover the two clock cycles that were wasted in mistakenly attempting to process them. Thus, this branch has prevented the pipeline from achieving its maximum possible throughput of one IPC.

In this example, a successful conditional branch caused a delay of two clock cycles in processing instructions. This delay is known as the *branch penalty* [7]. Depending on the details of the instruction set architecture and the way it is implemented by the pipeline, the branch penalty for a given design might be greater or less than two clock cycles. In the best case, if the branch condition could be tested and the program counter modified in stage 2 (before the end of cycle t_4 in our example), the branch penalty could be as small as one clock cycle. If determining the success of the branch, modifying the PC, and obtaining the first instruction from the target location took longer, the branch penalty might be three or even four cycles (the entire depth of the pipeline, meaning that its entire contents would have to be flushed). The number of lost cycles may vary from implementation to implementation, but branches in a program are never good for a pipelined processor.

It is worth noting that branching in programs can be a major factor limiting the useful depth of an instruction pipeline. In addition to the other reasons mentioned earlier to explain the diminishing returns we can achieve from pipelines with many stages, one can readily see that the deeper an instruction-unit pipeline, the greater the penalty that may be imposed by branching. Rather than one or two instructions, a fine-grained instruction pipe may have to flush several instructions on each successful branch. If branching instructions appear frequently in programs, a pipeline with many stages may perform no better—or even worse—than one with a few stages [8].

It is also worth mentioning that conditional branch instructions are not the only reason why the CPU cannot always initiate a new instruction into the pipeline every cycle. Any type of control transfer instruction, including unconditional jumps and subprogram calls and returns, may cause some delay in processing. Though there is no branch condition to check, these other instructions must still proceed a certain distance into the pipeline before being decoded and recognized as control transfers, during which time one or more subsequent instructions may have entered the pipe. Exception processing (including internally generated traps and external events such as interrupts) also requires the CPU to suspend execution of the sequential instructions in the currently running program, transfer control to a handler located somewhere else in memory, and then return and resume processing the original program. The pipeline must be drained and refilled upon leaving and returning, once again incurring a penalty of one or more clock cycles in addition to other overhead such as saving and restoring register contents.

22.3.4 Branch Prediction

Branch prediction is one approach that can be used to minimize the performance penalty associated with conditional branching in pipelined processors. Consider the example presented in Table 22.2. If the control unit could somehow be made aware that instructions I_1 through I_4 make up a program loop, it might choose to assume that the branch would succeed and fetch I_1 (instead of I_5) after I_4 each time. Using this approach, the full branch penalty would be incurred only once, upon exiting the loop, rather than each time through the loop. Of course, one could equally well envision a scenario where assuming that the branch would fail would be the better course of action. But how, other than by random guessing (which of course is as likely to be wrong as it is to be right), can the control unit predict whether or not a branch will be taken?

Branch prediction, which dates back to the IBM Stretch machine of the late 1950s [9], can be done either *statically* (before the program is run) or *dynamically* (by the control unit at run time) or as a combination of both techniques. The simplest forms of static prediction either assume all branches succeed (assuming they all fail would be equivalent to no prediction at all) or assume that certain types of branches always succeed, while others always fail [10]. As the reader might imagine, these primitive schemes tend not to fare much better than random guessing.

A better way to do static prediction, if the architecture supports it, is to let the compiler do the work. Version 9 of Sun Microsystems' (now Oracle's) scalable processor architecture (SPARC) provides a good example of this approach. Each SPARC V9 conditional branch instruction has two different op codes: one for "branch probably taken" and one for "branch probably not taken [11]." The compiler analyzes the structure of the high-level code and chooses the version of the branch it expects will be correct most of the time; when the program runs, the processor uses the op code as a hint to help it choose which instructions to fetch into the pipeline. If the compiler is right most of the time, this technique will improve performance. However, even this more sophisticated form of static branch prediction has not proven to be especially effective in most applications when used alone (without run-time feedback) [12].

Dynamic branch prediction relies on the control unit keeping track of the behavior of each branch encountered. This may be done by the very simple means of using a single bit to remember the behavior of the branch the last time it was executed. Or, for more accurate prediction, two bits may be used to record the action of the branch for the last two consecutive times it was encountered. If it has been taken, or not taken, twice in succession, that is taken as a strong indication of its likely behavior the next time, and instructions are fetched accordingly. If it was taken once and not taken once, the control unit decides randomly which way to predict the branch. Another, even more sophisticated dynamic prediction technique associates a counter of two or more bits with each branch [10]. The counter is initially set to a threshold value in the middle of its count range. Each time the branch succeeds, the counter is incremented; each time it fails, the counter is decremented. As long as the current count is greater than or equal to the threshold, the branch is predicted to succeed; otherwise, it is predicted to fail. The Intel Pentium processor used a two-bit, four-state counter like this to predict branches [13]. Note that for this

technique to work properly, the counter must saturate or “stick” at its upper and lower limits, rather than rolling over from the maximum count to zero, or vice versa. Even more elaborate schemes (including hybrid, adaptive, and two-level mechanisms) are possible [10], but there is a point of diminishing returns beyond which the cost of additional hardware complexity is not justified by significantly better performance on typical compiled code.

While dynamic branch prediction requires more hardware, in general, it has been found to perform better than static prediction (which places greater demands upon the compiler) [12]. Since dynamic prediction is dependent upon the details of a particular implementation rather than the features of the instruction set architecture, it also allows compatibility with previous machines to be more easily maintained. Of course, the two approaches can be used together, with the compiler’s prediction being used to initialize the state of the hardware predictor and/or as a tiebreaker when the branch is considered equally likely to go either way.

What are the performance effects of branch prediction? Obviously, performance is very sensitive to the success rate of the prediction scheme(s) used. Highly successful branch prediction can significantly improve performance, while particularly poor prediction may do no better (or possibly even worse) than no prediction at all. While a branch correctly predicted to fail may cost no cycles at all and one correctly predicted to succeed may incur only a minimal penalty (if any), a branch that is mispredicted either way will require the machine to recover to the correct execution path and so may incur a branch penalty as severe (or even more severe) than if the machine had no prediction scheme at all.

For comparison, let us first consider mathematically the throughput of a pipelined processor *without* branch prediction [14]. Any instruction in a program is either a branching instruction or a nonbranching instruction. Let p_b be the probability of any instruction being a branch; then of course $(1 - p_b)$ is the probability of it not being a branch. Also, let C_B be the average number of cycles per branch instruction and C_{NB} be the average number of cycles per nonbranching instruction. The average number of clock cycles per instruction is thus given by

$$C_{AVG} = p_b C_B + (1 - p_b) C_{NB}$$

In a pipelined processor, nonbranching instructions execute in one clock cycle, so $C_{NB} = 1$. (In practice, there may be certain exceptions to this rule, most notably stalls due to data dependencies between instructions, to be discussed in Section 22.3.7, but for now we shall proceed under the simplifying assumption that nonbranching instructions do not stall the pipe.) The average number of cycles per branch C_B depends on the fraction of branches taken (to the target) versus the fraction that are not taken and result in sequential execution. Let p_t be the probability that a branch is taken and $(1 - p_t)$ be the probability it is not taken; also let b be the branch penalty in clock cycles. Since no prediction is employed, failed branches execute in 1 cycle, while successful branches require $(1 + b)$ cycles. The average number of cycles per branch instruction is thus given by

$$C_B = p_t(1 + b) + (1 - p_t)(1) = 1 + p_t b$$

We can substitute this expression for C_B into the previous equation to determine the average number of cycles per instruction as follows:

$$C_{AVG} = p_b(1 + p_t b) + (1 - p_b)(1) = 1 + p_b p_t b$$

The throughput of the pipeline (the average number of instructions completed per clock cycle) is simply the reciprocal of the average number of cycles per instruction:

$$H = \frac{1}{C_{AVG}} = \frac{1}{1 + p_b p_t b}$$

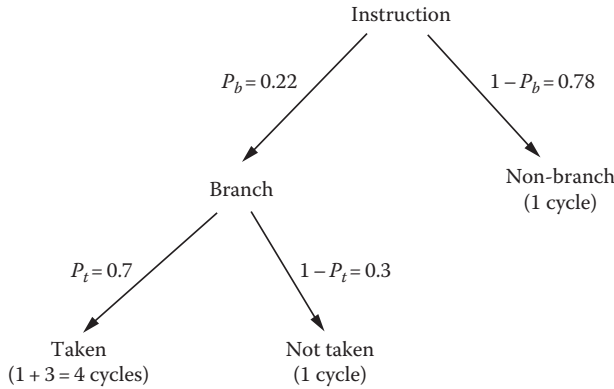

FIGURE 22.5 Probability tree diagram for conditional branching example. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.13.)

The probabilities p_b and p_t obviously will vary for different programs. Typical values for p_b , the fraction of branch instructions, have been found to be in the range of 0.1–0.3 [15]. The probability of a branch succeeding, p_t , may vary widely, but values in the 0.5–0.8 range are reasonable. As a numerical example, suppose for a given program that the branch penalty is three cycles, $p_b = 0.22$, and $p_t = 0.7$. Then the average number of cycles per instruction would be $1 + (0.22)(0.7)(3) = 1.462$, and the pipeline throughput would be approximately 0.684 instructions per cycle.

Another way to compute this result without memorizing the formula for C_{AVG} is to construct a simple probability tree diagram as shown in Figure 22.5. To obtain C_{AVG} , it is simply necessary to multiply the number of cycles taken in each case times the product of the probabilities leading to that case and then sum the results. Thus, we obtain $C_{AVG} = (0.22)(0.7)(4) + (0.22)(0.3)(1) + (0.78)(1) = 1.462$ as before, once again giving $H \approx 0.684$.

Now, suppose that the pipelined processor employs a branch prediction scheme to try to improve performance. Let p_c be the probability of a correct prediction, and let c be the reduced penalty associated with a correctly predicted branch. (If correctly predicted branches can execute as quickly as sequential code, c will be equal to zero.) Branches that are incorrectly predicted (either way) incur the full branch penalty of b cycles. In this scenario, the average number of cycles per branch instruction can be shown to be

$$C_B = 1 + b - p_c b + p_t p_c c$$

Substituting this into our original equation $C_{AVG} = p_b C_B + (1 - p_b)(1)$, we find that with branch prediction, the average number of cycles per instruction is given by

$$C_{AVG} = 1 + p_b b - p_b p_c b + p_b p_t p_c c$$

Returning to our numerical example, let us assume that b is still three cycles and p_b and p_t are still 0.22 and 0.7, respectively. Let us further assume that $c = 1$ cycle and the probability of a correct branch prediction, p_c , is 0.75. Substituting these values into the first equation, we find that the average number of cycles per branch instruction is $1 + 3 - (0.75)(3) + (0.7)(0.75)(1) = 2.275$. The second equation gives the overall average number of cycles per instruction as $1 + (0.22)(3) - (0.22)(0.75)(3) + (0.22)(0.7)(0.75)(1) = 1.2805$. The pipeline throughput H with branch prediction is $1/1.2805$ or approximately 0.781, a significant (approximately 14%) improvement over the example without branch prediction.

Again, if one does not wish to memorize formulas, the same result could be obtained using the probability tree diagram shown in Figure 22.6. Multiplying the number of cycles required in each

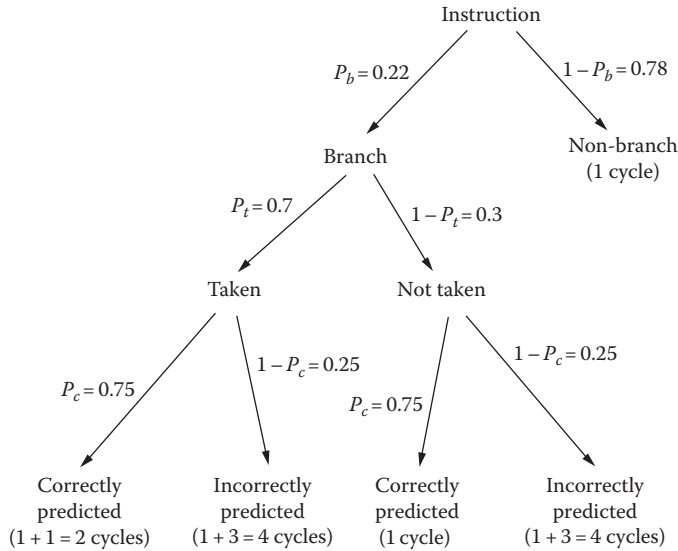

FIGURE 22.6 Probability tree diagram for example with branch prediction. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.14.)

case times the probability of occurrence and then summing the results, we get $C_{AVG} = (0.22)(0.7)(0.75)(2) + (0.22)(0.7)(0.25)(4) + (0.22)(0.3)(0.75)(1) + (0.22)(0.3)(0.25)(4) + (0.78)(1) = 1.2805$, the same result obtained from our equation.

As we mentioned earlier, the performance benefits derived from branch prediction depend heavily on the success rate of the prediction scheme. To illustrate this, suppose that instead of $p_c = 0.75$, our branch prediction scheme achieved only 50% correct predictions ($p_c = 0.5$). In that case, the average number of cycles per instruction would be $1 + (0.22)(3) - (0.22)(0.5)(3) + (0.22)(0.7)(0.5)(1) = 1.407$ for a throughput of approximately 0.711, not much better than the results with no prediction at all. If the prediction scheme performed very poorly, say, with $p_c = 0.3$, the pipeline throughput could be even worse than with no prediction—in this case, $1/1.5082 \approx 0.663$ instructions per cycle.

To facilitate branch prediction, it is common for modern processors to make use of a *branch target buffer* (also known as a *branch target cache* or *target instruction cache*) to hold the addresses of branch instructions, the corresponding target addresses, and the information about the past behavior of the branch [15]. Any time a branch instruction is encountered, this buffer is checked and, if the branch in question is found, the relevant history is obtained and used to make the prediction. A *prefetch queue* may be provided to funnel instructions into the pipeline [16]. To further improve performance, some processors make use of dual instruction prefetch queues to optimize branches [14]. Using this *multiple prefetch* approach, the processor fetches instructions from both possible paths (sequential and target). By replicating the prefetch queue (and possibly even the first few stages of the pipeline itself), the processor can keep both possible execution paths “alive” until the branch decision is made. Instructions from the correct path continue on to execution, while those from the incorrect path are discarded. Of course, for this approach to work, there must be sufficient space on the chip for the prefetch queues and sufficient memory (particularly instruction cache) bandwidth to allow for the simultaneous prefetching of both paths.

22.3.5 Delayed Control Transfers

Delayed control transfers are another approach that has been adopted by some designers to eliminate, or at least minimize, the penalty associated with control transfers (both conditional and unconditional) in pipelined processors. A *delayed branch* instruction is unlike any control transfer instruction the reader has likely encountered before. The branch instructions in most computer architectures take

FIGURE 22.7 Delayed branching example. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.15.)

effect immediately. That is to say, if the branch condition is true (or if the instruction is an unconditional branch), the next instruction executed after the branch itself is the one at the target location. A delayed branch, on the other hand, does not take effect immediately. The instruction sequentially following the branch is executed whether or not the branch succeeds [17]. Only after the instruction following the control transfer instruction, which is said to be in the *delay slot* [18], is executed will the target instruction be executed—with execution continuing sequentially from that point.

An example of delayed branching is shown in Figure 22.7. Let us assume that instructions I_1 through I_4 form a program loop, with I_4 being a conditional branch back to I_1 . In a “normal” instruction set architecture, I_5 would never be executed until the loop had finished iterating. If this instruction set were implemented with a pipelined instruction unit, I_5 would have to be flushed from the pipeline every time the branch I_4 succeeded. If the number of loop iterations turned out to be large, many clock cycles would be wasted fetching and flushing I_5 .

The idea of delayed branching, which only makes sense in an architecture designed for pipelined implementation, comes from the desire not to waste the time required to fetch I_5 each time the branch (I_4) is taken. “Since I_5 is already in the pipeline,” the argument goes, “why not go ahead and execute it instead of flushing it?” To programmers used to working in high-level languages or most assembly languages, this approach invariably seems very strange, but it makes sense in terms of efficient hardware implementation. (The delayed branch scheme appears to an uninitiated assembly programmer as a bug, but as all computing professionals should know, any bug that is documented becomes a feature.) I_5 appears to be—and is physically located in memory—outside the loop, but logically, in terms of program flow, it is part of the loop. The instructions are stored in the sequence I_1, I_2, I_3, I_4, I_5 —but they are logically executed in the sequence I_1, I_2, I_3, I_5, I_4 .

The trick in making use of this feature lies in finding an instruction that logically belongs before the branch, which is independent of the branch decision—neither affecting the branch condition nor being affected by it. (Of course, if the control transfer instruction is unconditional, any instruction that logically goes before it could be placed in its delay slot.) If such an instruction can be identified, it may be placed in the delay slot to make productive use of a clock cycle that would otherwise be wasted. If no such instruction can be found, the delay slot may simply be filled with a time-wasting instruction such as NOP. This is the software equivalent of flushing the delay slot instruction from the pipe.

Delayed control transfer instructions are not found in complex instruction set computer (CISC) architectures, which by and large trace their lineage to a time before pipelining was widely used. However, they are often featured in RISC architectures, which were designed “from the ground up” for a pipelined implementation. CISC architectures were intended to make assembly language programming easier by making the assembly language look more like a high-level language. RISC architectures, on the other hand, were not designed to support assembly language programming at all but rather to support efficient code generation by an optimizing compiler. So the fact that delayed branches make assembly programming awkward is not really significant as long as a compiler can be designed to take advantage of the delay slots when generating code.

There is no reason that an architecture designed for pipelined implementation must have only one delay slot after each control transfer instruction. In fact, the example presented earlier in Table 22.2 is of a

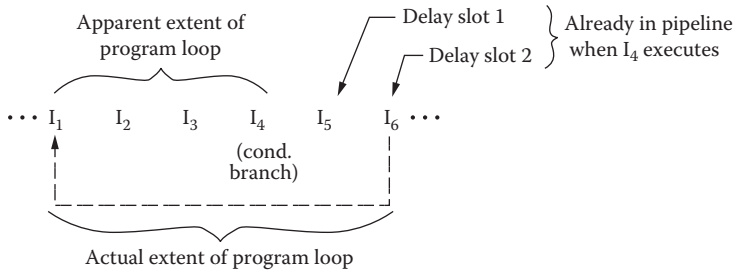

FIGURE 22.8 Example of control transfer with two delay slots. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.16.)

machine that could have two delay slots. (Machines with very deep pipelines might have even more.) Since instructions I_5 and I_6 will both have entered the pipeline before the branch at I_4 can be taken, they could both be executed before the target instruction if the architecture so specifies (see Figure 22.8). Of course, the more delay slots that exist after a conditional branch instruction, the more difficult it will be for the compiler (or masochistic assembly programmer) to find useful, independent instructions with which to fill them. But in the worst case, they can still be filled with NOPs, which keeps the hardware simpler than it would be if it had to be able to recognize this situation and flush the instructions itself. This is just one more example of the hardware/software trade-offs that are made all the time in computer systems design.

22.3.6 Memory Accesses: Delayed Loads and Stores

Control transfers are not the only occurrences that can interrupt and/or slow processing in a pipelined processor. Another potentially costly activity (in terms of performance) is accessing memory for operands. Register operands are generally accessible very quickly, such that they can be used for an arithmetic computation within the same clock cycle. Memory operands, even if they reside in cache, generally require at least one cycle to access before any use can be made of them. RISC architectures, in particular, attempt to minimize this problem by clearly subdividing their instruction sets into computational instructions (which operate only on register contents) and memory access (or load and store) instructions that do not perform computations on data. Even so, a problem may arise when a subsequent instruction tries to perform a computation on a data value being loaded by a previous instruction. For example, suppose the following two instructions appear consecutively in a program:

LOAD	VALUE, R5
ADD	R5, R4, R3

Given the slower speed of memory relative to most CPUs, the variable VALUE being loaded into register R5 might not be available by the time it was needed by the ADD instruction. One obvious solution to the problem would be to build in some sort of hardware interlock that would “freeze” or stall the pipeline until the data had been retrieved from memory and placed in R5. Only then would the ADD instruction be allowed to execute. The hardware is thus made responsible for the correct operation of the software—a typical, traditional computer design approach.

However, another way of approaching this problem is simply to document the fact that loads from memory always take at least one extra cycle to occur. The compiler, or the assembly language programmer, would be made aware that every load instruction has a “load delay slot [18].” In other words, the instruction immediately following a load must not make use of the value being loaded. (In some architectures, the following instruction may also not be another load.) If the load’s destination register is referenced by the following instruction, it is known that the value obtained will be the “old” value, not the new one being loaded from memory. This is another example of documenting what might appear to the casual user to be a bug, thus enshrining it as a feature of the instruction set! Instead of the hardware

compensating for delays in loading data and ensuring the correct operation of the software, the software is simply informed of the details of the hardware implementation and forced to ensure correctness on its own. (Note that a hardware interlock will still be required to detect data cache misses and stall the pipeline when they occur, since main memory access may take several clock cycles rather than one.) In the example earlier, correctness of operation is assured by simply inserting an unrelated but useful instruction—or an NOP if no such instruction can be found—between the LOAD and the ADD (or any other computational instruction) that uses the results of the LOAD.

Store operations (writes of data to memory) are less problematic than loads because the CPU is unlikely to need to retrieve the stored information from memory soon enough to pose a problem. (Since stores write data from a register to memory, presumably the CPU can use the copy of the data still in a register if it is needed.) However, back-to-back memory accesses may pose a problem for some machines because of the time required to complete an access. If two consecutive load or store operations are executed, it may be necessary to stall the pipeline. For that reason, stores in some architectures are also sometimes said to have a “delay slot,” which should not contain another load or store instruction. If it does, the pipeline may have to be stalled for one cycle to allow the first store to complete before a second memory access is done.

22.3.7 Data Dependencies and Hazards

Dependency relations among computed results, giving rise to pipeline *data hazards*, may also hold up operations in a pipelined CPU and keep it from approaching its theoretical throughput. In a nonpipelined processor, each instruction completes before execution of the next instruction begins. Thus, values computed by a previous instruction are always available for use in subsequent instructions, and the program always obtains the results anticipated by the von Neumann sequential execution model. Since a pipelined instruction unit overlaps the execution of several instructions, though, it becomes possible for results to become sensitive to the timing of instructions rather than just the order in which they appear in the program. This is obviously not a desirable scenario and must be corrected (or at least accounted for) if we want our pipelined machine to compute the same results as a purely sequential machine.

For an example of a common data dependency problem in a pipelined machine, consider the following situation (illustrated in Figure 22.9). Suppose a CPU with a four-stage pipeline like the one in our previous example executed the following sequence of instructions:

I ₁	ADD	R1, R2, R3
I ₂	SUB	R3, R4, R6
I ₃	XOR	R1, R5, R3

Cycle	Stage 1	Stage 2	Stage 3	Stage 4
1	I ₁			
2	I ₂	I ₁		
3	I ₃	I ₂	I ₁	
4	I ₄	I ₃	I ₂ ← I ₁	
5	I ₅	I ₄	I ₃	I ₂

(a)

Cycle	Stage 1	Stage 2	Stage 3	Stage 4
1	I ₁			
2	I ₂	I ₁		
3	I ₃	I ₂	I ₁	
4	I ₃	I ₂	—	I ₁
5	I ₄	I ₃	I ₂ ← I ₁	—

(Stall)

(b)

FIGURE 22.9 Data dependency problem in pipelined CPU. (a) Incorrect operation stage 3 needs result of I₁ at the beginning of cycle 4; not available until the end of cycle 4. (b) Correct operation due to stalling pipeline for 1 cycle after cycle 3; stage 3 will now have updated value for use in executing I₂. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.17.)

The last operand listed for each instruction is the destination. Thus, it can be seen that instruction I_2 uses the result computed by I_1 . But will that result be available in time for I_2 to use it?

In Figure 22.9a, we can see how instruction I_1 proceeds through the pipeline, with I_2 and I_3 following it stage by stage. The result from I_1 is not computed by stage 3 until the end of the third clock cycle and is not stored back into the destination register (R3) by stage 4 until the end of the fourth clock cycle. However, stage 3 needs to read R3 and obtain its new contents at the *beginning* of the fourth clock cycle so they can be used to execute the subtraction operation for I_2 . If execution proceeds unimpeded as shown, the previous contents of R3 will be used by I_2 instead of the new contents, and the program will operate incorrectly. This situation, in which there is a danger of incorrect operation due to the fact that the behavior of one instruction in the pipeline depends on that of another, is known as a *data hazard* [2]. This particular hazard is known as a *true data dependence* or (more commonly) a *read after write (RAW) hazard* [19] because I_2 , which reads the value in R3, comes after I_1 , which writes it.

To avoid the hazard and ensure correct operation, the control unit must make sure that I_2 actually reads the data after I_1 writes it. The obvious solution is to stall I_2 (and any following instructions) for one clock cycle in order to give I_1 time to complete. Figure 22.9b shows how this corrects the problem. Instruction I_2 now does not reach stage 3 of the pipeline until the beginning of the fifth clock cycle, and so it is executed with the correct operand value from R3.

RAW hazards are the most common data hazards and in fact the only possible type in a machine such as we have been considering so far, with a single-pipeline instruction unit in which instructions are always begun and completed in the same order and only one stage is capable of writing a result. Other types of data hazards, known as *write after read (WAR)* and *write after write (WAW)* hazards, are only of concern in machines with multiple pipelines (or at least multiple execution units, which might be “fed” by a common pipeline) or in situations where writes can be done by more than one stage of the pipe [20]. In such a machine, instructions may be completed in a different order than they were fetched (*out-of-order execution* or OOE) [21]. OOE introduces new complications to the process of ensuring that the machine obtains the same results as a nonpipelined processor.

Consider again the sequence of three instructions introduced earlier. Notice that I_1 and I_3 both write their results to register R3. In a machine with a single pipeline feeding a single ALU, we know that if I_1 enters the pipeline first (as it must), it will also be completed first. Later, its result will be overwritten by the result calculated by I_3 , which of course is the behavior expected under the von Neumann sequential execution model. But suppose the machine has more than one ALU that can execute the required operations. The ADD instruction (I_1) might be executed by one unit, while at the same time the XOR (I_3) is being executed by another. There is no guarantee that I_1 will be completed first or have its result sent to R3 first. Thus, it is possible that due to OOE, R3 could end up containing the wrong value. This situation in which two instructions both write to the same location, and the control unit must make sure that the second instruction’s write occurs after the first write, is known as an *output dependence* or WAW hazard [19].

Now, consider the relationship between instructions I_2 and I_3 in the example code. Notice that I_3 writes its result to R3 after the previous value in R3 has been read for use as one of the operands in the subtraction performed by I_2 . At least, that is the way things are supposed to happen under the sequential execution model. Once again, however, if multiple execution units are employed, it is possible that I_2 and I_3 may execute out of their programmed order. If this were to happen, I_2 could mistakenly use the “new” value in R3, which had been updated by I_3 rather than the “old” value computed by I_1 . This is one more situation, known as an *antidependence* or WAR hazard [19], which must be guarded against in a machine where OOE is allowed.

There is one other possible relationship between instructions that reference the same location for data and might have their execution overlapped in a pipeline(s). This “read after read” situation is the only one that never creates a hazard [19]. In our example, both I_1 and I_3 read R1 for use as a source operand. Since R1 is never modified (written), both instructions are guaranteed to read the correct value regardless of their order of execution. Thus, a simple rule of thumb is that for a data hazard to exist between instructions, at least one of them must modify a commonly used value.

22.3.8 Controlling Instruction Pipelines

Controlling the operation of pipelined processors in order to detect and correct for data hazards is a very important but very complex task, especially in machines with multiple execution units. In a machine with only one pipelined instruction execution unit, RAW hazards are generally the only ones a designer must worry about. (The exception would be in the very unusual case where more than one stage of the pipeline is capable of writing a result.) Control logic must keep track of (or “reserve”) the destination register or memory location for each instruction in progress and check it against the source operands of subsequent instructions as they enter the pipe. If a RAW hazard is detected, the most basic approach is to simply stall the instruction that uses the operand being modified (as shown in Figure 22.9b) while allowing the instruction that modifies it to continue. When the location in question has been modified, the reservation placed on it is released and the stalled instruction is allowed to proceed. This approach is straightforward, but forced stalls obviously impair pipeline throughput.

Another approach that can minimize, or in some cases eliminate, the need to stall the pipeline is known as *data forwarding* [22]. By building in additional connectivity within the processor, the result just computed by an instruction in the pipeline can be forwarded to the ALU for use by the subsequent instruction at the same time it is being sent to the reserved destination register. This approach generally saves at least one clock cycle compared to the alternative of writing the data into the first instruction’s destination register and then immediately reading it back out for use by the following dependent instruction.

Finally, designers can choose not to build in control logic to detect, and interlocks or forwarding to avoid, these RAW hazards caused by pipelining. Rather, they can document pipeline behavior as an architectural feature and leave it up to the compiler to reorder instructions and/or insert NOPs to artificially stall subsequent instructions, allowing a sufficient number of cycles to elapse so that the value in question will definitely be written before it is read. This solution certainly simplifies the hardware design but is not ideal for designing a family of computers since it ties the instruction set architecture closely to the details of a particular implementation, which may later be superseded. In order to maintain compatibility, more advanced future implementations may have to emulate the behavior of the relatively primitive earlier machines in the family. Still, the approach of handling data dependencies in software is a viable approach for designers who wish to keep the hardware as simple as possible.

Machines with multiple execution units encounter a host of difficulties not faced by simpler implementations. Adding WAW and WAR hazards to the RAW hazards inherent to any pipelined machine makes the design of control logic much more difficult. Two important control strategies were devised back in the 1960s for high-performance, internally parallel machines of that era. Variations of these methods are still used in the microprocessors of today. These design approaches are known as the *scoreboard method* and *Tomasulo’s method*.

The scoreboard method for resource scheduling dates back to the Control Data Corporation (CDC) 6600 supercomputer, which was introduced in 1964. James Thornton and Seymour Cray were the lead engineers for the 6600 and contributed substantially to this method, which was used later in the Motorola 88000 and Intel *i860* microprocessors. The machine had ten functional units that were not pipelined but did operate concurrently (leading to the possibility of OOE). The CDC 6600 designers came up with the idea of a central clearinghouse, or *scoreboard*, to schedule the use of functional units by instructions [23]. As part of this process, the scoreboard had to detect and control interinstruction dependencies to ensure correct operation in an OOE environment.

The scoreboard is a hardware mechanism—a collection of registers and control logic—that monitors the status of all data registers and functional units in the machine. Every instruction is passed through the scoreboard as soon as it is fetched and decoded in order to check for data dependencies and resource conflicts before the instruction is *issued* to a functional unit for execution. The scoreboard checks to make sure the instruction’s operands are available and that the appropriate functional unit is also available; it also resolves any write conflicts so that correct results are obtained.

There are three main parts, consisting of *tables* or sets of registers with associated logic, to the scoreboard: *functional unit status*, *instruction status*, and *destination register status* [24]. The functional unit status table contains several pieces of information about the status of each functional unit. This information includes a *busy* flag that indicates whether or not the unit is currently in use, two fields indicating the numbers of its *source registers* and one field indicating its *destination register* number, and *ready* flags for each of the source registers to indicate whether they are ready to be read. (A source register is deemed to be ready if it is not waiting to receive the results of a previous operation.) If a given functional unit can perform more than one operation, there might also be a bit(s) indicating which *operation* it is performing.

The instruction status table contains an entry for each instruction from the time it is first decoded until it completes (until its result is written to the destination). This table indicates the current status of the instruction with respect to four steps: whether or not it has been *issued*, whether or not its *operand(s)* has been *read*, whether or not its *execution is complete*, and whether or not the *result has been written* to the destination.

The destination register status table is the key to detecting data hazards between instructions. It contains one entry for each CPU register. This entry is set to the number of the functional unit that will produce the result to be written into that register. If the register is not the destination of a currently executing instruction, its entry is set to a null value to indicate that it is not involved in any write dependencies. Tables 22.3 through 22.5 show examples of possible contents of the functional unit status, instruction status, and destination register status tables for a machine with four functional units and eight registers. The actual CDC 6600 was more complex, but this example will serve for illustrative purposes.

TABLE 22.3 Scoreboard Example: Functional Unit Status Table

Unit Name	Unit Number	Busy?	Destination Register	Source Register 1	Ready?	Source Register 2	Ready?
Adder/ Subtractor 1	0	No	—	—	—	—	—
Adder/ Subtractor 2	1	Yes	5	2	Yes	7	Yes
Multiplier	2	Yes	0	1	Yes	3	Yes
Divider	3	No	—	—	—	—	—

TABLE 22.4 Scoreboard Example: Instruction Status Table

Instruction	Instruction Address	Instruction Issued?	Operands Read?	Execution Complete?	Result Written?
ADD R1, R4, R6	1000	Yes	Yes	Yes	Yes
ADD R2, R7, R5	1001	Yes	Yes	Yes	No
MUL R1, R3, R0	1002	Yes	Yes	No	No
MUL R2, R6, R4	1003	No	No	No	No
ADD R0, R5, R7	1004	No	No	No	No
—	—	—	—	—	—

TABLE 22.5 Scoreboard Example: Destination Register Status Table

	R7	R6	R5	R4	R3	R2	R1	R0
Functional unit number	—	—	1	—	—	—	—	2

The tables show a typical situation with several instructions in some stage of completion. Some functional units are busy and some are idle. Unit 0, the first adder/subtractor, has just completed the first ADD operation and sent its result to R6, so it is momentarily idle. Unit 1, the second adder/subtractor, has just completed the second ADD operation. However, the result has yet to be written into R5 (in this case, simply because not enough time has elapsed for the write operation to complete; in some situations, the delay could be a deliberate stall due to a WAR hazard between this and a previous instruction). Therefore, this instruction is not complete, and the reservations on the functional unit and destination register have not been released. Unit 2, the multiplier, has the first MUL operation in progress. Notice that R0 is reserved in the destination register status table as the result register for unit 2. As long as this is true, the control logic will not issue any subsequent instruction that uses R0.

As new instructions are fetched and decoded, the scoreboard checks each for dependencies and hardware availability before issuing it to a functional unit. The second MUL instruction has not yet been issued because the only multiplier, functional unit 2, is busy. Hardware (unit 0) is available such that the third ADD instruction could be issued, but it is stalled due to data dependencies: neither of its operands (in R0 and R5) is yet available. Only when both of these values are available can this instruction be issued to one of the adder/subtractor units. The new R5 value will be available soon, but until the first multiply completes (freeing unit 2 and updating R0), neither of the two instructions following the first MUL can be issued.

As long as scoreboard entries remain, subsequent instructions may be fetched and checked to see if they are ready for issue. (In Table 22.4, the last scoreboard entry is still available and the first one is no longer needed now that the instruction has completed, so two additional instructions could be fetched.) If all scoreboard entries are in use, no more instructions can be fetched until some instruction currently tracked by the scoreboard is completed. The limited number of scoreboard entries, along with the frequent stalls caused by all three types of data hazards and the fact that all results must be written to the register file before use, is the major limitation of the scoreboard approach.

Another important control strategy was first used in the IBM 360/91, a high-performance scientific computer introduced in 1967 [25]. Its multiple pipelined execution units were capable of simultaneously processing up to three floating-point additions or subtractions and two floating-point multiplications or divisions in addition to six loads and three stores. The operation of the floating-point registers and execution units (the heart of the machine's processing capability) was controlled by a hardware scheduling mechanism designed by Robert Tomasulo [26].

Tomasulo's method is essentially a refinement of the scoreboard method with some additional features and capabilities designed to enhance concurrency of operations. One major difference is that in Tomasulo's method, detection of hazards and scheduling of functional units are distributed, not centralized in a single scoreboard. Each data register has a *busy* bit and a *tag* field associated with it. The busy bit is set when an instruction specifies that register as a destination and cleared when the result of that operation is written to the register. The tag field is used to identify which unit will be computing the result for that register. Note that this information is analogous to that kept in the destination status register table of a scoreboard.

Another principal feature of Tomasulo's method that differs from the scoreboard method is the use of *reservation stations* [26] to hold operands (and their tags and busy bits, plus an operation code) for the functional units [24]. Each reservation station is essentially a set of input registers that are used to buffer operations and operands for a functional unit. The details of functional unit construction are not important to the control strategy. For example, if the machine has three reservation stations for addition/subtraction (as the 360/91 did), it does not matter whether it has three nonpipelined adders or one three-stage pipelined adder (as was actually the case). Each reservation station has its own unit number and appears to the rest of the machine as a distinct "virtual" adder. Likewise, if there are two reservation stations for multiplication, the machine appears to have two virtual multipliers regardless of the actual hardware used.

The tags associated with each operand in Tomasulo's method are very important because they specify the origin of each operand independently of the working register set. Though program instructions are

written with physical register numbers, by the time an instruction is dispatched to a reservation station, its operands are no longer identified by their original register designations. Instead, they are identified by their tags, which indicate the number of the functional unit (actually the number of a virtual functional unit—one of the reservation stations) that will produce that operand. Operands being loaded from memory are tagged with the number of their *load buffer* [26] (in a modern machine, they might be tagged by cache location, but the 360/91 had no cache). Once an operand has been produced (or loaded from memory) and is actually available in the reservation station, its tag and busy bit are changed to 0 to indicate that the data value is present and ready for use. Any time a functional unit is ready to accept operands, it checks its reservation stations to see if any of them have all operands present; if so, it initiates the requested operation. Thus, although programs for the machine are written sequentially using the von Neumann model, the functional units effectively operate as *dataflow* machines in which execution is driven by the availability of operands.

This use of tags generated “on the fly,” rather than the original register numbers generated by the programmer or compiler, to identify operands is known as *register renaming* [27]. The register renaming scheme significantly reduces the number of accesses to data registers; not only do they not have to be read for operands if data are coming directly from a functional unit but also only the last of a series of writes to the same register actually needs to be committed to it. The intermediate values are just sent directly to the reservation stations as necessary. Tomasulo’s register renaming scheme is instrumental in avoiding or minimizing stalls due to WAR and WAW hazards and thus achieves a significant advantage over the scoreboard method.

Another important feature of the 360/91 that helped to reduce or eliminate stalls due to RAW hazards was the use of a *common data bus* (CDB) to forward data to reservation stations that need a just-calculated result [26]. Because of this data forwarding mechanism (which goes hand in hand with the register renaming scheme), the reservation stations do not have to wait for data to be written to the register file. If the tag of a value on the CDB matches the tag of an operand needed by any reservation station(s), the operand is captured from the bus and can be used immediately. Meanwhile, the register file also monitors the CDB, loading a new value into any register with a busy bit set whose tag matches the one on the bus. Figure 22.10 is a simplified view of a machine with Tomasulo scheduling and a CDB architecture like the IBM 360/91.

Tomasulo’s method has some distinct disadvantages. Not only does it require complex hardware for control but its reliance on a single, shared bus makes it hard to scale up for a machine with many registers

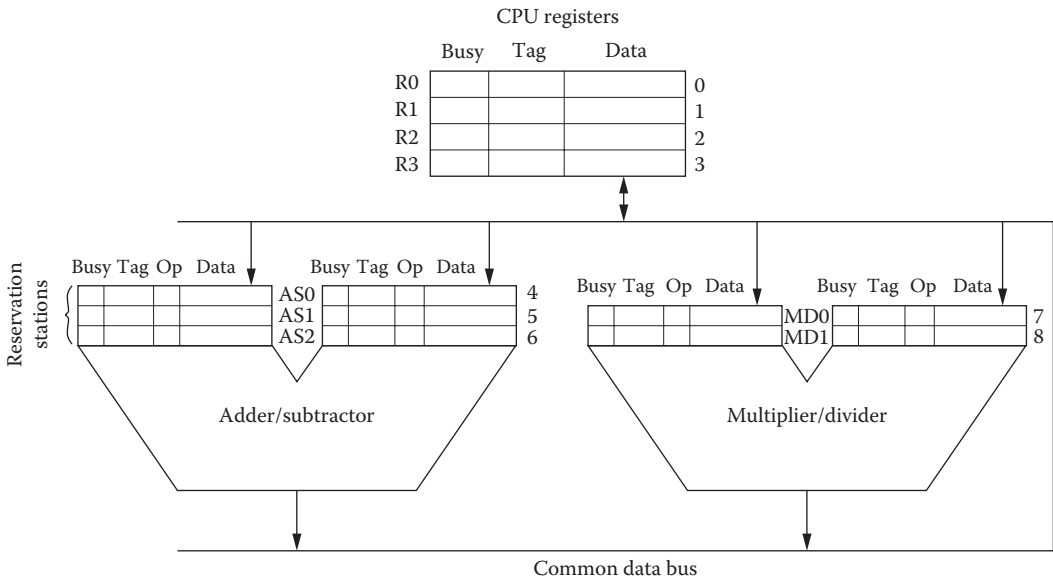

FIGURE 22.10 Example architecture with CDB and reservation stations. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.18.)

and/or functional units (typical of modern CPUs). Of course, given sufficient “real estate” on the chip, additional shared internal buses can be constructed to remove the CDB bottleneck. Likewise, the larger tags (and greater number of tag comparisons) needed in a more complex machine can be accommodated if sufficient space is available. On the other hand, the great selling point for Tomasulo’s method is the fact that it helps encourage concurrency of execution (to a greater degree than the scoreboard method) while preserving the dependency relationships inherent to programs written under the von Neumann sequential execution model. Tomasulo’s method in particular helps get better performance out of architectures with multiple pipelines. Because of this, approaches based on or very similar to this method are used in many modern, *superscalar* (see Section 22.3.10) microprocessors including the more advanced members of the Alpha, MIPS, Precision Architecture RISC (PA-RISC), Pentium, and PowerPC families.

22.3.9 Superpipelined Architectures

We learned in the preceding sections that pipelining is an effective way to improve the processing performance of computer hardware. However, a simple arithmetic or instruction-unit pipeline can only improve performance by a factor approaching, but never reaching or exceeding, the small number of stages employed. The fundamental limitation on performance improvement using pipelining is the number of stages into which the task is subdivided. A three-stage pipeline can at best yield a speedup approaching a factor of 3; a five-stage pipeline can only approach a 5:1 speed ratio. The simplest and most straightforward approach to achieving further performance improvement, then, is simply to divide the pipeline into a greater number of smaller stages in order to clock it at a higher frequency. There is still only one pipeline, but by increasing the number of stages, we increase its *temporal parallelism*—it is working on more instructions at the same time. This use of a very deep, very high-speed pipeline for instruction processing is called *superpipelining*.

One of the first superpipelined processors was the MIPS R4000 (introduced in 1991), which had an eight-stage pipeline [28] instead of the four- or five-stage design that was common in RISC architectures at the time. The eight stages were instruction fetch (first half), instruction fetch (second half), instruction decode and register fetch, execution, data cache access (first half), data cache access (second half), tag check, and write back. By examining this decomposition of the task, one can see that the speed of the cache had been a limiting factor in CPU performance. In splitting up memory access across two stages, the MIPS designers were able to better match that slower operation with the speed of internal CPU operations and thus balance the workload throughout the pipe.

The MIPS R4000 illustrated both the advantages and disadvantages of a superpipelined approach. On the plus side, it was able to achieve a very high clock frequency for its time. The single-pipeline functional unit was simple to control and took up little space on the chip, leaving room for more cache and other components including a floating-point unit and a memory management unit. However, as with all deeply pipelined instruction execution units, branching presented a major problem. The branch penalty of the R4000 pipeline was “only” three cycles (one might reasonably expect an even greater penalty given an eight-stage implementation). However, the MIPS instruction set architecture had been designed for a shallower pipeline and so only specified one delay slot following a branch. This meant that there were always at least two stall cycles after a branch—three if the delay slot could not be used constructively [28]. This negated much of the advantage gained from the chip’s higher clock frequency. The R4000’s demonstration of the increased branch delays inherent to a single superpipeline was so convincing that this approach has largely been abandoned. Most current machines that are superpipelined are also *superscalar* (see succeeding text) to allow speculative execution down both paths from a branch.

22.3.10 Superscalar Architectures

A *superscalar* machine is one that uses a standard, von Neumann-type instruction set but can issue (and thus often complete) multiple instructions per clock cycle. Obviously, this cannot be done with

a single conventional pipeline; so an alternate definition of superscalar is a machine with a sequential programming model that uses multiple pipelines. Superscalar CPUs attempt to exploit whatever degree of *instruction-level parallelism* (ILP) exists in sequential code by increasing *spatial parallelism* (building multiple execution units) rather than temporal parallelism (building a deeper pipeline). By building multiple pipelines, designers of superscalar machines can get beyond the theoretical limitation of one IPC inherent to any single-pipeline design and achieve higher performance without the problems of superpipelining.

Quite a few microprocessors of the modern generation have been implemented as superscalar designs. Superscalar CPUs are generally classified by the maximum number of instructions they can issue at the same time. (Of course, due to data dependencies, structural hazards, and/or branching, they do not *actually* issue the maximum number of instructions during every cycle.) The maximum number of instructions that can be simultaneously issued depends, as one might expect, on the number of pipelines built into the CPU. Digital Equipment Corporation's (DEC) Alpha 21064 (a RISC processor introduced in 1992) was a "2-issue" chip [29], while its successors the 21164 (1995), 21264 (1998), and 21364 (2003) were all "4-issue" processors [30]. Another way of saying the same thing is to call the 21064 a *two-way superscalar* CPU, while the 21164 and following chips are said to be *four-way superscalar*. The MIPS Technologies R10000 [31], R12000, R14000, and R16000 are also four-way superscalar processors. Even CISCs can be implemented in superscalar fashion: as far back as 1993, Intel's first Pentium chips were based on a two-way superscalar design [32]. The Pentium had essentially the same instruction set architecture as the 486 processor but achieved higher performance by using two execution pipelines instead of one.

In order to issue multiple instructions per cycle from a sequentially written program and still maintain correct execution, the processor must check for dependencies between instructions using an approach like those we discussed previously (the scoreboard method or Tomasulo's method) and issue only those instructions that do not conflict with each other. Since OOE is possible, all types of hazards can occur; register renaming is often used to help solve the problems. Precise handling of exceptions is more difficult in a superscalar environment, too. Of course, the logic required to detect and resolve all of these problems is complex to design and adds significantly to the amount of chip area required. The multiple pipelines also take up more room, making superscalar designs very space sensitive and thus more amenable to implementation technologies with small feature (transistor) sizes. (Superpipelined designs, by contrast, are best implemented with technologies that have short propagation delays.) These many difficulties of building a superscalar CPU are offset by a significant advantage: with multiple pipelines doing the work, clock frequency is not as critical in superscalar machines as it is in superpipelined ones. Since generating and distributing a high-frequency clock signal across a microprocessor are far from a trivial exercise, this is a substantial advantage in favor of the superscalar approach.

Of course, superscalar and superpipelined designs are not mutually exclusive. Some CPUs have been implemented with multiple, deep pipelines, making them both superpipelined and superscalar. Sun's UltraSPARC processor [33], introduced in 1995, was an early example of this hybrid approach: it was both superpipelined (nine stages) and four-way superscalar. A more recent (2003) example is IBM's PowerPC 970 CPU [34]. Even CISC processors such as the AMD Athlon [35] have combined superscalar and superpipelined design in order to maximize performance. Given sufficient chip area, superscalar design is a useful enhancement that makes superpipelining much more practical. When a branch is encountered, a superscalar/superpipelined machine can use one (or more) of its deep pipelines to continue executing sequential code, while another pipeline(s) executes speculatively down the branch target path. Whichever way the branch decision goes, at least one of the pipelines will have correct results; any that took the wrong path can be flushed. Some work is wasted, but processing never comes to a complete halt.

22.3.11 Very Long Instruction Word Architectures

Superscalar CPU designs have many advantages, as we saw in the preceding pages. However, there remains the significant problem of scheduling which operations can be done concurrently and which

ones have to wait and be done sequentially after others. Determining the precise amount of ILP present in a program is a complex exercise that is made even more difficult by having to do it “on the fly” within the limitations of hardware design and timing constraints. How can we get the benefits of multiple instruction issue found in superscalar CPUs without having to build in complex, space- and power-consuming circuitry to analyze multiple types of data dependencies and schedule the initiation of operations? A look back at one of the basic RISC design principles provides one possible answer: “let the compiler do the work.” This idea is the foundation of a relatively new class of architectures known by the acronym (coined by Josh Fisher of Yale University) *VLIW*, which stands for very long instruction word [36].

The centerpiece of a VLIW architecture is exactly what the name implies: a machine language instruction format that is fixed in length (as in a RISC architecture) but much longer than the 32–64 bit formats common to most conventional CISC or RISC architectures (see Figure 22.11 for an example). Each “very long” instruction contains enough bits to specify not just one machine operation but several to be performed simultaneously. Ideally, the VLIW format includes enough *slots* (or groups of bit fields) to specify operands and operations for every functional unit present in the machine. If sufficient ILP is present in the high-level algorithm, all of these fields can be filled with useful operations, and maximum use will be made of the CPU’s internal parallelism. If not enough logically independent operations can be scheduled at one time, some of the fields will be filled with NOPs, and thus some of the hardware will be idle, while other units are working.

The VLIW approach gives essentially the same effect as a superscalar design but with most or all of the scheduling work done statically (offline) by the compiler, rather than dynamically (at run time) by the control unit. It is the compiler’s job to analyze the program for data and resource dependencies and pack the “slots” of each VLIW with as many concurrently executable operations as possible. Since the compiler has more time and resources to perform this analysis than would the control unit and since it can see a “bigger picture” of the code at once, it may be able to find and exploit more ILP than would be possible in hardware. Thus, a VLIW architecture may be able to execute more (equivalent) instructions per cycle than a superscalar machine with similar capabilities.

Finding and expressing the parallelism inherent in a high-level program is quite a job for the compiler; however, the process is essentially the same whether it is done in hardware or software. Doing scheduling in software allows the hardware to be kept simpler and hopefully faster. One of the primary characteristics of the original, single-pipeline RISC architectures was reliance on simple, fast hardware with optimization to be done by the compiler. A VLIW architecture is nothing more nor less than the application of that same principle to a system with multiple pipelined functional units. Thus, in its reliance on moving pipeline scheduling from hardware to software (as well as in its fixed-length instruction format), VLIW can be seen as the logical successor to RISC.

The VLIW concept goes back further than most computing professionals are aware. The first VLIW system was the Yale ELI-512 computer (with its Bulldog compiler) built in the early 1980s [36], just about the time that RISC architectures were being born. Josh Fisher and some colleagues from Yale University started a company named Multiflow Computer, Inc., in 1984 [37]. Multiflow produced several TRACE systems, named for the trace scheduling algorithm used in the compiler [36]. Another company, Cydrome Inc., which was founded about the same time by Bob Rau, produced a machine known as the Cydra-5 [37]. However, the VLIW concept was clearly ahead of its time. (Keep in mind that RISC architectures—which were a much less radical departure from

conventional design—also had a hard time gaining acceptance at first.) Both companies failed to thrive and eventually went out of business.

For quite some time after this, VLIW architectures were only found in experimental, research machines. IBM got wind of the idea and started its own VLIW project in 1986 [38]. Most of the research involved the (very complex) design of the compilers; IBM’s hardware prototype system was not constructed until about 10 years after the project began. This system is based on what IBM calls the Dynamically Architected Instruction Set from Yorktown (DAISY) architecture [39]. Its instructions are 759 bits long; they can simultaneously specify up to 8 ALU operations, 4 loads or stores, and 7 branch conditions. The prototype machine contains only 4 MB of data memory and 64K VLIWs of program memory, so it was obviously intended more as a proof of the VLIW concept (and of the compiler) than as a working system.

Commercially available CPUs based on the VLIW concept entered the market in 2001 with the introduction of the IA-64 architecture [40], which was jointly developed by Intel and Hewlett-Packard (HP) and initially implemented in the Itanium (Merced) processor. Subsequent chips in this family include the Itanium 2 (2002), Itanium 2 9000 series (2006), 9100 series (2007), 9300 series (code name Tukwila, 2010), and 9500 series (code name Poulson), introduced in 2012. Intel does not use the acronym VLIW, preferring to refer to its slightly modified version of the concept as EPIC (which stands for explicitly parallel instruction computing). However, EPIC’s lineage is clear: VLIW pioneers Fisher and Rau went to work with HP after their former companies folded and contributed to the development of the new architecture [40]. The IA-64 instruction set incorporates 128-bit “bundles” (see Figure 22.12) containing three 41-bit RISC-type instructions [40]; each bundle provides explicit dependency information. This dependency information (determined by the compiler) is used by the hardware to schedule the execution of the bundled operations. The purpose of this arrangement (with some of the scheduling done in hardware in addition to that done by software) is to allow binary compatibility to be maintained between different generations of chips. Ordinarily, each generation of a given manufacturer’s VLIW processors would be likely to have a different number and/or types of execution units and thus a different instruction format. Since hardware is responsible for some of the scheduling and since the instruction format is not directly tied to a particular physical implementation, the Itanium processor family is architecturally somewhere between a “pure VLIW” and a superscalar design (though arguably closer to VLIW).

There are several disadvantages to the VLIW approach, which IBM, HP, and Intel hoped would be outweighed by its significant advantages. Early VLIW machines performed poorly on branch-intensive code; IBM has attempted to address this problem with the tree structure of its system, while the IA-64 architecture addresses it with a technique called *predication* (as opposed to prediction, which has been used in many RISC and superscalar processors) [40]. The predication technique uses a set of *predicate registers*, each of which can be used to hold a true or false condition. Where conditional branches would normally be used in a program to set up a structure such as if/then/else, the operations in each possible sequence are instead *predicated* (made conditional) on the contents of a given predicate register. Operations from both possible paths (the “then” and “else” paths) then flow through the parallel,

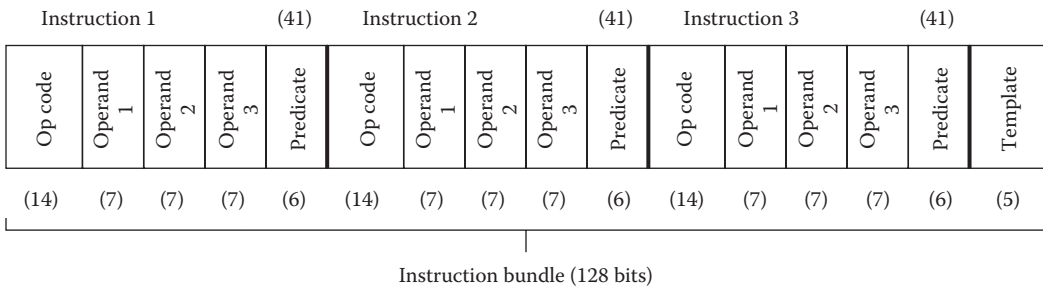

FIGURE 22.12 IA-64 EPIC instruction format. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 4.21.)

pipelined execution units, but only one set of operations (the ones with the predicate that evaluates to true) are allowed to write their results.

Another problem that negatively affected the commercial success of early VLIW architectures was the lack of compatibility with established architectures. Unless one had access to all the source code and could recompile it, the existing software could not be run on the new architectures. This problem was addressed in IBM's DAISY prototype by performing dynamic translation (essentially, run-time interpretation) of code for the popular PowerPC architecture [39]. Early (pre-2006) EPIC processors also supported the execution of the huge existing Intel IA-32 (x86) code base, as well as code compiled for the HP PA-RISC architecture, through hardware emulation at run time. However, the performance proved to be poor compared to both native IA-64 code running on Itanium series chips and IA-32 code running on existing IA-32 processors. Thus, starting with the Itanium 2 9000 series (Montecito) processors, a software emulator known as the IA-32 Execution Layer [41] was introduced to improve performance on legacy x86 code.

Yet another VLIW disadvantage is poor code density. Since not every VLIW instruction has useful operations in all its slots, some bit fields are inevitably wasted, making compiled programs take up more space in memory than they otherwise would. No real cure has been found for this problem, as the available hardware resources are constant, while the ILP available in software varies. However, this issue has been considerably ameliorated by the fact that memory prices have trended downward over time.

VLIW architectures have several advantages that would seem to foretell their future success. The most obvious is the elimination of most or all scheduling logic from the hardware, freeing up more space for additional functional units, more on-chip cache, multiple cores, etc. Simplifying the control logic may also reduce overall delays and allow the system to operate at a higher clock frequency than a superscalar CPU built with the same technology. Also, as was previously mentioned, the compiler (relatively speaking) has “all day” to examine the entire program and can potentially uncover much more ILP in the algorithm than could a real-time, hardware scheduler. This advantage, coupled with the presence of additional functional units, should allow VLIW machines to execute more operations per cycle than are possible with a superscalar approach. Since the previously steady increase in CPU clock speeds has started to flatten out, the ability of VLIW architectures to exploit ILP would seem to bode well for their success in the high-performance computing market. However, in actual practice, IA-64 chips account for only a small fraction of Intel's overall sales, and Itanium-based systems represent only a fraction of the overall server and high-performance computing market (almost all of it in systems made by HP) [42]. It appears that this trend is likely to continue, and at least in the near future, the vast majority of high-end systems will be based on multicore, and in many cases *multithreaded* (see succeeding text), implementations of more conventional architectures and/or increasingly powerful and popular *graphics processing units* (GPUs).

22.3.12 Multithreaded Architectures

Previously, in Section 22.3.8, we mentioned that Tomasulo's scheduling algorithm for machines using OOE was based on a dataflow approach. Though they outwardly perform as von Neumann machines and are programmed using the conventional, sequential programming paradigm, processors with Tomasulo schedulers operate internally as dataflow machines—a type of “non-von Neumann” architecture. While pure dataflow machines never became popular in their own right, they did inspire this and certain other innovations that have been applied to more traditional CPU designs.

One other way in which dataflow concepts have influenced conventional computer designs is in the area of multithreaded, superthreaded, and hyper-threaded processors. Consider the behavior of programs in conventional machines. We think of programs running on a single instruction stream single data stream (SISD) or multiple instruction stream multiple data stream (MIMD) architecture as being comprised of one or more, relatively coarse-grained, *processes*. Each process is an instruction stream consisting of a number of sequentially programmed instructions. Multiple processes can run on an MIMD system in truly concurrent fashion, while on an SISD machine, they must run one after another in time-sliced

fashion. In a dataflow machine, each individual machine operation can be considered to be an extremely “lightweight” process of its own and to be scheduled when it is ready to run (has all its operands) and when hardware (a processing element) is available to run it. This is as fine grained a decomposition of processes as is possible and lends itself well to a highly parallel machine implementation. However, for a number of reasons, massively parallel dataflow machines are not always practical or efficient.

The same concept, to less of a degree (and much less finely grained), is used in *multithreaded* systems. Multithreaded architectures, at least in some aspects, evolved from the dataflow model of computation. The idea of dataflow, and multithreading as well, is to avoid data and control hazards and thus keep multiple hardware functional units busy, particularly when latencies of memory access or communication are high and/or not a great deal of ILP is present within a process. While each *thread* of execution is not nearly as small as an individual instruction (as it would be in a true dataflow machine), having more, “lighter-weight” threads instead of larger, monolithic processes and executing these threads in truly concurrent fashion are in the spirit of a dataflow machine since it increases the ability to exploit replicated hardware. *Time-slice* multithreading, or *superthreading* [43], is a dataflow-inspired implementation technique whereby a single, superscalar processor executes more than one process or thread at a time. In each clock cycle, the control unit’s scheduling logic can issue multiple instructions belonging to a single thread, but on a subsequent cycle, it may issue instructions belonging to another thread (Figure 22.13 illustrates this approach). In effect, process/thread execution on a superthreaded machine is still time sliced (as it is in traditional uniprocessor architectures), but the time slice can be as small as one clock cycle.

The superthreaded approach can lead to better use of hardware resources in a superscalar processor due to mitigation of dependency-based hazards, since instructions from one thread are unlikely to depend on results from instructions belonging to other threads. It can also reduce cycles wasted due to access latencies since instructions from other threads can still execute, while a given thread is waiting on data from memory. However, the utilization of hardware resources is still limited by the inherent ILP,

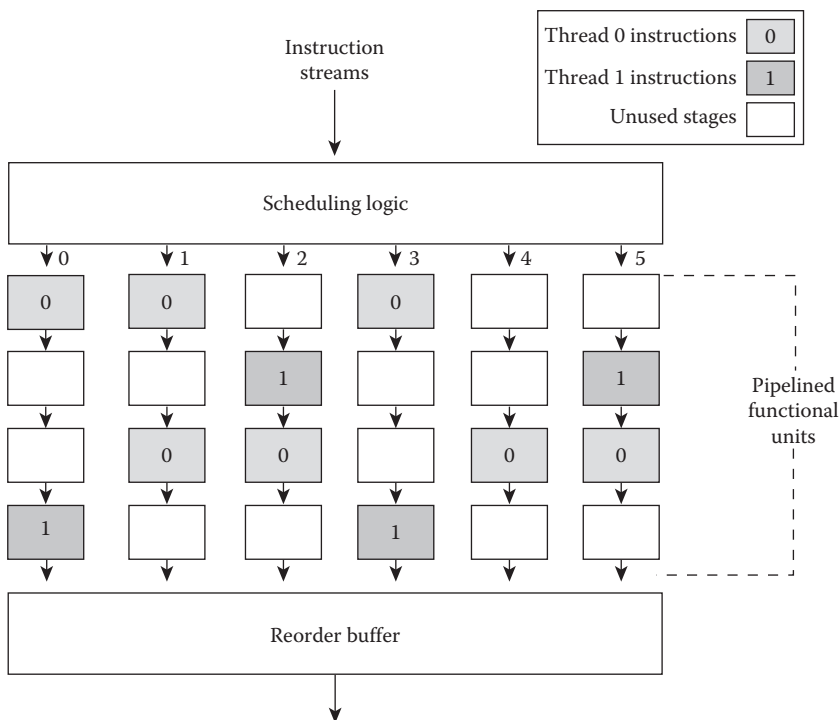

FIGURE 22.13 Instruction execution in superthreaded processor. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 7.5.)

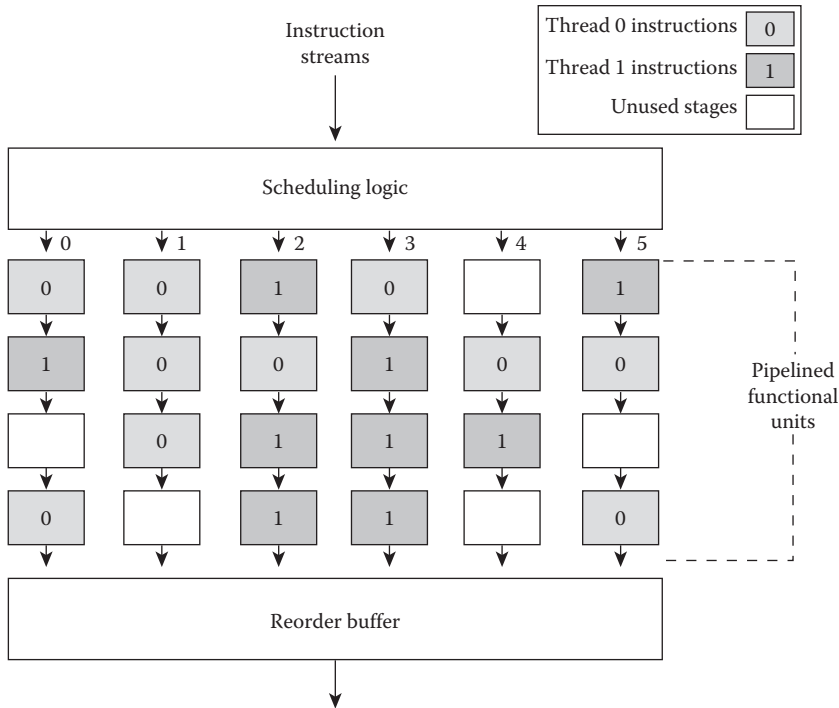

FIGURE 22.14 Instruction execution in hyper-threaded processor. (From Dumas II, J.D., *Computer Architecture: Fundamentals and Principles of Computer Design*, CRC Press, Boca Raton, FL, 2006, Figure 7.6.)

or lack thereof, in the individual threads. (Studies have shown that, on average, a single thread only has sufficient ILP to issue about 2.5 instructions per clock cycle.) To address this limitation, *simultaneous* multithreading (SMT), also known as *hyper-threading* [43], goes a step beyond superthreading.

Compared to superthreading, hyper-threading (which is used in some of the latest generation CPUs from Intel [44]; the IBM POWER5, POWER6, and POWER7 processors [45]; and others) gives the scheduling logic more flexibility in deciding which instructions to issue at what time. In a hyper-threaded processor, it is not necessary that all the instructions issued during a given clock cycle belong to the same thread [43]. For example, a 6-issue superscalar machine could issue 3 instructions from thread 0 and 3 from thread 1 at the same time, or four from thread 0 and two from thread 1 as illustrated in Figure 22.14.

In effect, SMT internally splits a single, physical superscalar processor into two or more logically separate CPUs, each executing its own instruction stream by sharing processor resources that might otherwise go unused if only a single thread were executing. (Of course, some CPU resources including the program counter and certain other system registers may have to be replicated to allow for hyper-threading.) SMT implementation can significantly increase the efficiency of resource utilization and improve overall system performance as seen by the user when multiple tasks (or a single application coded with multiple threads) are running [43]. Because of its adoption by the largest manufacturer of microprocessors and other industry giants, SMT/hyper-threading could prove to be the most lasting legacy of the dataflow approach.

22.4 Research Issues

Pipelined mainframe processors have been in use since the 1960s, and pipelined microprocessors since the 1980s; so much of the basic research in the field was done decades ago. The use of delay slots to mitigate the performance penalty associated with control transfers is “old hat” among RISC architectures but cannot readily be retrofitted to legacy architectures such as the Intel x86 without destroying the

backward compatibility that is their chief competitive advantage. Likewise, the use of branch prediction is well established; algorithms that work well in most circumstances have been developed, and future improvements in this area are likely to have only marginal effects on performance. OOE coupled with scheduling techniques such as scoreboarding and Tomasulo's algorithm can improve single-threaded performance only to the extent that ILP exists within that thread, but most general-purpose, scalar applications exhibit relatively limited ILP. This restricts the performance that can be achieved using superscalar (or even VLIW) approaches.

For applications that have large amounts of inherent data parallelism, the most promising current research area appears to be GPU computing [46]—a subject that is addressed in another chapter of this handbook. In just 1 year between the release of the November 2011 and 2012 lists of the world's top 500 supercomputers [47], the number of systems using GPU accelerators/coprocessors increased from 39 to 62. All signs point to a continuation of this trend for the foreseeable future, and there is still much research and development to be done in the area of GPU computing.

For more conventional applications that are better parallelized at the process or thread level, multicore (see Chapters 23 and 24) and multithreaded architectures provide the most likely path to continuing performance increases. Since the vast majority of general-purpose and high-performance systems use Intel processors [48] and since most modern Intel processors (with the exception of the previous generation Core architecture CPUs) including the Core i7, Xeon 5500 and 5600 (Nehalem and Westmere) series, Itanium 9300, and Atom use hyper-threading, this technology seems likely to see continued use in larger systems. Chips such as the IBM POWER5, POWER6, and POWER7 series processors as well as the Sun Microsystems' (now Oracle) UltraSPARC T1, T2, T2+, T3, and T4 processors demonstrate the commitment of other major computer manufacturers to multithreading as well.

Some of the issues that are significant to multithreaded architectures include limitations on single-threaded performance when multiple threads are running and disadvantages associated with sharing of memory resources including cache and translation lookaside buffers (TLBs). It is an observed fact that some applications perform noticeably worse on hyper-threaded processors due to contention with other threads for CPU resources such as instruction decoding logic, execution units, and branch predictors [43,49]. With each new design, manufacturers must struggle to balance hardware resources with the anticipated needs of applications. As an alternative, some multithreaded CPUs, for example, the UltraSPARC T4, provide a mechanism for multithreading to be effectively turned off—temporarily dedicating an entire core's hardware to running a single thread that had been suffering from a bottleneck using the Solaris operating system's "Critical Thread Optimization" feature [50]. However, more research and development are needed to provide convenient and efficient means for systems to detect when this is occurring and to use this information to switch back and forth between single-threaded and multithreaded modes for optimum overall performance.

Sharing of memory resources between threads running on a common core creates issues not only for performance but also for security. Obviously, when the instruction and/or data caches belonging to a core are shared between two or more threads, the effective cache size available to each thread—and thus the hit ratio for each—is less than it would be if only one thread were running. Effective cache size may not be cut exactly in half if two running threads share some common code or data, but it is extremely unlikely that they would share everything; thus, some degradation of performance is almost inevitable. Important research questions here involve determining the optimum cache size, line size, and other design parameters for multiple threads to share a common cache with the least disruption. But perhaps an even more important topic is preventing threads from sharing the cache "too much"—in other words, spying on data belonging to other threads. As far back as 2005, researcher Colin Percival discovered that it was possible for a malicious thread running on a Pentium 4 CPU with hyper-threading to use cache access patterns to steal a cryptographic key from another thread running on the same core [51]. While operating systems can be configured to block this attack vector, manufacturers of multithreaded CPUs now know they must keep information security in mind when designing cache line replacement policies; this will surely be an ongoing concern as more processors of this type are designed.

22.5 Summary

No other part of a modern computer system is as complex as its CPU(s). In this chapter, we have examined several advanced design concepts involving internal concurrency of operations within a single CPU core. (Multicore/multiprocessing systems will be addressed in Chapters 23 and 24.) The concept of pipelining was the main focus of our attention, since almost all commonly used methods for enhancing the performance of a CPU are based on pipelining and since, as a result, almost all modern microprocessors are internally pipelined to some extent. As the reader has seen, while the potential performance benefits of pipelining are obvious, “the devil is in the details”—particularly when pipelines become very “deep” and/or when multiple pipelines are used in one processor core.

Of course, the examples provided earlier as illustrations of pipelined, superpipelined, superscalar, VLIW, and multithreaded architectures were kept relatively simple so as not to lose the reader in a myriad of implementation details—details that would have to be addressed in any practical, real-world design. Put another way, we have only scratched the surface of the intricacies of this subject. Computer engineers may spend their entire careers designing high-performance microprocessors and not learn everything there is to know about it—and even comprehensive knowledge of technical details can quickly become obsolete as technology changes. Certainly no single handbook chapter can do full justice to this highly specialized discipline. However, it is hoped that the information in this chapter will be sufficient to provide most computing professionals with a sufficient understanding of these techniques and their implications for performance, to make them better equipped to make wise choices among the many competing computer systems in the constantly changing market of the present and the future.

Key Terms

Arithmetic pipeline: A pipeline designed to perform a given arithmetic operation repetitively.

Arithmetic pipelines are often used in vector supercomputers due to the nature of their operands and the operations performed on them but are rarely found in general-purpose machines.

Branch penalty: The time wasted when instructions that sequentially follow a control transfer instruction are brought into the pipeline but must be aborted (nullified) by the control logic because the control transfer causes nonsequential execution. Depending on the specifics of the instruction set and the details of the pipeline’s implementation, the branch penalty may be as little as one clock cycle or as great as the time required to drain the entire pipeline of instructions.

Branch prediction: A technique that attempts to improve the performance of an instruction-pipelined processor by guessing whether or not a given conditional control transfer instruction will succeed or fail and fetching subsequent instructions into the pipeline accordingly. Branch prediction can be done either *statically* (before the program is run) or *dynamically* (by the pipeline control logic, while the program is running).

Central Processing Unit (CPU): The portion of a digital computer system that performs computational work by fetching program instructions from memory and executing them. A CPU normally consists of a *control unit*, which controls and sequences hardware operations, plus a *datapath* that consists of storage registers and computational hardware (e.g., an ALU) for performing binary calculations.

Data forwarding: A technique in which the result of a computation, which is needed for use in a subsequent computation, is delivered directly to the hardware functional unit performing the second computation rather than being stored into its destination register and then read back out for use in the second computation. Data forwarding can improve the performance of a pipelined machine by eliminating or reducing pipeline stalls.

Dataflow computer: A computer in which the order of performing operations is determined by the availability of operands and computational hardware, rather than by the sequential programming paradigm associated with von Neumann-type computing architectures.

- Delayed branch:** A conditional control transfer instruction that attempts to eliminate or reduce the branch penalty (wasted clock cycles) of a successful branch by documenting, as an architectural feature, the execution of one (or more) instruction immediately following the branch, whether or not the branch succeeds. The instruction(s) following the branch is said to be in the branch *delay slot(s)*.
- Flow-through time:** The time taken for the first iteration of a task to be completed by a pipeline. Assuming that each subtask is performed by one pipeline stage, that a clock signal is used to advance operations to the next stage, and that the pipeline does not stall for any reason, the flow-through time of a pipeline with s stages will be s clock cycles.
- ILP:** A measure of how many instructions within a computer program can be executed at the same time without altering the results that would be produced by executing them sequentially according to the von Neumann paradigm. The more inherent parallelism a program has at the instruction level, the better it can take advantage of internally parallel processor designs (e.g., superscalar or VLIW).
- Instruction-unit pipeline:** A pipeline used to process a variety of machine instructions that may perform different functions but can be subdivided into a similar number and type of steps. Instruction-unit pipelines are common in modern scalar, general-purpose microprocessors.
- Pipeline register:** A parallel-in, parallel-out storage register comprising a set of flip-flops or latches, which is used to separate the logic used in different pipeline stages in order to keep one stage from interfering with the operation of another. The pipeline registers are clocked with a common signal such that each stage's outputs are advanced to the following stage's inputs simultaneously.
- Pipeline throughput:** The number of task iterations completed by a pipeline per clock cycle. In a pipelined instruction-processing unit, throughput is the number of instructions executed per clock cycle (IPC). The ideal throughput of a single pipeline is one IPC, but in practice it is always less due to control transfers, memory accesses, and/or stalls due to data hazards.
- Pipelining:** A technique used to improve performance when a task is performed repetitively. A pipeline breaks the task into several subtasks, each performed by a different *stage* of the pipeline, and overlaps the performance of subtasks for subsequent task iterations. Since successive task iterations are started before previous ones have completed, a given number of iterations can be completed in less time as compared to a purely sequential implementation.
- RAW hazard:** Also known as a *true data dependence*, this is a relationship between instructions that exist when an instruction reads a datum that was produced by a previous instruction. In a purely sequential processor, correct operation would be guaranteed, but in a pipelined processor, it is possible that the subsequent instruction could read the datum before the previous instruction's write was completed, leading to erroneous use of "old" data.
- Simultaneous multithreading:** Also known as *hyper-threading*, this is a CPU design technique in which the processor executes instructions from multiple threads concurrently. During any given clock cycle, instructions from more than one thread may be issued.
- Superpipelined processor:** A CPU that uses a deep pipeline structure; in other words, one that has a large number of very simple stages. By finely subdividing the processing of instructions, a superpipelined processor may be able to sustain a higher clock frequency than other processors built using similar technology. Because of the large number of stages, control transfers can cause performance problems.
- Superscalar processor:** A CPU in which more than one instruction can be issued for execution per clock cycle, and thus, more than one instruction may be completed per clock cycle. This is generally accomplished by having more than one pipeline available for processing instructions. The decision about which instructions can be issued simultaneously without producing incorrect results is made by the pipeline control logic while the program is running.
- Time-slice multithreading:** Also known as *superthreading*, this is a CPU design technique in which the processor executes instructions from different threads during successive clock cycles. During any given clock cycle, instructions from only one thread are issued.

Very long instruction word (VLIW) processor: A CPU with multiple pipelined functional units, similar in hardware design to a superscalar processor. Because of its internally parallel structure, the CPU can issue (and thus complete) multiple instructions per clock cycle. However, the scheduling of instruction issue is done largely (or completely) by the compiler at program translation time, rather than by the control unit at run time.

Write after read (WAR) hazard: Also known as an *antidependence*, this is a relationship between instructions that exist when an instruction writes a datum that was to have been read by a previous instruction. In a processor with in-order execution, correct operation would be guaranteed, but in a processor with multiple pipelines leading to the possibility of OOE, it is possible that the subsequent instruction could overwrite the datum before the previous instruction's read was completed, leading to erroneous use of "too new" data.

Write after write (WAW) hazard: Also known as an *output dependence*, this is a relationship between instructions that exist when more than one instruction writes a common datum. In a processor with in-order execution, correct operation would be guaranteed, but in a processor with multiple pipelines (and/or multiple write stages) leading to the possibility of OOE, it is possible that a previous instruction could write its result after a subsequent instruction had already done so, leading to an erroneous final value of the datum in question.

Much of the computing done today is performed using parallel computers—searching for information (such as used by Google across its applications), analyzing data (such as enabled by the Apache Hadoop map–reduce system for scalable distributed computing), and simulating complex systems (such as done for weather prediction by NOAA). Even the computer present in cell phones is often a parallel processor (handling the user interface, applications, and radio)! In many cases, the exact nature of the parallel computer is hidden from the user—the hardware details are abstracted away from both the user and the programmer. However, understanding the basics of how parallel architectures work will help both users and programmers appreciate, optimize, and improve their ability to use these systems.

Parallel or concurrent execution has many different forms within a computer system. Multiple computers can be executing pieces of the same program in parallel, a single computer can be executing multiple operations or instructions in parallel, or there can be some combination of the two. Parallelism can be exploited at several levels: thread or task level, operation or instruction level, or even some lower machine level (such as done in many AMD and Intel processors). Parallelism may be exhibited in space, with multiple independent computation units (commonly referred to as function units (FU)) or, in time, with a single FU that is many times faster than several instruction or operation issuing units and is shared between them. This chapter attempts to remove some of the complexity regarding parallel architectures but necessarily leaves out significant detail; however, we try to provide suitable references to the reader to follow up for more details both within these volumes and in the open literature. Two recommended introductions to uniprocessor computer architecture are Flynn [7] and Hennessy and Patterson [8]; a recommended introduction to multiprocessor systems is Culler, Singh, and Gupta [4].

With many possible forms of parallelism, we need a framework to describe parallel architectures. One of the oldest and simplest such structures is the stream approach (sometimes called the Flynn taxonomy) [6] that is used here as a basis for describing parallel architectures; it is fundamentally implementation agnostic and can apply to traditional processors as well as to custom computation engines. We will place

modern variations and extensions in this framework to show how even what appear to be radically new ideas have their basic characteristics grounded in this fundamental model. These characteristics provide a qualitative feel for the architecture for high-level comparisons between different processors.

23.1 Stream Model

A parallel architecture has, or at least appears to have, multiple interconnected *processor elements* (PE) that operate concurrently to solve a single overall problem. PE may operate independently or may execute in lockstep with other PE depending on the nature of the architecture; a PE that operates independently of the other PE is typically referred to as a *core*. Cores are capable of executing independently of other cores but are distinguished from *processors* in that they do not have the interface and communications logic to interface with the rest of a system; processors are typically packaged in a chip or other self-contained module* that is integrated into the system as a major design element.

Initially, the various parallel architectures can be described using the *stream* concept. A stream is simply one (single; S) or more (multiple; M) actions on data objects or the actual data themselves. There are both actions (instructions; I) and objects (data; D), and the four combinations of these streams describe most familiar parallel architectures (illustrated in Figure 23.1):

1. SISD—single instruction stream, single data stream. This classification is the traditional uniprocessor (Figure 23.1a).
2. SIMD—single instruction stream, multiple data streams. This classification includes both vector processors and massively parallel processors as well as general-purpose graphics processors (Figure 23.1b).
3. MISD—multiple instruction streams, single data stream. This classification includes data streaming processors, data flow machines, and systolic arrays (Figure 23.1c).
4. MIMD—multiple instruction streams, multiple data streams. This classification includes both traditional multiprocessors (including chip multiprocessors) and networks of workstations and cloud-computing environments (Figure 23.1d).

FIGURE 23.1 The stream model. (a) SISD, (b) SIMD, (c) MISD, (d) MIMD.

* In times past, processors were in equipment racks, chassis, boards, chips, etc. Going forward, there is no telling how processors may be packaged or integrated with other features in the future.

The key point to keep in mind is that the stream description of architectures uses the *programmer's* view of the machine (the architecture) as its reference point—the *designer's* view of the machine (the implementation) may be very different and is likely to be much more detailed and complex.* For a programmer to exploit parallelism in their application, they usually need to understand how a parallel architecture is organized; there is the dream of automatic parallelism by either hardware or software, but as of yet that dream is still far from what can be realized in most cases. Note that the stream classification describes only the high-level interaction between instruction and data streams—it does not describe a particular hardware implementation or the means that the various streams are coordinated and synchronized. Thus, a real implementation may be very different than the architecture represented by the stream classification but must ensure that any difference between architecture and implementation is completely transparent to the programmer. Even though an SISD processor can be highly parallel in its execution of operations (as is the case in both superscalar and very long instruction word processors), it still appears to the programmer that the processor executes a single stream of instructions on a single stream of data objects. Understanding the details of a particular implementation may enable the programmer (or compiler) to produce optimized and better-performing code for a particular implementation, but such understanding is not necessary to be able to produce functional (and, typically, reasonably well-performing) code.

There are many factors that determine the overall effectiveness of a parallel processor organization and hence its performance improvement when implemented. What is particularly challenging is that performance can have many different measurements, or metrics, depending on what is desired by the analyst or reviewer of this information. Performance may be the speedup of the measured system compared to the a particular reference system as determined by the observed (wall-clock) time to execute a program, it may be the power consumed to execute the program, or it may be any other definable and measurable value that is of interest. Both Jain [12] and Lilja [15] provide background on performance analysis.

23.2 SISD

The SISD class of processor architecture is the most familiar class to most people—it is found in older video games, home computers, engineering workstations, mainframe computers, cell phones, automobiles, toaster ovens, and even digital watches. From the programmer's view, there is no parallelism in an SISD organization, yet a good deal of real concurrency can be present and can be exploited, resulting in improved performance, or can be abused, resulting in reduced performance. *Pipelining* is an early technique to improve performance that is still used in almost all current processor implementations. Other techniques, such as executing multiple operations or instructions concurrently (in parallel), exploit parallelism using a combination of hardware and software techniques.

23.2.1 Pipelined Processors

Pipelining is a straightforward approach to exploiting parallelism that allows concurrent processing of different phases from multiple instructions in an instruction stream rather than requiring completing the processing of all phases of a single instruction in an instruction stream before starting to process the next instruction. These phases often include fetching an *instruction* from memory (instruction fetch; IF), decoding an instruction to determine its *operation* and *operands* (decode; DE), accessing its operands (register fetch; RF), performing the computation as specified by the operation (execution; EX), and storing the computed value (writeback; WB). Timing diagrams showing the processing of an operation with execution following these phases is shown in Figure 23.2a for a non-pipelined processor and in Figure 23.2b for a pipelined processor.

* Ideally, the *user's* view is much simpler than either the programmer's or the designer's view and is limited to the observable behavior of the application.

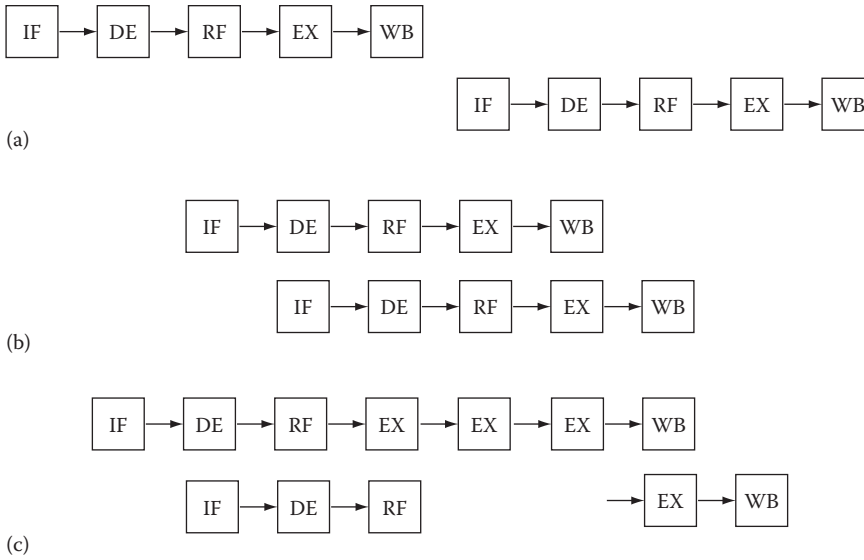

FIGURE 23.2 Instruction issue for scalar processors. (a) Canonical non-pipelined execution. (b) Pipelined execution. (c) Pipelined execution with dependency stall and result bypass.

For both cases, the *latency*, or execution time, of each individual instruction is the same but the overall execution throughput, or *bandwidth*, in terms of cycles per instruction (CPI) or instructions per cycle (IPC) is improved by pipelining; pipelining results in execution requiring fewer CPI (effective execution latency) or completing more IPC (execution bandwidth). The advantage of using pipelining is that multiple instructions have their processing overlapped with each instruction at a different phase of its processing, effectively eliminating all non-computation overhead (where EX is the computationally limiting phase and the rest are overhead). For our hypothetical pipeline, the non-pipelined case has a throughput of five cycles per one instruction or 5 CPI; with the addition of pipelining, we get a throughput of 1 CPI in steady state. This performance is the best that can be achieved by a processor without true concurrent execution—that is, overlapping execution phases for multiple operations in addition to overlapping their overhead phases.

Implementing pipelining assumes that the phases are completely independent between different instructions and therefore can be overlapped—when this assumption does not hold, hardware* must delay processing the dependent later operations or instructions producing a pipeline *stall*; this stall enforces (avoids) the *dependency* as shown in Figure 23.2c; however, it does increase the latency of the dependent instruction and reduces the overall throughput. In this example, the result from the first instruction is delayed and the second instruction must delay the execution phase until the required result becomes available. However, because the result of the first instruction is *bypassed* directly from output of the execution phase of the first instruction to the input of the execution phase of the second instruction the second instruction is then able to begin execution immediately resulting in a two-cycle stall (for the additional two EX phase cycles for the first instruction); without bypassing, execution would have to wait until after the results are available in the register file after WB and then would have to begin executing from the RF phase resulting in a four-cycle stall (now including the WB and an additional two EX phase cycles for the first instruction as well as the RF phase cycle for the second instruction).

* Note that some processors have relied on the programmer, or compiler, to ensure that there are no dependencies between instructions; sometimes this condition required using special no-operation instructions to avoid dependencies. Delayed branches were one instruction that required great care by the programmer (or compiler) to get the correct execution behavior.

Although the first instruction must still perform its register write (during WB), bypassing allows a subsequent instruction to use the value earlier than a simple pipeline would make it available thereby reducing its latency and increasing overall throughput.

23.2.2 Superscalar Processors

To do better than we can with pipelining, we need to use new techniques to discover or to expose the parallelism in the instruction stream. These techniques use some combination of static scheduling (performed by the programmer or the compiler before execution) and dynamic analysis (performed by the hardware during execution) to allow the execution phase of different operations to overlap—potentially yielding an execution rate of greater than one operation every cycle. Because historically most instructions consist of only a single operation (and thus a single computation), this kind of parallelism has been named *instruction-level parallelism* (ILP).

Two common high-performance SISD architectures that exploit ILP are *superscalar* and *VLIW* processors. A superscalar processor uses hardware to analyze the instruction stream and to determine which operations are independent and can be executed concurrently by the hardware; these ready operations are selected by the hardware and routed to the appropriate FU. Figure 23.3a shows the issue of ready operations from a window of available operations. These operations are executed out of order which requires additional hardware to make sure that all operations see the proper results. A larger instruction window makes more operations available for dependency analysis and issue; however, it also increases the hardware cost and complexity used to ensure that all dependencies are correctly satisfied and that all operations execute correctly.

An additional problem with executing operations out of order is how to handle *exceptions* and *interruptions* that occur during execution in an out-of-order processor—there may be many operations before the problem operation which have not executed and many operations after it which have. One solution is for hardware to handle the problem precisely* by determining the affected operation or instruction—then waiting for all previous operations or instructions to complete; at that point, either hardware or software can handle the problem precisely at the affected operation or instruction. Another solution is to handle the problem imprecisely† taking action at the point that the problem is detected and requiring software to fix up any complications resulting from operations or instructions that are incomplete prior to or already executed following the problem operation; the imprecise approach simplifies the hardware dramatically at the expense of software complexity and can result in unrecoverable problems that might have been recoverable with precise exceptions. Some processors, such as the DEC Alpha,

FIGURE 23.3 Instruction issue for superscalar processors. (a) Superscalar. (b) VLIW.

* Precise ⇒ associated with the causing operation or instruction

† Imprecise ⇒ not associated with the causing operation or instruction

use a hybrid precise–imprecise approach that handles problems precisely for most operations (integer and other short-latency operations) but imprecisely for others (long-latency floating-point operations), optimizing the common case and minimizing both hardware and software complexity.

In contrast to superscalar processors, a VLIW processor depends on the programmer or the compiler to analyze the available operations and to schedule independent operations into wide instruction words; the operations in a wide instruction word can be routed without hardware analysis to the appropriate FU. Because operation scheduling is performed statically by the compiler, it is possible to have very wide issue widths without excessive hardware complexity; however, in order to use all of the resources for a wide machine, the compiler must be able to find and schedule enough operations to fill the machine which can be a significant problem. Figure 23.3b shows the direct issue of operations from a wide instruction word to all FU in parallel. VLIW processors have significant challenges associated with exceptions and interrupts as well, but because their execution is always in the order scheduled by the compiler, software has a better chance of success in recovering from the problem than it does with imprecise interrupts in a superscalar processor. Note that there is no reason that VLIW processors could not apply superscalar techniques to execute operations out of order and to handle exceptions and interrupts smoothly (e.g., see Rudd [18] or Wang et. al [21]) however, this approach has not been implemented commercially to the authors' knowledge.

Both superscalar and VLIW use the same compiler techniques to achieve their superscalar performance with the main differences being the complexity of the hardware (superscalar is much more complex) and the tolerance that the processor has to how well the schedule is matched to the processor (VLIW is very intolerant). The practical difference between superscalar and VLIW is that if a program is scheduled inappropriately for the processor a superscalar processor will still execute correctly and may find parallelism from the instruction stream; however, a VLIW processor may fault or, worse, silently produce incorrect answers in the same situation. However, a VLIW processor is likely to have more predictable execution behavior and may prove to be more efficient (in terms of hardware complexity or power consumption); on some applications, a VLIW processor may even have higher performance than a superscalar processor in spite of its execution inflexibility.

23.2.3 SISD Wrap-Up

A SISD processor has four primary characteristics. The first characteristic is whether or not the processor is capable of executing multiple operations concurrently. The second characteristic is the mechanism by which operations are scheduled for execution—statically at compile time, dynamically at execution, or possibly both. The third characteristic is the order that operations are issued and retired relative to the original program order—these can be in order or out of order. The fourth characteristic is the manner in which exceptions are handled by the processor—precise, imprecise, or a combination of the two based on the executing instruction type.

Tables 23.1 through 23.3 present early representative (pipelined) scalar and super scalar (both superscalar and VLIW) processor families. These processor designs migrated from scalar to compatible superscalar processor (except for the DEC Alpha and the IBM/Motorola/Apple PowerPC processors that were designed from the ground up to be superscalar). Since these processors were designed, the trend has

TABLE 23.1 Typical Scalar Processors

Processor	Year of Introduction	Number of FU	Issue Width	Scheduling	Issue/Complete Order

^a There are actually many more than 9 FU, but there are 9 issue ports that limit the possible combinations of operation issue into the larger pool of physical FU.

been toward improving the resources and capabilities for a processor than their issue width. Common approaches have included increasing the number and type of FU to enable more complex operations to be issued concurrently, increasing the frequency and pipeline depth to increase throughput, and increasing the size and performance of caches to reduce the effective memory latency. More recently, with reaching the “power wall,” the trend has been to replicate cores on a processor enabling greater parallelism by executing more threads concurrently but also reducing the performance of an individual thread; these processors exploit MIMD parallelism. Table 23.7 (in Section 23.5) shows the trend for cores in Intel multicore processors. The high-level characteristics for these processors have stabilized on a per-core basis but performance improves each generation from process changes, design optimizations, and new computation capabilities; in addition, die-size reductions enable more cores per die that is not seen at the core level. See Section 23.5 for more information on MIMD processors.

There have been very few VLIW processors to date although advances in compiler technology may cause this to change. VLIW processors have not been very successful as general-purpose processors primarily because of the challenges finding sufficient ILP using only static analysis in the compiler or hand coding and optimizing by experienced programmers. However, there are applications where the VLIW processors are very effective and most current VLIW processors are used as embedded processors, multimedia accelerators, or graphics processors (GPU); for these applications, there can be significant performance advantages and the cost–performance trade-offs are more important than increased software-development costs.

23.3 SIMD

The SIMD class of processor architecture includes both array and vector processors. The SIMD processor is a natural response to the use of certain regular data structures, such as vectors and matrices. From the programmer’s view, an SIMD architecture appears very similar to programming a simple SISD

processor in that there is a single instruction stream; however, the key difference is that many of these operations perform computations on aggregate data. For example, one instruction might add each pair of elements of two vectors or matrices. Because regular structures are widely used in scientific computing, the SIMD processor has been very successful in these environments.

Two types of SIMD processor will be considered: the *array processor* and the *vector processor* that differ both in their implementations and in their data organizations. An array processor consists of many interconnected PE that are dependent and which share a common instruction stream; these PE operate on the aggregate data elements concurrently across all of the PE. A vector processor consists of a single PE that has both traditional scalar instructions and FU as well as special vector instructions and vector FU; the vector units operate on vectors executing the computation sequentially, one element at a time, but very efficiently, initiating computations rapidly and possibly overlapping computations as the computation on one element is independent of the computations on all other elements.

23.3.1 Array Processors

The array processor is a set of interconnected parallel PE (typically hundreds to tens of thousands). PE operate in lockstep in response to a single broadcast instruction from a control processor and thus all PE synchronously execute exactly the same instruction in each cycle. If supported, when the execution path in different threads diverges, the control processor must issue instructions from each divergent thread to all PE until their paths reconverge; only those PE associated with the execution path for that divergent thread then execute the instructions. When divergence occurs, this method results in a significant slowdown and performance penalty as many of the PE are idle during divergent execution.

Each PE has its own private memory and data are distributed across the elements in a regular fashion that is dependent on both the structure of the data and the structure of the computation to be performed on the data. When allowed, direct access to global memory or to another PE's local memory is expensive; however, constant scalar values can be broadcast by the control processor along with the instruction to all PE. The high remote-data access cost requires that the data be distributed carefully. For performance reasons, it is sometimes easier to duplicate data values and computations than it is to route the intermediate data between PE.

A suitable application for use on an array processor has several key characteristics: a significant amount of data that have a regular structure; computations on the data that are uniformly applied to many or all elements of the data set; simple and regular patterns relating the computations and the data; and minimal communications requirements between computations on individual elements. An example of an application that has these characteristics is the solution of the Navier–Stokes equations; however, applications that have significant matrix computations and very little execution divergence are likely to benefit from the concurrent capabilities of an array processor.

The programmer's reference point for an array processor is typically the high-level language level—the programmer is concerned with describing the relationships between the data and the computations on the data but is not directly concerned with the details of scalar and array instruction scheduling. In fact, in many cases, the programmer is not even concerned with the size of the array processor. In general, the programmer specifies the size and structure of the data along with distribution information and the compiler maps the implied virtual processor array (which is sized and shaped based on the size of the data and computation) onto the physical PE (which are actually implemented in hardware); it then generates code to perform the required computations and the management of virtual-to-real PE mappings is performed by some combination of hardware and software methods.

The primary characteristic of an SIMD processor is whether the memory model is shared or distributed. The interconnect network is also important; for more information on interprocessor interconnects, see Chapter ?? . Table 23.4 shows several representative SIMD architectures. Note that there have not been a significant number of SIMD architectures developed recently due to a limited application base and market requirement for SIMD processors. In addition, the ready availability of high-performance general-purpose

TABLE 23.4 Typical Array Processors

Processor	Year of Introduction	Memory Model	PE	Number of Processors
Burroughs BSP	1979	Shared	General purpose	16
Thinking Machines CM-1	1985	Distributed	Bit-serial	up to 65,536
Thinking Machines CM-2	1987	Distributed	Bit-serial	4,096–65,536
MasPar MP-1	1990	Distributed	Bit-serial	1,024–16,384

multiprocessor (MIMD) systems and general-purpose graphics processors (GP-GPU) allows exploiting similar parallelism with more flexibility and broader capabilities than available with traditional SIMD processors. Section 23.5 discusses MIMD systems and Section 23.6.1 discusses GP-GPU systems.

23.3.2 Vector Processors

A vector processor is a single processor that resembles a traditional SISD processor except that some of the FU (and registers) operate on vectors—aggregate data comprising sequences of data values—which are operated on as a single entity by the hardware. Vector processor FU typically have a very high clock rate enabling them to be deeply pipelined; in addition, execution phases are overlapped, which is allowed because the calculations are defined on individual data elements and cross element dependencies are not allowed. Although this deep pipeline results in as long or longer latency than a normal scalar FU to compute on the first data element, it produces the results of computations on the remaining elements very rapidly. The vector-processor computation process results in a significant speedup for the overall vector computation that cannot be matched by scalar FU that must explicitly perform the same set of computations on each element in turn.

Early vector processors computed on vectors that were stored in memory. The primary advantage of this approach is that the vectors could be of arbitrary lengths and were not limited by processor resources; however, memory-based vector operations have a high start-up cost due to the long *latency* to get the vector from main memory, limited memory system *bandwidth*, and memory system contention which all proved to be significant limitations. Modern vector processors require that vectors be explicitly loaded from memory into special vector registers and stored back into memory—the same approach that modern scalar processors have taken for similar reasons. However, because vector registers have low latency and preserve intermediate values for reuse without passing back through memory, modern register-based vector processors achieve significantly higher performance than the earlier memory-based vector processors for the same implementation technology.

Vector processors improve performance further using result bypassing (*chaining*) that allows a follow-on vector computation to commence as soon as the first value is available from the preceding computation, pipelining the execution of different vector instructions across different FU. Instead of waiting for the entire vector to be processed, the follow-on computation can be significantly overlapped with the preceding computation that it is dependent on as long as there are available FU. Chaining allows sequential computations to be efficiently compounded and to behave as if they were performed by a single operation with a total latency equal to the latency of the first operation with the pipeline and chaining latencies of the remaining operations but without the per-instruction start-up overhead that would be incurred to perform the same vector computations without chaining. For example, division could be synthesized by chaining a reciprocal operation with a multiply operation at only incrementally greater execution latency than either operation alone (although requiring two FU to perform the chained computation). Chaining typically works for the results of load operations as well as normal computations.

As with the array processor, the programmer's view for a vector machine is the high-level language. In most cases, the programmer sees a traditional SISD machine; however, because vector machines excel on computing with vectors, the programmer typically writes code with simple vectorizable loops that

TABLE 23.5 Typical Vector Processors

Processor	Year of Introduction	Memory or Register Based	Number of Processor Units	Number of Vector Units
Cray 1	1976	Register	1	7
CDC Cyber 205	1981	Memory	1	2–5
Cray T90	1995	Register	4–32	2
NEC SX-9	2008	Register	4–8192	48

can be recognized by the compiler and converted into individual vector instructions. Programmers can also help the compiler by providing hints that help the compiler to locate the vectorizable sections of the code. This situation is purely an artifact of the fact that the programming languages are typically scalar oriented and do not support the treatment of vectors as an aggregate data type but only as a collection of individual values. As new languages are defined that make vectors a fundamental data type, then the programmer is exposed less to the details of the machine and to its SIMD nature; although programs in these languages include more information available to enable automatic parallelization, the compiler may still not be able to exploit all of the performance in a given machine, trading off performance for portability just as we saw previously with superscalar.

The vector processor has two primary characteristics. One characteristic is the location of the vectors—vectors can be memory or register based; the other characteristic is the vector length. Vector processors have developed dramatically from simple memory-based vector processors to modern multiple-processor vector processors that exploit both SIMD vector and MIMD-style processing. Table 23.5 shows some representative vector processors.

There are fewer and fewer big-iron SIMD processors. Currently, SIMD computations are performed on general-purpose SISD processors using instructions that operate on sub-elements of small fixed-length aggregate data structures. These special SIMD instructions look like register-based instructions in a vector processor but instead perform computations in parallel on sub-elements from wide data registers that have far fewer data elements than a vector processor would have in its vector registers. For example, Intel's current version of their Advanced Vector Instructions operate on 256-bit aggregate data structures; the sub-elements of this aggregate data structure can represent four 64-bit values or eight 32-bit values. Other vector extensions may support different aggregate-data sizes and data sub-element sizes. These new SIMD are often programmed explicitly by the programmer using custom libraries or explicit vector primitives inserted manually into the code rather than being directly supported in traditional programming-language; however, over time new programming languages and improved compilers will extend their ability to perform SIMD computations without explicit programmer involvement.

23.4 MISD

Although the term MISD processor is not widely used, conceptually this is an important architectural classification. Here the instructions (or functional operations) are in a fixed configuration specific to an application and the data are streamed across the operation configuration. It is, in many respects, a pipelined processor wherein the programmer can rearrange or create pipeline stages to match the application. Physically, realizing this programmable pipeline has been a challenge.

Abstractly, the MISD can be represented as multiple independently executing FU operating on a single stream of data, forwarding results from one FU to the next. On the microarchitecture level, this is exactly what the vector processor does. However, in the vector pipeline, the operations are simply fragments of an assembly level operation, as distinct from being a complete operation in themselves. Surprisingly, some of the earliest attempts at computers in the 1940s could be seen as the MISD concept. They used plugboards for programs, where data in the form of a punched card were introduced into the first stage of a multistage processor. A sequential series of actions was taken

where the intermediate results were forwarded from stage to stage until at the final stage a result would be punched into a new card.

There are more interesting examples of the MISD organization. Data flow machines were pioneered by Prof. Jack Dennis of MIT in the 1970s and 1980s [5]. These machines can use either static or dynamic data flow, the latter allowing limited run time reconfiguration of the data flow pipeline; they can also use either synchronous or asynchronous clocking; finally, they can use either a single data or data streaming. It is only the data-streaming data flow machine that matches the MISD category.

In a more recent development, the Maxeler Technologies Maximum Performance Computing (MPC) products [16] implement static, synchronous data flow machines that are custom designed to match an application's data flow graph. FPGAs are used to realize the data flow machine.

The systolic array [14] is a special form of MISD wherein all nodes of an (usually rectangular) array consist of data processing units (DPU). These are minimally configured PE. Each node is activated by the arrival of data and the result is shared with its neighbors in a mesh topology. It has been effectively used in computations such as matrix multiply.

The programmer's view of an MISD machine depends very heavily on the specific machine organization. It is hard to generalize without this machine knowledge.

23.5 MIMD

The MIMD class of parallel architecture interconnects multiple cores (typically SISD) into a *multicore processor* (when combining multiple cores onto a single die) or *multiprocessor* (when combining multiple processors into a single system). A *core* is a single hardware structure that executes one or more threads but that is not a stand-alone processor, lacking general communications and peripheral support. A *thread* is the combination of an instruction stream with all of its execution state and data—it represents the programmer's view of an SISD processor. Each core supports the execution of one or more threads.

Although there is no requirement that all processor cores or processors be identical, most MIMD configurations are homogeneous with identical cores throughout the system. Homogeneity simplifies the hardware design, operating system implementation, and the programmer's challenge to use the system effectively. Most multicore processors and multiprocessor systems are homogeneous. One well-known example of a heterogeneous MIMD processor is the IBM/Sony Cell processor [9], which has a single conventional RISC main core (SPU) and eight computation cores (SPE).

For simplicity, in this section, we limit ourselves to homogeneous MIMD organizations. However, although each individual core in the system is identical, the notion of homogeneity is complicated by the multiple levels of hierarchy in current multicore and multiprocessor systems. We have multiple threads on a core, multiple cores on a processor, multiple processors on a board, multiple boards in a box, and so forth—so even though each core in such a homogeneous system is the same, different pairs of cores have access to different resources and may also have different communication characteristics resulting in very nonhomogeneous behavior. Because performance may vary depending on where the threads in an application are executing, there are many challenges for the programmer to use such a system effectively. Although it is important to appreciate the kinds of hierarchy associated with multicore or multiprocessor systems (especially if trying to optimize an application on a particular multicore or multiprocessor system), we only discuss the general concept of MIMD here as the variables are many and all are system and configuration dependent.

Both SIMD and MIMD systems are similar in some respects in that they perform many computations concurrently; the greatest difference between SIMD array processors and an MIMD multiprocessor is that the SIMD array processor executes a single instruction stream executing the same instruction synchronously across all PE in the array, while an MIMD multiprocessor executes different instruction streams asynchronously across all cores in the system. Although it may be the case that each core in an MIMD system is running the same program (sometimes referred to as single program multiple data (SPMD)),

there is no reason that different cores should not run different programs that are completely unrelated. In fact, most use of multiprocessor systems is to run multiple independent programs concurrently—not to run a single program (or even multiple programs) cooperatively—across all cores in the system; this usage is common across workstations, desktops, laptops, and even mobile devices running multiple applications on mainstream operating systems such as Microsoft Windows, Apple OS-X, Linux, Apple IOS, and Google Android.

The interconnection network in both the SIMD array processor and the MIMD processor passes data between PE. However, in the MIMD processor, the interconnection network is typically much more general and is used to share data as well as to synchronize the independent cooperating threads running across the MIMD processor. Interconnection networks are very diverse including bus interconnects, where all cores share a common bus to communicate; star interconnects, where all cores interconnect via a common hub; ring interconnects, where all cores connect to two other cores and each core forward nonlocal communications to cores further around the ring; and multidimensional interconnects where cores are connected in complex ways requiring careful routing to get the data from the source to the requester. There are many variations on interconnects including multi-level interconnects with different interconnect topologies at each level. For more information on interprocessor interconnects, see Chapter ??.

One key characteristic of a multiprocessor system is the location of memory in the system; the location affects the latency to access the memory and optimizing memory accesses is one of the programmer's key performance challenges. When the memory of the processor is distributed across all processors and only the cores local to that processor have access to it, all sharing and communications between processors (both sharing of data and synchronizing threads) must be done explicitly using messages between processors. Such an architecture is called a *message-passing architecture*. When the memory of the processor is shared across all processors and all cores have access to it, sharing and communicating between threads can be done explicitly or implicitly (and, unfortunately, sometimes inadvertently) through normal memory operations. Such an architecture is called a *shared-memory architecture*. If the shared memory is in a central location and all processors have the same access latency to the shared memory, then it is called a uniform memory access (UMA) latency multiprocessor; bus-based multiprocessors with a centralized main-memory system are a common example of a UMA processor. If the shared memory is distributed across the processors in the system, then it is called a *distributed shared-memory (DSM) architecture* processor; in a DSM architecture, processors see different access latencies to different memory locations and it is thus called a *non-uniform memory access (NUMA) latency multiprocessor*. Because of their hierarchical nature, most multiprocessor systems are NUMA although even a single-processor multicore system locally be an NUMA system depending on its internal architecture of caches and memory channels.

In any multiprocessor system where data are shared, producing the right observable memory behavior is a challenge; in fact, one problem with shared memory is that the “right” behavior for shared memory is not well defined. There are two significant problems that arise when sharing data. One is *memory consistency* describing the ordering constraints for sequences of memory accesses that may be observed by different threads in the system; the other is *memory coherency*, also called *cache coherency*, describing the value constraints on memory accesses to the same location that may be observed by different threads in the system.

Memory consistency is the programmer-visible ordering effects of memory references both within a core and between different cores and processors in a multicore or multiprocessor system. The memory consistency problem is usually solved through a combination of hardware and software techniques. The appearance of perfect memory consistency may be guaranteed for local memory references only—and thus different processors may see different memory content depending on the implemented memory consistency policy. In the most unconstrained case, memory consistency is only guaranteed through explicit synchronization between processors to ensure that all processors see the same memory content.

Memory coherency, or cache coherency, is the programmer invisible mechanism to ensure that all PE see the same value for a given memory location and is normally associated with how caches behave.

The memory coherency problem is usually solved exclusively through hardware techniques. This problem is significant because of the possibility that multiple cores have copies of data from the same address in their local caches and cache coherency describes whether or not different threads accessing this data see the same value as well as the protocol used to ensure this coherency requirement.

There are two primary techniques to maintain cache coherency. The first is to ensure that all affected cores are informed of any change to the shared memory state—these changes are broadcast throughout the MIMD processor and each core monitors the interconnect to track these state changes (commonly by “snooping” communications on the interconnect). The second is to keep track of all cores using a memory address in a directory entry for this address; when there is a change made to the shared memory state for a shared address, each core in the directory for that address is informed. In either case, the result of a change can be one of two things—either the new value is provided to the affected cores, allowing them to update their local value, or other copies of the value are invalidated, forcing these cores to request the data again when it is needed.

Both memory consistency and memory coherency are complex problems and there are many associated trade-offs in hardware and software complexity as well as in performance. There are certainly complexity and scalability advantages to relaxing both memory consistency and coherency, but whether the programmer is able to use such a system effectively is a difficult question to answer. For more information on memory consistency and memory coherency, see Chapter ??.

Scalability for multicore and multiprocessor systems can be challenging as well. For small systems, a few cores are directly connected (typically by a common system bus, but more and more by a point-to-point link such as AMD HyperTransport [10] or Intel QuickPath Interconnect [11]); in these systems, snooping is adequate and minimizes complexity at the cost of coherency traffic on the bus or interconnect traffic. However, as the number of cores in a system increases, it is more likely that there will be a large multi-hop or multidimensional interconnect requiring significant latency to get between cores; there may also be significantly more data sharing that increases the communications bandwidth through the network, further exacerbating the problem. The resulting traffic on the interconnect as well as the long communication latencies associated with these larger systems may make broadcast and snooping undesirable or unusable. In large systems, directory-based memory coherency becomes significantly better because the amount of communications required to maintain coherency is limited to only those processors requesting, owning, and holding copies of the data. Snooping may still be used within a small cluster of PE to track local changes and the cluster would appear to behave as a single memory consumer to the rest of the network.

The hardware implementation of a distributed memory machine is far easier than that of a shared memory machine when memory consistency and cache coherency are taken into account as all information sharing between processors on a distributed memory system is performed through explicit messages rather than through shared memory. However, programming a distributed memory processor can be much more difficult because the applications must be written to exploit, and to not be limited by, the requirement to use of message passing to communicate between threads. On the other hand, despite the problems associated with maintaining consistency and coherency, programming a shared memory processor can take advantage of whatever communications paradigm is appropriate for a given communications requirement and can be much easier to program.

Early multiprocessor systems had few processors; Table 23.6 shows some classic multiprocessor systems. Over time, systems grew larger and the complexity of the systems increased significantly although the basic concepts did not change dramatically through the years. More recently, there have been significant practical changes in multiprocessor systems with single-processor multicore systems becoming common—although these processors are similar to multiprocessor systems through the years, they are often used to run multiple independent programs rather than collaborative programs. In addition, these multicore processors are then used to build larger multiprocessor systems which may then be used for a single application, much like was the case for earlier multiprocessor systems. Table 23.7 shows a few of these processors that can be assembled into much larger multiprocessor systems.

TABLE 23.6 Representative Discrete MIMD Systems

System	Year of Introduction	PE	Number of Processors	Memory Distribution	Programming Paradigm	Interconnection Type
Alliant FX/2800	1990	Intel i860	4–28	Central	Shared memory	Bus + crossbar

TABLE 23.7 Intel Multicore Processors for MIMD Server Systems

Processor	Year of Introduction	Number of Cores	Threads per Core	Effective Cache Size
Xeon (Paxville)	2005	2	2	4 MB
Itanium 2 9050 (Montecito)	2006	2	1	24 MB
Xeon X3350 (Yorkfield)	2008	4	1	12 MB
Xeon E7-8870 (Westmere-EX)	2011	10	2	30 MB
Itanium 9560 (Poulson)	2012	8	2	32 MB

TABLE 23.8 TOP500 Supercomputers (The Top Three) as of November 2012

Rank	System	Core	Interconnect	Total Cores
1	Titan – Cray XK7	Opteron 6274 16C, NVIDIA K20x	Cray Gemini	560,640
2	Sequoia – BlueGene/Q	Power BQC 16C	Custom	1,572,864
3	K computer	SPARC64 VIIIfx	Tofu	705,024

Table 23.8 shows the current top three systems in the Supercomputer Top 500 [20]. These systems use large numbers of high-performance general-purpose multicore processors and the top-ranked Titan system is a hybrid system containing general-purpose processors and GP-GPU processors to achieve its performance.

The primary characteristic of an MIMD processor is the nature of the memory address space—it is either local to each processor or shared across all processors. The number of cores in a processor, the number of processors in the system, the memory hierarchy including both caches and memory (and the constraints associated with memory accesses), and the interconnection are also important in characterizing an MIMD processor.

23.6 High-Performance Computing Architectures

Up to this point, we have focused on traditional multiprocessor systems that can be readily described using the Flynn taxonomy. Many of these systems have high performance and fall neatly into the taxonomy. In this section, we discuss three high-performance computing approaches that are becoming ubiquitous but are not readily placed into this simple taxonomy. First, we discuss GPU used for highly parallel general-purpose computing, thus referred to as GP-GPU; we also discuss manycore processors that address similar parallelism but instead use general-purpose CPU cores. Finally, we discuss

cloud-computing architectures that are, in a sense, virtual MIMD systems rather than multiprocessor systems themselves but that distinction can be easily transparent to the programmer.

23.6.1 GP-GPU and Manycore Systems

General-purpose use of graphics processors has skyrocketed and resulted in new graphics processors being designed for highly parallel general-purpose use; these processors are called general-purpose GPU (GP-GPU) processors. Parallel applications for GP-GPU are becoming more and more commonplace as the availability of GP-GPU systems (including sharing compatible GPU processors in the graphics subsystem to perform GP-GPU computations in addition to processing graphics) is becoming more common. Unfortunately, GP-GPU have some of the same performance complications of SIMD processors as they are not as flexible as general-purpose processors; thus, they are difficult to program and have a limited range of applications that are suitable for execution on them. In contrast, manycore architectures are derived from general-purpose multiprocessors and although are not as highly parallel as GP-GPU processors are programmed more like traditional multiprocessors and have a broader range of applications that are suitable for execution on them.

NVIDIA calls their Tesla GP-GPU architecture a Single Instruction Multiple Thread (SIMT) architecture; SIMT is a hierarchical hybrid architecture comprising MIMD and SIMD elements that is capable of running many threads across the processor. In this high-level description, we use terms consistent with the rest of the chapter; NVIDIA has their own terminology that is matched to the SIMT architecture and their GP-GPU implementations. For more information on the Tesla GP-GPU architecture, see [13,19].

An SIMT processor contains one or more streaming multiprocessors (the MIMD element) running one or more threads; each streaming multiprocessor comprises a large number of PE running in lock-step (the SIMD element), specialized computing resources, and a memory hierarchy. Both the streaming multiprocessors and the PE are virtualized; thread scheduling is performed using a combination of hardware and software and is very efficient. As with SIMD processors, divergent execution within a streaming multiprocessor still suffers significant performance penalties just as in an SIMD processor under similar execution conditions; however, because each streaming multiprocessor is independent, divergent execution between streaming multiprocessors is not a problem.

The GP-GPU programmer develops an application specifying the number of threads and how those threads are to be distributed across streaming multiprocessors and their PE. By structuring the program carefully, it may be possible (but challenging!) to avoid some of the SIMD complications while achieving the same kind of performance as a SIMD processor.

In contrast to the GP-GPU, the Intel Many Integrated Core (MIC) manycore processor has far fewer cores on the processor than the GP-GPU has PE, but each core is a complete processor that executes independently and can execute the same or different program. Where the flexibility of the manycore processor comes into its own is when each thread is running the same application but follows a different thread of execution—something that the manycore processor is very good at but that the GP-GPU processor is unable to do without suffering significant performance penalties. The manycore processor uses many more cores that are much smaller and simpler than are used in a typical multicore processor; however, in principle, it is very similar to a traditional MIMD processor as discussed in Section 23.5.

What is common across both GP-GPU and manycore architectures is the ability to execute a large number of threads very efficiently. In the case of the GP-GPU processor, these threads tend to be short and execute very quickly along the same execution path; in the case of the manycore processor, these threads tend to be longer and more heavyweight and can execute arbitrary execution paths. Both are used as coprocessors and are controlled by a separate main processor that offloads computations to them and then may be able to continue on with other work (increasing system parallelism) until the coprocessor computations are complete. Table 23.9 shows representative GP-GPU and manycore systems that are currently available.

TABLE 23.9 Massively Parallel GP-GPU and Manycore Coprocessors

Coprocessor	Independent Cores	PE/FU per Core	Threads per Core	Local Memory
NVIDIA Tesla Kepler K20X	14	192 PE	2048	6 GB
AMD Radeon™ HD 7970	32	64 PE	10	3 GB
Intel Xeon Phi 5110P	60	2 FU	4	8 GB

23.6.2 Cloud Computing

A cloud-computing architecture is significantly different from the rest of the multiprocessor architectures discussed in this chapter in that it is essentially a virtual MIMD multiprocessor system (and probably runs on multiple physical multiprocessor systems as well). Early forms of cloud computers were very ad hoc creations, mostly for scientific applications. One well-known community-based virtual cloud computer is the SETI@home project; botnets use similar techniques although, unlike the SETI@home project, they use stolen resources for malicious and criminal purposes. Early workgroup-level cloud computers include the Beowulf computer [17] and Network of Workstations (NOW) [1], but there have been many variations on this theme.

Modern cloud computing is often done in large server farms and uses the notion that computer systems can be aggregated to form a loosely coupled virtual multiprocessor system that can be shared across multiple users. Cloud-computing systems can provide either direct or indirect access to a virtual computer system using SISD, MIMD, or even GP-GPU systems. With direct access, users are provided with their own virtual multiprocessor system and associated administration, application, and development software for their use. With indirect access, users are provided with access to specific services through a service-oriented architecture (SOA) that is an application provided by the cloud-computing infrastructure.

One advantage of cloud computing is that the physical computer systems assigned to a customer can be scaled and configured to adapt to customer demands; they may also be distributed geographically so that the physical computer systems are located near customer centers or low-cost power sources. Another advantage is that physical computer systems are shared among many customers so that the customers do not have to purchase and maintain their own cluster. The individual computer systems may also have diverse functionality (in both performance capabilities and software resources) to provide both cost and performance flexibility and to allow tailoring the compute resources used to each application's computation requirements.

23.7 Afterward

In this chapter, we have reviewed a number of different parallel architectures organized by the stream model. We have described some general characteristics that offer some insight into the qualitative differences between different parallel architectures but, in the general case, provide little quantitative information about the architectures themselves—this would be a much more significant task although there is no reason why a significantly increased level of detail could not be described. Any model, such as the stream model, is merely a way to categorize and characterize processor architectures and if it becomes too detailed and complicated, then it may lose its benefits; the stream model's main benefits are its high-level nature and simplicity. However, there is a place for more detailed models as well; for a more comprehensive characterization of processor characteristics, see Blaauw and Brooks [3] or Bell and Newell [2].

Just as the stream model is incomplete and overlapping (consider that a vector processor can be considered to be a SIMD, MISD, or SISD processor depending on the particular categorization desired), the characteristics for each class of architecture are also incomplete and overlapping. However, the insight gained from considering these general characteristics leads to an understanding of the qualitative differences between gross classes of computer architectures, so the characteristics that we have described provide similar benefits and liabilities.

This is not meant to imply that the aggregate of the stream model along with the relevant characteristics is a complete and formal extension to the original taxonomy—far from it. There are still a wide range of processors that are problematic to describe well in this (and likely in any) framework. Whatever the problems with classifying and characterizing a given architecture, processor architectures, particularly multiprocessor architectures, are developing rapidly. Much of this growth is the result of significant improvements in compiler technology that allow the unique capabilities of an architecture to be efficiently exploited by the programmer with more and more assistance by the compiler.

In many cases, the design (or, perhaps more properly, the success) of a system is based on the ability of a compiler to produce code for it. It may be that a feature is unable to be utilized if a compiler cannot exploit it and thus the feature is wasted (although perhaps the inclusion of such a feature would spur compiler development—there is the chicken-and-egg conundrum). It may also be that an architectural feature is added specifically to support a capability that a compiler can easily support (or already supports in another processor), and thus performance is immediately improved. And in the future, it may be that dynamic code optimization or translation could exploit these new features even in code that was not compiled to take advantage of them; however, that capability is still a research effort. Whether for producing great code or for taking advantage of new features, compiler development is clearly an integral part of system design and architectural effectiveness is no longer limited only to the processor itself. System models must keep up with architecture development and be updated appropriately and new models must be developed to account for these new architectures; these models may include software aspects as well to account for the close coupling between hardware and software that makes these new architectures function to their fullest potential.

Defining Terms

Array processor: An *array processor* is an SIMD processor that executes a single instruction stream on many interconnected that are execute in lockstep. Data are distributed across the array and PE processed in parallel by all the PE.

Bandwidth: *Bandwidth* represents the rate (volume) of computation or data passing through the system or interconnect.

Bypass: A *bypass* is the mechanism used in a pipelined processor to route the result of an operation or instruction to a dependent operation or instruction before the result is available for reading from its register or memory location.

Cache coherency: See *Memory coherency*.

Chaining: *Chaining* is used in vector processors where the results between dependent operations are bypassed element by element from one FU to another. The end result is that compound operations have a latency only incrementally longer than an individual operation resulting in significantly increased execution bandwidth.

Core: A *core* is a logic structure that comprises decode and control logic in addition to PE and provides the ability to execute an instruction stream independently from other cores. As used in this chapter, a core is distinguished from a processor in that a core does not have the communications and peripheral logic to integrate into a system. Cores are the primary logic structures in a processor and include one or more PE.

Dependency: *Dependency* describes the relationship between operation and instruction where the results produced by one instruction are consumed by a subsequent instruction. Dependent instructions must be executed sequentially.

Distributed shared-memory architecture: A *DSM* is a multiprocessor system where the memory is distributed across all processors; although the memory is shared, the distributed nature of the memory results in having a NUMA latency that makes thread and data placement a significant factor in realized performance.

- Exception:** An *exception* refers to an unexpected event produced internal to the core or processor as a side effect of executing operations or instructions; in contrast, an interrupt is produced external to the core or processor.
- Instruction:** An *instruction* is the machine-readable representation of one or more independent operations that may be executed concurrently by a core or PE. Although often used indistinguishably with instruction (because most processors use instructions containing only one operation), as used in this chapter, an instruction is distinguished from an operation by being the container of operations rather than the specification of the computation to be performed.
- Instruction-level parallelism:** ILP is when multiple operations or instructions are extracted from the instruction stream and executed concurrently; it differs from pipelined parallelism in that not only is the overhead overlapped but also the execution as well. Operation or instruction execution may be performed in order or out of order depending on the processor capabilities.
- Interrupt:** An *interrupt* refers to an unexpected event produced external to the core or processor; it may come from a peripheral or another processor. In contrast, an exception occurs internal to the core or processor as a result of executing operations or instructions.
- Latency:** *Latency* is the time required to complete an action. For execution of an operation or instruction, latency is the time required from the initial fetch to the successful completion of the operation or instruction; execution results may be available prior to the end of the execution process through bypassing. For memory, latency is the time required to make the request to memory and to receive the result.
- Memory coherency:** *Memory coherency* is the programmer-invisible mechanism to ensure that all PE see the same value for a given memory location and is normally associated with how caches behave. It is also known as cache coherency.
- Memory consistency:** *Memory consistency* is the programmer-visible ordering effect of memory references both within a core and between different cores and processors in a multicore or multi-processor system.
- Message-passing architecture:** A *message-passing architecture* is a multiprocessor system that uses messages for all communications between processors (or other computer systems) including sharing data as well as synchronization.
- Multicore processor:** A *multicore processor* comprises a number of cores that share communications and peripheral logic to integrate into a system.
- Multiprocessor:** A *multiprocessor* comprises multiple interconnected processors.
- Nonuniform memory access:** An *NUMA* architecture has memory access latencies that are a factor of the location of the processor and referenced data within the system.
- Operand:** An *operand* specifies the constant value or a storage location—typically either a register or a memory location—that provides data that are used in the execution of the operation or that receives data from the results of an operation.
- Operation:** An *operation* is the specification of the computation to be performed by a core or PE. It specifies the computation to be performed as well as the operands and other details used to produce the desired computation result. Although often used indistinguishably with operation, as used in this chapter, an instruction is distinguished from an operation by being the container rather than the specification of the computation to be performed.
- Pipelining:** *Pipelining* is the mechanism that partitions the execution of an instruction into independent phases that be performed in sequence by a core or PE. In addition, these phases can be overlapped with phases from other instructions. Because of overhead, the latency of an individual instruction may be increased, but pipelining improves the resource utilization and execution bandwidth in the core or PE. When there is a dependence or conflict between two instructions, the later instruction is delayed (or stalled) until the dependence or conflict is resolved.
- Processor:** A *processor* is a stand-alone element in a computer system. As used in this chapter, a processor is distinguished from a core in that a processor has the communications and

peripheral logic to integrate into a system with other processors, memory, and other devices. Processors include one or more cores along with other resources that add additional features and functionality to the processor.

Processor element: A *PE* is a logic structure that provides computation functions to a processor. As used in this chapter, a PE is distinguished from a core in that a PE does not have the decode and control logic to give it the ability to execute an instruction stream independently. PE are the primary logic structures in SIMD and GP-GPU processors.

Shared-memory architecture: A *shared-memory architecture* is a multiprocessor system using shared memory for all communications between processors. Memory may be located anywhere in the system and accessed by all interconnected processors.

Stall: A *stall* is the delay inserted during execution so that an operation or instruction is that is dependent on (or conflicts with) a previous operation or instruction is properly executed.

Superscalar: *Superscalar* describes an instruction-level parallel processor that dynamically analyzes the instruction stream and executes multiple operation or instruction as dependencies and operand availability allow. Most processors today are superscalar processors and have one operation per instruction.

Thread: A *thread* is an independent instruction stream that includes its own unique execution context. Although related, hardware threads and software threads are at significantly different abstraction levels. Hardware threads are low-level threads that are managed and executed directly by hardware; software threads are high-level threads that have much more information on how they relate to each other including thread priority, inter-thread dependencies, and data sharing.

Uniform memory access: A *UMA* architecture has memory access latencies that are constant independent of the location of the processor and referenced data within the system.

Vector processor: A *vector processor* is an SIMD processor that executes a single instruction stream on vector objects computing element-by-element on deeply pipelined FU. Operations may be chained to reduce the *latency* of compound operations.

Very long instruction word: *VLIW* describes an instruction-level parallel processor that relies on the compiler to statically analyze the program and to produce an instruction stream where the operations in every instruction are dependence-free. The hardware executes all of the operations in an instruction in parallel without further dependence analysis.

Further Information

There are many good sources of information on different aspects of parallel architectures. The references for this chapter provide a selection of of texts that cover a wide range of issues in this field. There are many professional journals that cover different aspects of this area either specifically or as part of a wider coverage of related areas. Some of these are the following:

- *IEEE Transactions on Computers, Transactions on Parallel and Distributed Systems, Computer, Micro*
- *ACM Transactions on Computer Systems, Computing Surveys*
- *Journal of Supercomputing*
- *Journal of Parallel and Distributed Computing*
- *Journal of Instruction-Level Parallelism*

There are also a number of conferences that deal with various aspects of parallel processing. The proceedings from these conferences provide a current view of research on the topic. Some of these are the following:

- *International Symposium on Computer Architecture (ISCA)*
- *Supercomputing (SC)*
- *International Symposium on Microarchitecture (MICRO)*

- *International Conference on Parallel Processing (ICPP)*
- *International Symposium on High Performance Computer Architecture (HPCA)*
- *Symposium on the Frontiers of Massively Parallel Computation*

24.1 Introduction

In the decade 1990–2000, processor chip architectures have benefited from tremendous advances in manufacturing processes, enabling cheap performance increases from both increasing clock frequencies and decreasing gate size on silicon. These advances in turn enabled an explosive expansion of the software industry, with a large focus on computers based on general-purpose uni-processors. This architecture model, which is of the Von Neumann computer, had emerged at the end of the 1980s as the de facto target of all software developments.

Until the turn of the twenty-first century, system engineers using uni-processors as building blocks could assume ever-increasing performance gains, by just substituting a processor by the next generation in new systems. Then they ran into two obstacles. One was the *memory wall* [45], that is, the increasing divergence between the access time to memory and the execution time of single instructions. To overcome this wall, architects have designed increasingly complex uni-processors using techniques such as branch predictors and out-of-order execution OoOE to automatically find parallelism in single-threaded programs and keep processor pipelines busy during memory accesses. The second is the *sequential performance wall* [1,34], also called “Pollack’s rule” [31], that is, the increasing divergence in single processors between performance gains by architectural optimizations and the power-area cost of these optimizations.

To “cut the Gordian knot,” in the words of Ronen et al. [34], the industry has since (post-2000) shifted toward multiplying the number of processors on chip, creating increasingly larger chip multiprocessors (CMPs) by processor counts, now called *cores*. The underlying motivation is to *exploit explicit concurrency* in software and distribute workloads across multiple processors to increase performance. The responsibility to find parallelism was pushed again to the software side, where it had been forgotten for 15 years.

During the period 2000–2010, this shift to multicore chips has caused a commotion in those software communities that had gotten used to transparent frequency increases and implicit instruction-level parallelism (ILP) for sequential programs without ever questioning the basic machine model targeted by programming languages and complexity theory. “The free lunch is over” [40], and software ecosystems then had to acknowledge and understand explicit on-chip parallelism and energy constraints to fully utilize current and future hardware.

This transition was disruptive for audiences used to systems where the processor fetches instructions one after another following the control flow of *one program*. Yet the commotion was essentially specific to those traditional audiences of general-purpose uni-processors that had grown in the period 1990–2000. In most application niches, application-specific knowledge about available parallelism had long mandated dedicated support from the hardware and software toward increased performance: scientific and high-performance computing (HPC) have long exploited dedicated single instruction, multiple data (SIMD) units; embedded applications routinely specialize components to program features to reduce logic feature size and power requirements; and server applications in data center have been optimized toward servicing independent network streams, exploiting dedicated I/O channels and hardware multithreading (HMT) for throughput scalability. Moreover, a host of research on parallel systems had been performed in the previous period, up to the late 1980s, and best practices from this period are now surfacing in the software industry again.

In the rest of this chapter, we review the development of multicore processor chips during the last decade and their upcoming challenges.

24.2 Underlying Principles

24.2.1 Multicore Architecture Principles

Two observations from circuit design have motivated the transition to multicore processor chips.

As noted by Bell et al. [4], the scalability of multiple-instruction issue in conventional processors is constrained by the fact that ILP is not improved linearly with the addition of silicon. Scaling up implicit concurrency in superscalar processors gives very large circuit structures. For example, the logic required for out-of-order issue scales quadratically with issue width [22] and would eventually dominate the chip area and power consumption. This situation had been summarized by Pollack [31] who stated that the performance of a single core increased with the square root of its number of transistors.

Meanwhile, the power cost of single-core ILP is disadvantageous. Not only does Pollack’s rule suggest more power consumption due to the growing silicon cost per core, to increase the instructions per second (IPS) count, the processor’s clock frequency must also increase. As noted in [34], maximum power consumption (*Power*) is increased with the core operating voltage (*V*) and frequency (*F*) as follows:

$$Power = C \times V^2 \times F$$

where *C* is the effective load capacitance of all units and wires on core. Within some voltage range, *F* may go up with supply voltage V ($F = k \times V^{\alpha-1}$, $\alpha \leq 1$). This is a good way to gain performance, but power is also increased (proportional to $V^{2+\alpha}$). For a given core technology, this entails that a linear increase in IPS via frequency scaling requires at least a quadratic increase in power consumption.

From this circuit perspective, the advantage of explicit parallelism by investing transistor counts toward multiple, simpler cores becomes clear: assuming available concurrency in software, two cores

running at half the frequency can perform together the same IPS count at less than half the power usage. Moreover, by keeping the cores simple, more transistors are available to increase the core count on chip and thus maximum IPS scalability.

This perspective also reveals the main challenge of multicore chips: the purported scalability is strongly dependent on the ability of software to exploit the increasing core counts. This is the issue of programmability, covered in the rest of this chapter.

Beyond issues of power and performance, another factor has become visible in the last decade: fault management.

Both transient and permanent faults can be considered. Transient faults are caused mostly by unexpected charged particles traversing the silicon fabric, either emitted by atomic decay in the fabric itself or its surrounding packages, or by cosmic rays, or by impact from atmospheric neutrons; as the density of circuits increases, a single charged particle will impact more circuits. Permanent faults are caused by physical damage to the fabric, for example, via heat-induced stress on the metal interconnect or atomic migration. While further research on energy efficiency will limit heat-induced stress, atomic migration unavoidably entails loss of function of some components over time. This effect increases as the technology density increases because the feature size, that is, the number of atoms per transistor/gate, decreases.

To mitigate the impact of faults, various mechanisms have been used to hide faults from software: redundancy, error correction, etc. However, a fundamental consequence of faults remains: as fault tolerance kicks in, either the *latency changes* (e.g., longer path through the duplicated circuit or error correction logic) or the *throughput changes* (e.g., one circuit used instead of two).

To summarize, the increasing number of faults is a source of unavoidable *dynamic heterogeneity* in larger chips. Either components will appear to enter or leave the system dynamically, for example, when a core must stop due to temporary heat excess, or their characteristics will appear to evolve over time beyond the control of applications. This in turn requires to evolve the abstract model of the chip that programmers use when writing software.

Exposing the chip's structure in abstract models as a network of loosely coupled cores, that is, a *distributed system on chip*, instead of a tightly coupled "central processing unit," will facilitate the management of this dynamic heterogeneity in software.

24.2.2 Multicore Architecture Models

Any computing system today is a composition of memories, caches, processors, I/O interfaces, and data links as "basic blocks." A given architecture is a concrete assembly of these components. In contrast, an *architecture model* is an abstract description of how components are connected together, to capture the general properties common to multiple concrete architectures. Architecture models are in turn characterized by their *typology*, their *topology*, and the *concurrency management primitives* they expose at the hardware/software interface.

The *typology* reports which different types of components are used. In multicore chips, we can distinguish *homogeneous* or "symmetric" designs, where all repeated components have the same type, from *heterogeneous* designs that may use, for example, general-purpose cores in combination with on-chip accelerators, cores with different cache sizes, or cores with different instruction sets. Historically, homogeneous designs have been preferred as they were simpler to program: most multicores prior to 2010 were so-called symmetric multiprocessor (SMP) systems. However, some heterogeneity has since become mandatory: not only as a way to manage faults and energy usage, as highlighted earlier, but also to increase execution efficiency for fixed applications by specializing some functional units to the most demanding software tasks.

The *topology* indicates how components are connected together. In multicores, the topology determines how cores can communicate with each other and the latency and bandwidth of communication. We can distinguish three design spectra for topologies.

The first is the *memory topology*, that is, how cores are connected to main memory. At one end of this spectrum, “UMAs” describe interconnects where a single memory is shared symmetrically by all cores and hence provides homogeneous latency/bandwidth constraints. At the other end, individual or groups of cores have their own local memory, and remote accesses become orders of magnitude more expensive than local accesses. This is where one finds “NUMAs.” The position of any specific architecture on this spectrum is a cost trade-off: UMAs are simpler to program but require more silicon and energy to provide increased bandwidth to the shared memory.

The second spectrum is the *cache topology*, that is, how caches are connected to cores, memory, and other caches. At one end of this spectrum, congruent with UMAs, the cache topology can be represented as a *cache tree*, where the common memory forms the root of the tree and the cores form the leaves. This topology fully preserves the notion of “cache hierarchy” from the perspective of individual cores, where there is only one path to main memory and local performance is determined only by the hit and miss rates at each level of requests emitted locally. At the other end, congruent with NUMAs, more diversity exists. With *distributed coherent cache* architectures, a network protocol between caches ensures that updates by one part of the system are consistently visible from all other parts. These are also called cache-coherent NUMAs (ccNUMAs) or distributed shared memory (DSM) architectures. Again, the choice is a cost trade-off: cache trees provide a shorter latency of access to main memory on average but cost more silicon and energy to operate than loosely coupled caches.

Example memory and cache topologies are given in Figure 24.1.

The third spectrum is the *inter-core topology*, that is, what direct links are available between cores for direct point-to-point communication. In most multicores, regardless of the memory architecture, a dedicated *signaling network* is implemented to notify cores asynchronously upon unexpected events. The exchange of notifications across this network is commonly called inter-processor interrupt (IPI) delivery. Inter-core networks-on-chip (NoCs) also exist that offer arbitrary data communication between cores; 2D mesh topologies are most common as they are cheap to implement in tiled designs.

Finally, the *concurrency management primitives* determine how software can exploit the hardware parallelism. There are three aspects to this interface: control, synchronization, and data movement.

In most designs that have emerged from the grouping of cores previously designed for single-core execution, such as most general-purpose SMP chips in use today, the interface for control and synchronization is quite basic. For control, cores execute their flow of instructions until either a “halt” instruction

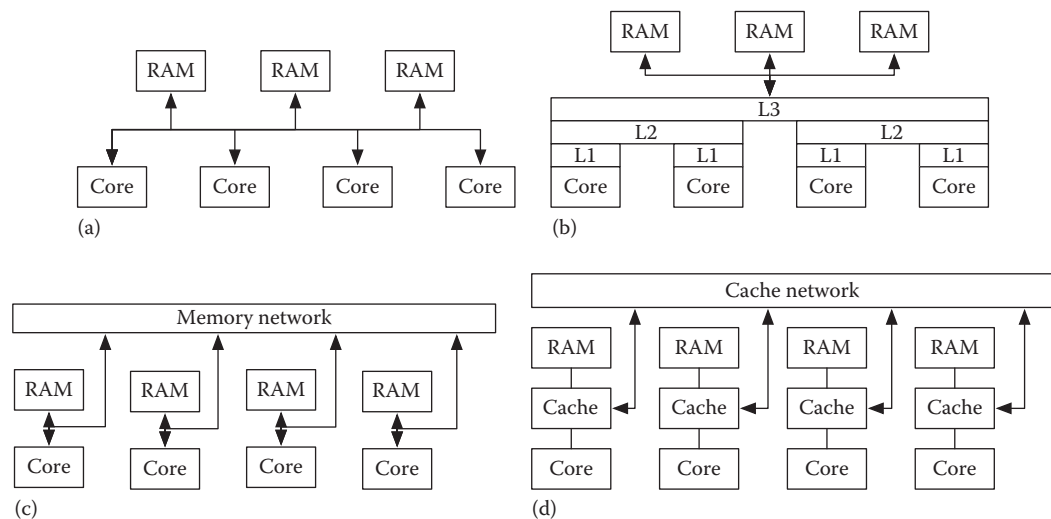

FIGURE 24.1 Example memory and cache topologies. (a) UMA with no caches. (b) UMA with cache tree. (c) NUMA with no caches. (d) NUMA with caches.

is encountered or an IPI is delivered that stops the current instruction flow and starts another. The only primitive for inter-core control is IPI delivery and regular load/store operations to a shared memory. In this context, the only synchronization mechanisms available to software are either *busy loops* that access a memory location until its contents are changed by another core or *passive waiting* that stops the current core, to be awakened by a subsequent IPI from another core. Additional mechanisms may be present but are still unusual. For example, *hardware primitives for synchronization barriers* may be available, whereby two or more cores that execute a barrier will automatically wait for one another.

For data movement, the near universal primitives are still memory load and store instructions: using a shared memory, programs running across multiple cores can *emulate virtual channels by using buffer data structures* at known common locations. In addition to loads and stores, dedicated *messaging primitives* may exist to send a data packet to a named target core or wait upon reception of a packet, although they are still uncommon.

In any case, whichever primitives are available are typically abstracted by the operating systems in software to present a standardized programming interface to applications, such as those described in the remainder of this chapter. Thanks to this abstraction layer, most of the diversity in concurrency management interfaces is hidden to application programmers. However, it is still often necessary to obtain knowledge about which underlying primitives are provided by an architecture to understand its cost/performance trade-offs.

24.2.3 Multicores with Intra-Core Parallelism

Independently and prior to the introduction of multicores, architects had enhanced individual cores to offer internal parallelism. The purpose of internal parallelism is to increase utilization of the processor pipeline, by enabling the overlap of computations with waiting instructions such as I/O or memory accesses. When cores with internal parallelism are combined together to form a multicore chip, two scales of parallelism exist and their interaction must thus be considered.

24.2.3.1 Out-of-Order Execution

In processors with OoOE, instructions wait at the start of the pipeline until their input operands are available, and ready instructions are allowed to enter the pipeline in a different order than program order. Result order is then restored at the end of the pipeline. The key concept is that missing data operands do not prevent the pipeline from executing unrelated, and ready instructions, and *utilization* is increased. For more details, see [12, Chapters 2 and 3] and the chapter on performance enhancements in this volume.

OoOE introduces new challenges for multicore synchronization. For example, a common idiom is to place a computation result into a known memory cell, then write a flag “the result has been computed” into another. If memory stores are performed in order, another core can perform a busy loop, reading the flag until it changes, with the guarantee that the computation result is available afterwards. With OoOE, this pattern is invalidated: although the *program* on the producer core specifies to write the result and only then write the flag, instruction reordering may invert the two stores.

To address this type of situation, new primitives must be introduced to *protect the order of externally visible side effects* in presence of OoOE. The most common are memory barriers, or *fences*. These must be used by programs explicitly between memory operations used for multicore synchronization. When the processor encounters a fence, it will block further instructions until the memory operations prior to the fence have completed. This restores the effect order required by the program, at the expense of less ILP in the pipeline and thus lower utilization.

24.2.3.2 Hardware Multithreading

The key motivation for multithreading in a single core is to exploit the waiting time of blocked threads by running instructions from other threads [33,35]. This is called thread-level parallelism (TLP); it can

tolerate longer waiting times than ILP. To enable this benefit of TLP even for small waiting times like individual memory loads or floating-point unit (FPU) operations, multithreading can be implemented in hardware (HMT). With HMT, a processor core will contain multiple program counters (PCs) active simultaneously, together with independent sets of physical registers for each running hardware thread. The fetch unit is then responsible for feeding the core pipeline with instructions from different threads over time, switching as necessary when threads become blocked [23,38,39,41,42].

Because each hardware thread executes an independent instruction stream via its own PC, operating systems in software typically register the hardware threads as independent *virtual processors* in the system. Subsequently, from the perspective of software, care must be taken to distinguish virtual from hardware processors when enumerating hardware resources prior to parallel work distribution. Indeed, when work is distributed to two or more hardware threads sharing the same core pipeline, performance can only increase *until all waiting times in that pipeline are filled with work*. Once a pipeline is fully utilized, no more performance can be gained with hardware threads on that core even though there may be some idle hardware threads available.

24.2.4 Programming Principles

As with all parallel computing systems, multicore programming is ultimately constrained by Amdahl's and Gustafson's laws.

In [2], Amdahl explains that the performance of one program, that is, its time to result or *latency*, will stay fundamentally limited by its longest chain of dependent computations, that is, its *critical path*, regardless of how much platform parallelism is available. The first task of the programmer is thus to shorten the critical path and instead expose more concurrent computations that can be parallelized. When the critical path cannot be shortened, the latency cannot be reduced further with parallelism. However, Gustafson's law [11] in turn suggests that the problem sizes of the parallel sections can be expanded instead, to increase use of the available parallelism and increase *throughput*, that is, computations per second, at constant latency.

Within these boundaries, software design for multicores involves the following concerns:

- Programmers and software frameworks *expose concurrency* in applications. This activity takes two forms. An existing program is *relaxed from ordering constraints* to add concurrency; for example, a sequential loop may be annotated to indicate it can be carried out in parallel. Alternatively, new code can be composed from *concurrent building blocks*, such as primitive map/reduce operators. This activity typically occurs statically, during software development.
- Meanwhile, software frameworks and operating systems *map and schedule program concurrency to the available hardware parallelism*. This activity typically occurs at run-time, to carry out program execution over the available cores.

The connection point between these two activities is the *parallel programming model*. Different languages or software libraries will offer different programming models; each offers both *programming abstractions* toward programmers to specify “what to do” and *operational semantics* that provide an intuition of “how the program will behave” at run-time. Parallel programming models typically diverge from traditional programming models in that they avoid letting the programmer specify “how” to carry out computations, so as to give maximum flexibility to the underlying platform.

Parallel programming models can be categorized along two axes, illustrated in Figure 24.2, depending on how they expose computations and communication.

In one corner, *fork-join parallelism* and *bulk-synchronous parallelism (BSP)* [44] are the most common. With fork-join, a program exposes concurrency by specifying at which points separate threads can start (fork) to compute separate parts of a computation; sequence is then enforced by expressing synchronization on termination (join) of previously created threads. In the higher-level variant BSP, an overall repetitive computation is expressed as a sequence of wide parallel sections, with computations

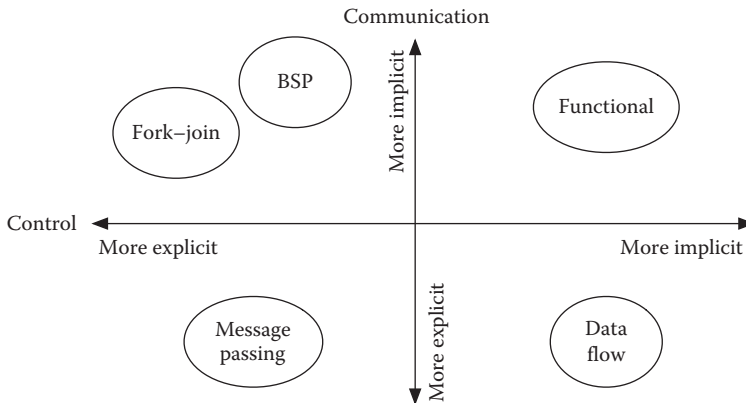

FIGURE 24.2 High-level classification of parallel programming models.

occurring during the parallel section and communication occurring during the synchronization step. With these models, control is specified by the structure of the program, while typically communication is left implicit.

At the corner of explicit control and communication, *message passing* describes a collection of idioms where a program specifies independent processes that act collectively by exchanging data across explicit channels. Message passing stems from decades of research over communicating processes [13,25–27]. It encompasses the most versatile techniques to program multicores, at the expense of a more explicit and error-prone model for programmers.

Diagonally opposed, *functional programming models* encompass the programming style of pure functional languages, where programmers are stimulated to specify only the input–output data relationships of their algorithms using symbolic operations, without introducing or assuming knowledge about the execution environment. These models provide the most flexibility for the platform by removing programmer involvement from mapping and scheduling concurrency, although it thus incurs the expense of a greater technology challenge to fully optimize execution.

Finally, *data-flow programming models* are related to functional models in that the programmer does not specify how to carry out computations. However, whereas with functional programs the data relationships may be implicitly carried by using references (pointers) in data structures, data-flow programs make data edges between computations explicit. This in turn simplifies the mapping of communication to the platform’s topology.

A given programming language or software library may expose multiple programming models. The choice of one over another in applications is mostly driven by the trade-off between programmer productivity, technological maturity of the platform, and performance: more implicit models are easier to program with but more difficult to manage for the platform.

24.3 Impact on Practice

After the HPC and general-purpose computing industries stumbled on the sequential performance wall in the last decade, the move to multicore chips has enabled the following breakthroughs:

- For HPC, the grouping of multiple cores on the same chip has enabled an increase of interconnect bandwidths by an order of magnitude, in turn enabling yet higher throughput scalability of supercomputers. As of 2012, nearly all systems from the supercomputer TOP500* are based on multicore chips.

* <http://top500.org/>.

- For general-purpose computing, the investment of silicon toward multiple cores in combination with the general trend toward mobile computing has altered the marketing of processor products dramatically: instead of advertising on frequency alone, most manufacturers now effectively report on a combination of multiapplication benchmarks and energy consumption.

For personal computing, even without considering performance gains in individual applications, the democratization of multicore chips has enabled a separation of workload between user applications and system tasks such as user interface management, networking, or disk accesses and thus results in a smoother user experience overall. This effect is noticeable for desktop computers, smart phones, and tablets, which all nowadays use general-purpose cores. For selected application domains, such as video games and image processing, significant performance gains have been reached successfully; this effect is even multiplied when combined with many-core compute accelerators and graphical processing units (GPUs).

In data centers, multicores have enabled a finer grain control over the resources handed over to client applications. By separating client applications over separate cores, interference between clients is reduced and resource billing is simplified (resources can be billed per unit of space and time, instead of per actual workload that is more difficult to compute). Some throughput increases have also been possible thanks to multicores, most noticeably for database servers and networked processes such as web servers. However, the preferred way to increase throughput in data centers is still to extend the number of network nodes instead of replacing existing nodes by new nodes with larger core counts.

Meanwhile, multicore processors are a success story for embedded systems, where they are commonly called multiprocessor systems-on-chip (MPSoCs). In these systems, processor chips are typically co-designed with software applications; different cores are implemented on chip to support specific application components. For example, a mobile phone processor chip may contain separate cores for managing wireless networks, encoding/decoding multimedia streams and general-purpose application support. By specializing a processor design to an application, hardware and energy costs are reduced while taking advantage of the parallelism to improve performance. While the embedded landscape is still much focused on application-specific chip designs, it is expected that the field's expertise with mapping and managing application components over heterogeneous resources will propagate to all other uses of multicores during the upcoming decade.

24.3.1 Current Landscape of Multicore Chips

All major technology vendors now have multicore product offerings and continue to invest towards increasing core counts.

After introducing its first mainstream dual-core offerings around 2005 via its Core and Xeon product lines, Intel's processors now nearly all feature a minimum of 2–4 cores. As of this writing, the most popular Core i5 and i7 processors, based on the Sandy Bridge micro-architecture [46], feature 4 cores running at about 3 GHz. These chips use 32 nm silicon technology and nearly a billion transistors. They integrate an on-chip GPU accelerator with 6–12 additional compute cores; the general-purpose cores also optionally feature Hyper-Threading [23] for a maximum of 2 hardware threads per core. The next generation based on the Ivy Bridge micro-architecture is expected to offer similar features at a reduced silicon and power budget.

Meanwhile, AMD has reduced its competition push on single-threaded performance and pushed its multicore road map further. Its Opteron product line currently contains chips with up to 12 general-purpose cores based on the Bulldozer micro-architecture [8]. Frequencies range from 1 to 3 GHz; the chips also use the 32 nm technology. The upcoming Fusion product line, which uses general-purpose cores based on both Bulldozer and the new Bobcat micro-architecture [7], invests more silicon real estate towards on-chip accelerator cores (e.g., 80 in Brazos chips, 160–400 in Lynx/Sabine chips).

On the embedded/mobile computing market, ARM leads the way towards the generalization of multicore platforms. The most licensed architecture towards general-purpose applications is the

Cortex-A design, now available with 2 to 4 cores on chip and frequencies up to 2 GHz in its “MPCore” variant. The most visible user of Cortex-A is currently Apple, which equips its smart phone and tablet offerings with its own A4 and A5 chips based on Cortex-A. The upcoming ARM design Cortex-A15 is planned to feature up to 8 cores on chip, together with optional on-chip accelerators depending on vendor requirements.

On the server market, Oracle (previously Sun Microsystems) has stepped forward with its Niagara [21] micro-architecture. Niagara processors combine multiple cores with HMT, resulting in high core counts per chip: the most recent product, the SPARC T4 [37], exposes 64 hardware threads to software. Although Niagara was previously advertised for throughput due to its lower initial single-thread performance, the latest generations running around 3 GHz with OoOE now compete across all general-purpose workloads.

As can be seen in this overview, the trends suggest a continued increase of core counts on the main processor chip, together with the integration of accelerators. However, separately packaged many-core accelerator chips are still being developed. The two major vendors are nowadays NVidia and AMD, the latter having acquired ATI in 2006. With clock frequencies below 1 GHz but core counts in the hundreds, their accelerator chips deliver orders of magnitude higher peak floating-point performance than general-purpose cores with twice the frequency at the same generation. The main challenge to these designs is bandwidth to memory, where communication between the accelerator and the main processor chip is constrained by the inter-chip system bus. This bottleneck constitutes the main push towards integration with general-purpose cores on the same silicon die.

24.3.2 Shared Memory Multiprogramming for Multicores

For shared memory multiprogramming, the common substrate underlying programming languages and libraries is constituted by *threads*, directly inherited from the era of time sharing on uni-processors. On multicores, threads execute simultaneously instead of interleaved, but these two abstractions remain otherwise identical to their original definition: programs create or *spawn* threads, then the operating system selects cores to execute the workload. The leading low-level application programming interfaces (APIs) to manage threads are the POSIX interface [15] (“pthreads”) and the Java virtual machine interface. To enable more fine-grained control over thread-to-core mappings, some operating systems also offer APIs to *pin* threads to specific cores (e.g., `pthread_setaffinity`). These basic interfaces are there to stay: as of 2011, new standards for the C [18] and C++ [17] languages have been published that integrate a native standard threading API similar to POSIX.

Upon these basic interfaces, different programming languages and libraries provide different parallel programming models for application developers. With less than a decade of renewed interest in multiprogramming, these software frameworks for multicores have not yet stabilized and a large diversity of approach still exists across vendors, hardware platforms, and operating systems.

For performance-oriented applications, the leading interfaces are currently OpenMP [29] for C, C++, and FORTRAN and Intel’s Threading Building Blocks (TBB) [16,32] for C++. OpenMP is specialized towards the parallelization of existing sequential code by the addition of annotations, or *pragmas*, to indicate which portions of code can be executed concurrently. An example is given in Figure 24.3: A loop is annotated to declare it can be run in parallel when the function “scale” is called; at run-time, the value of “n” is inspected and the workload is distributed across the available cores.

In contrast to OpenMP, TBB is oriented towards the acceleration of new code, where programmers use TBB’s control and data structures directly. Primitive constructs are provided for parallel map/reduce, searches, pipelines, sorting algorithm, as well as parallel implementations of container data structures (queues, vectors, hash maps). An example is given in Figure 24.4: The object “`scaler`” is responsible for carrying out the computation over subranges of the array, and TBB ensures that `scaler`’s operator is called in parallel over the available cores.

```

void scale(int n, int a[]) {
    #pragma omp parallel for
    for (i = 0; i < n; i++)
        a[i] = 2 * i;
}

```

FIGURE 24.3 Example OpenMP program fragment.

```

struct scaler {
    vector<int>& a_;
    scaler(vector<int>& a) : a_(a) {}
    void operator()(const blocked_range<size_t>& r) const {
        for (size_t i = r.begin(); i != r.end(); ++i)
            a_[i] = 2 * i;
    }
};

void scale(int n, vector<int>& a) {
    parallel_for(blocked_range<size_t>(0, n), scaler(a));
}

```

FIGURE 24.4 Example TBB program fragment.

Both OpenMP and TBB manage program concurrency in a similar fashion. When reached during execution, the program code generated by the compiler for concurrency constructs causes calls to the language run-time systems to define *tasks*. The run-time system in turn runs a *task scheduler* that spreads the tasks defined by the program over *worker threads*, which it has previously configured to match the number of underlying cores. In both interfaces, primitives are available to control the task scheduler and query the number of worker threads.

When accelerators are involved, typically the accelerator cores cannot run regular application code because they do not support recursion or arbitrary synchronization. To program them, it is still customary to use a different set of APIs. The current leading standards are NVidia's CUDA interface [20], specialized towards its own chips, and OpenCL [19] which intends to provide a unified interface to accelerators. With both interfaces, the application programmer defines *computation kernels*, which can execute on the accelerator cores, and uses the interface's API to trigger data movement and computations using kernels.

An example is given in Figure 24.5. As the example suggests, the main challenge of accelerator-based programming is data movement between the accelerator and main memory. While it is often possible to combine accelerator computations and thus reduce the need for communication, many cases exist where the application structure prevents keeping the data on the accelerator's memory. Again, the industry is moving towards tighter integration of accelerators and general-purpose cores on the same chip, in an effort to alleviate this communication overhead.

24.3.3 Distributed Programming on Chip

It is also possible to consider a multicore chip as a network of single-core nodes sharing a very efficient interconnect. Using this model, a multicore chip can be programmed using *explicitly communicating processes* instead of threads communicating implicitly via shared memory.

Abstractions to program multiple processing units using communicating processes had existed for decades and are now coming back with the advent of multicores. The typical interface for scientific computing, coming from the HPC community, is MPI [24]: it exposes a process management and message passing interface to C, C++, FORTRAN, and Java code. Implementations of MPI are nowadays able to distribute workloads over multiple cores in a single chip as well as over a network of nodes. Meanwhile, the advent of networked applications in the last decade has caused a large diversity of other frameworks for inter-process

```

// the following defines the kernel.
__kernel void scale_kernel(__global int *a) {
    size_t i = get_global_id(0);
    a[i] = 2 * i;
}
// the kernel is used as follows:
void scale(int n, int a[]) {
    /* need to copy the data to GPU memory first */
    void *gpu_mem = gcl_malloc(sizeof(int)*n, a,
        CL_MEM_COPY_HOST_PTR|CL_MEM_READ_WRITE);
    /* then define a range to operate over the data */
    cl_ndrange r = { 1, {0}, {n,0,0}, {0} };
    /* then call the kernel */
    scale_kernel(&r, gpu_mem);
    /* then copy back the data from GPU to main memory */
    gcl_memcpy(a, gpu_mem, sizeof(int)*n);
    /* then release the GPU memory */
    gcl_free(gpu_mem);
}

```

FIGURE 24.5 Example OpenCL program fragment.

message queuing and brokering in business applications: Java Message Service (JMS), Microsoft Message Queuing (MSMQ), WebSphere Message Broker from IBM, and Apache ActiveMQ are examples. These interfaces are nowadays commonly used to drive processes running over separate cores in the same chip.

24.3.3.1 Post-2010: Era of Multiscale Concurrency

While general-purpose programmers have been struggling to identify, extract, and/or expose concurrency in programs during the last decade, a large amount of untapped higher-level concurrency has also appeared in applications, ready to be exploited. This is a consequence of the increasing number of features or *services* integrated into user-facing applications in the age of the Internet and ever-increasing support of computers for human activities. For example, while a user's focus may be geared towards the decoding of a film, another activity in the system may be dedicated to downloading the next stream, while yet another may be monitoring the user's blood nutrient levels to predict when to order food online, while yet another may be responsible for backing up the day's collection of photographs on an online social platform, etc.

Even programs that are fundamentally sequential are now used in applications with high-level concurrency at scales that were unexpected. For example, the compilation of program source code to machine code is mostly sequential as each pass is dependent on the previous pass' output. However, meanwhile entire applications have become increasingly large in terms of their number of program source files; so even though one individual compilation cannot be accelerated via parallelism, it is possible to massively parallelize an entire application build. While this form of parallelism had been known in large enterprise projects, the advent of multicores makes it accessible to any programmer working with commodity platforms.

24.4 Research Issues

As this book gets published, the multicore programming challenge has taken a new form. Explicit concurrency has appeared in software, both from increased understanding by programmers and by new technology in compilers and software run-time systems to discover concurrency automatically in applications. Meanwhile, CMPs now contain dozens of cores for general-purpose computations and accelerators offer hundreds of smaller cores for specialized computing, and the trends suggest at least a tenfold increase before the end of silicon scaling. The main challenge for software engineers is thus now

less to find concurrency, but rather to *express* and *map* it efficiently to the available parallel hardware. Meanwhile, the main challenge for architects is to balance the need of software practitioners to manipulate *simple machine models* while providing *scalable* systems. The architecture and software engineering communities have thus started to work together to overcome the following new challenges:

- Choose which *parallel machine models* to communicate to programmers to give them an intuition of the underlying hardware resources.
- Choose which *programming abstractions* to offer through the software stack to describe concurrency in applications.
- Determine how to *schedule concurrency over parallel resources* in operating software.
- For known application or fields, determine how to *codesign hardware and software* so that the hardware parallelism aligns with application concurrency.

24.4.1 Platform Challenge: Communication Costs

As the example from Figure 24.5 illustrates, the cost of communication is becoming a growing design constraint for algorithms. In upcoming multicore chips, the latency to access memory from cores, or even to communicate between cores, will become large compared to the pipeline cycle time. Any nonlocal data access will become a serious energy and time expenditure in computation. This is a new conceptual development compared to the last decade, where processor speed was still the main limiting factor and memory access latencies were kept under control using ever-growing caches.

From the software architect's perspective, this *communication challenge* takes two forms. For one, either programmers or the concurrency management logic in operating software must become increasingly *aware of the topology* of the platform, so as to match the dependencies between application components to the actual communication links present in hardware. This requirement will require new abstractions and investments in programming languages and operating software, since the current technology landscape still mostly assumes SMPs and UMAs. The second aspect is that the *cost of computations* is no more a function only of the number of "compute steps," correlated with CPU time; it must also involve the "communication steps" correlated with on-chip network latencies. This is a major conceptual shift that will require *advances in complexity theory* before algorithm specifications can be correlated to actual program behavior in massively parallel chips.

From the hardware architect's perspective, the communication challenge takes three forms. One is to develop *new memory architectures* able to serve the bandwidth requirements of growing core numbers. Indeed, the energy and area costs of central caches that serve all cores symmetrically grow quadratically with their capacity and number of clients; caches will thus dominate silicon usage until more distributed cache systems are developed. However, distributed caches in turn require *weaker memory consistency* semantics [28] to be cost advantageous; a generalization of weakly consistent memory architectures will in turn have a dramatic impact on software ecosystems. The second aspect to be covered by hardware architect is *latency tolerance*: as the time cost of nonlocal data accesses grows, individual cores must provide mechanism to overlap computation with communication. A step in this direction is HMT, which will be increasingly complemented with hardware support for point-to-point messaging between cores, such as found in the recent TILE architecture [5]. The third aspect is *dark silicon* [10]: any given design will be fully utilized only by some applications, while most of the silicon will be underutilized by most applications. The role of architects will thus be to determine the best trade-offs between investing silicon real estate towards cores or towards communication links.

24.4.2 Software Challenge: Matching Abstractions to Requirements

A lot of attention has been given on the parallelization of existing software and comparatively less on the improvement of software to better program parallel platforms. There are, in effect, three broad strategies to *optimize performance and cost* on multicore systems.

The first is to provide better abstractions *to programmers* to compose subprograms so that the resulting critical path becomes shorter—that is, decrease the amount of synchronization programmers use—for a given functional specification of the input–output relationship. This is the classical effort towards increasing the amount of concurrency, which must continue as the amount of on-chip parallelism increases; beyond parallelization of individual algorithms, this effort must now also take place at the level of entire applications.

The second strategy is to determine ways to shorten programs to *describe less computations* to be performed at run-time, that is, simplify the input–output relationship. There are two known strategies to do this:

- Let *programmers* use domain-specific knowledge that reduces expectations on program outputs, for example, reduce output “quality” in image processing by introducing non-determinism when the difference is not perceptible. This is the domain of *approximate programming* [36,43] and domain-specific languages (DSLs).
- When *compilers and software run-time systems* transform programs, exploit extra application-level knowledge to remove excess code from the individual subprograms being combined [3].

The third strategy is for programmers to *remove unnecessary constraints* on the execution of algorithms. This strategy stems from the observation that most control and data structures in use today have been designed at a time where computers were predominantly sequential and thus may carry implicit requirements to preserve ordering even when it is not relevant to the application. For example, many programmers use lists and arrays as containers, which implicitly carry a strong ordering guarantee. In contrast, languages like C++ or Haskell provide high-level *type classes* (contracts) that enable the programmers to state their requirements, for example, an non-iterable associative container, and let the implementation choose a suitable parallelizable implementation, for example, a distributed heap or hash table. Research is still ongoing in this direction [6,9,30].

24.5 Summary

The move towards increasing core counts on chip was both an answer to overcome the sequential performance wall [1,34] and to bring higher communication bandwidths to parallel computing. The expected benefits of multicores were both higher performance and lower energy costs, thanks to frequency scaling.

The foremost challenge with multicores is not new, as it was shared by early practitioners with parallel architectures until the 1980s. This “concurrency challenge” requires software engineers to acknowledge platform parallelism and spend extra effort to express concurrency in applications. In response to this, new language and operating software technology has been developed in a short time, resulting in a large diversity of platforms, which have not yet matured nor stabilized. While this diversity creates opportunities in the highly dynamic IT industry, it also means that experience gained by practitioners in the last decade will likely need to be revisited in the coming 10 years.

The move to CMPs, especially with increasing core counts and accelerators on chip, also entails new technological and conceptual issues. More active components in the system imply faults or otherwise resource heterogeneity that must be understood and modeled. Communication links between cores and between cores and memory must be accounted for when mapping application components to the chip’s resources. Real parallelism between application components implies that programmers cannot stop an application and observe a consistent global state. The benefits of multiple cores on performance can only be reaped by reducing synchronization, which for some applications means decreasing reliance on determinism. These issue in turn require new abstractions to describe and manipulate the computing system at a high level, and research has barely started to characterize which general aspects of multicore parallelism will be relevant in the next era of growing software concurrency.

Defining Terms

Concurrency vs. parallelism: “Concurrency is non-determinism with regards to the order in which events may occur. Parallelism is the degree to which events occur simultaneously” [14].

Operating software: A software composed of operating systems, compilers, and language run-time systems, in charge of mapping the concurrency expressed in software to the available parallel resources in hardware.

Programming model: A conceptual model available to users of a given programming language. Consists of programming abstractions that allow programmers to specify “what to do” and operational semantics that give programmers an intuition of “how the program will behave.” Parallel programming models are special in that they discourage programmers from specifying how to carry out computation, so as to leave operating software maximum flexibility to map and schedule the program’s concurrency.

Scalability: The ability of a system to approximate a factor N performance improvement for a factor N cost investment (e.g., silicon area, number of cores, energy, frequency).

Throughput vs. latency: Throughput is the number of computations achieved by unit of time, whereas latency is the number of seconds necessary to achieve a unit of computation. Parallelism can decrease latency down to a program’s critical path, whereas throughput typically remains scalable as the workload on concurrent sections can be arbitrarily increased.

Topology of architecture models: The topology of an architecture consists of how components are connected to each other. On multicore processor chips, one can consider separately the memory topology, that is, how cores are connected to main memory; the cache topology, that is, how caches are connected to cores, main memory and each other; and the inter-core topology.

Typology of architecture models: The typology of an architecture consists of the set of component types that participate in the design. For example, heterogeneous multicore architectures have more than one processor type.

Acronyms

API	application programming interface
BSP	bulk-synchronous parallelism
ccNUMA	cache-coherent NUMA
CMP	chip multiprocessor
DSL	domain-specific language
DSM	distributed shared memory
FPU	floating-point unit
GPU	graphical processing unit
HMT	hardware multithreading
HPC	high-performance computing
ILP	instruction-level parallelism
IPI	inter-processor interrupt
IPS	instructions per second
MIMD	multiple instruction, multiple data
MPSoC	multiprocessor system-on-chip
NoC	network-on-chip
NUMA	nonuniform memory architecture
OoOE	out-of-order execution
PC	program counter
SIMD	single instruction, multiple data
SMP	symmetric multiprocessor

SPMD	single program, multiple data
TBB	threading building blocks
TLP	thread-level parallelism
UMA	uniform memory architecture

Organization of Chapter

Molecular computing involves computation done at the molecular scale. DNA computing is a class of molecular computing that does computation by the use of reactions involving DNA molecules. DNA computing has been by far the most successful (in scale and complexity of the computations and molecular assemblies done) of all known approaches to molecular computing, perhaps due in part to the very well-established biotechnology and biochemistry on which its experimental demonstration relies, as well as the frequent teaming of scientists in the field with multiple essential disciplines including chemistry, biochemistry, physics, material science, and computer science.

This chapter surveys the field of DNA computing. It begins in Section 25.1 with a discussion of the underlying principles, including motivation for molecular and DNA computations (Section 25.1.1), brief overviews of DNA structures (Section 25.1.2), chemical reaction systems (Section 25.1.3), DNA reactions (Section 25.1.4), and classes of protocols and computations (Section 25.1.5). Then, the chapter discusses potential applications of DNA computing research (Section 25.2). The main section on research issues (Section 25.3) overviews how DNA computation is done, with a discussion of DNA hybridization circuits (Section 25.3.1), including both solution-based and localized hybridization circuits. It also discusses design and simulation software for the same. We discuss DNA detectors in Section 25.3.2, DNA replicators in Section 25.3.3, DNA nanorobotic devices in Section 25.3.4, and DNA dynamical systems in Section 25.3.5. Section 25.3.6 overviews research on tiling assembly computations, including

theoretical models and results in Section 25.3.6.1, experimental methods for assembly of tiling lattices in Section 25.3.6.2, design and simulation software in Section 25.3.6.3, assembly in various dimensions in Sections 25.3.6.4 and 25.3.6.5, stepwise tiling assemblies in Section 25.3.6.6, activatable tiles in Section 25.3.6.7, and tiling error-correction methods in Section 25.3.6.8.

25.1 Underlying Principles

25.1.1 Motivation: Why Do Molecular Computation and Why Use DNA for Computation and Self-Assembly?

In an era where electronic computers are powerful and inexpensive, why do we need molecular computation? One response to this question is that conventional electronic devices have been miniaturized to the point where traditional top-down methods for manufacturing these devices are approaching their inherent limits due to constraints in photolithographic techniques and further miniaturization is not cost-effective. On the other hand, bottom-up manufacturing methods such as molecular self-assembly have no such scale size limits. Another response is that molecular computation provides capabilities that traditional computers cannot provide; there are computations that need to be done in environments and at scales where a traditional computer cannot be positioned, for example, within a cell or within a synthetic molecular structure or material.

Why use nucleic acids such as DNA for computation and self-assembly?

DNA and nucleic acids in general are unique in multiple aspects:

1. First of all, they hold and can convey information encoded in their sequences of bases. Most of their key physical properties are well understood.
2. Their tertiary structure is much more predictable, compared to molecules such as proteins.
3. Their hybridization reactions, which allow for addressing of specific subsequences, are also well understood and productively controllable.
4. They allow for a large set of operations to be performed on them. Well-known enzymatic reactions for manipulation of DNA exist.
5. Finally, there is a well-developed set of methods such as gel electrophoresis, Förster Resonance Energy Transfer (FRET), Plasmonics, and Atomic Force Microscopy (AFM) imaging for quantifying the success of experiments involving DNA and DNA nanostructures.

Before we delve into how molecular computation is done, we will discuss DNA structure and function, how information may be stored in it, and what environment it needs to efficiently do computation.

25.1.2 Brief Overview of DNA Structure

DNA is a polymer that can exist in either single- or double-stranded form. Each strand of DNA is made up of a repeating set of monomers called *nucleotides*. A nucleotide consists of three components, a 5-carbon sugar molecule, a nitrogenous base, and a phosphate group. The ...-phosphate-sugar-phosphate-... covalent bond forms the backbone of a DNA strand. The phosphate group is attached to the 5th carbon atom (C5) on one end and C3 on another end. This gives the DNA strand directionality, and the two ends of a DNA strand are commonly termed the 5' (prime) and the 3' ends. This can be seen in Figure 25.1.

25.1.2.1 DNA Bases

Nitrogenous bases are the component of nucleotides that are not involved in forming the backbone of a strand. There are five types of these bases, named adenine(A), guanine(G), cytosine(C), thymine(T), and uracil(U). Only four of these, A, G, C, and T, are present in DNA, while T is replaced by U in RNA.

Bases A and G belong to a class called *purines*, while C, T, and U fall under the *pyrimidines* class. Figure 25.2 shows the difference in structure of purines and pyrimidines. A purine class has a pyrimidine ring fused to an imidazole ring and contains four nitrogen atoms as opposed to two nitrogen atoms in a pyrimidine class.

FIGURE 25.1 DNA backbone (on left) and DNA bases involved in hydrogen bonding (middle). (From Campbell, N. et al. *Biology*, 5th edn., Benjamin Cummings, 1999.)

FIGURE 25.2 Structure of DNA/RNA bases.

25.1.2.2 ssDNA and dsDNA Structure: The Double Helix

DNA can exist either in single-stranded DNA (ssDNA) form or as a result of two complementary ssDNA binding together via hydrogen bonds to form double-stranded DNA (dsDNA). The two ssDNA are always *antiparallel* when bound, that is, one strand has 5' to 3' direction, while the other has a 3' to 5' direction. DNA exists as a double helix, as shown in Figure 25.3.

The nitrogenous bases in each ssDNA bind with a complementary base in the other strand to give rise to this structure: A binds with T, and G binds to C. This pairing of bases is called the *Watson–Crick bonding* in DNA, as shown in detail in Figure 25.4. An important note is that a *purine always binds to a pyrimidine* and this can be seen in Figure 25.1.

ssDNA and dsDNA can have different helical conformations, namely, the A, B, C, D, T, and Z forms. The most common dsDNA forms are A, B, and Z, and they can transform from one conformation to another based on the hydration conditions, the pH, and the ionic concentration of the environment. The most common form of DNA is the B form, which it assumes when hydrated. A relative comparison of the these three conformations is shown in Table 25.1.

FIGURE 25.3 Double helix form of dsDNA (B form). (From Lavery, R., DNA structure, <http://www.phys.ens.fr/monasson/Houches/Lavery/L1.ppt>.)

FIGURE 25.4 Watson–Crick hydrogen bonding.

TABLE 25.1 Comparison of A, B, and Z Forms of DNA

Characteristic	A-DNA	B-DNA	Z-DNA
Helix sense	Right-handed	Right-handed	Left-handed
Residues per turn (base pairs)	11	10.4	12
Axial rise	2.55 Å	3.4 Å	3.8 Å
Helix pitch	28 Å	35 Å	45 Å
Base pair tilt	20°	-6°	7°
Helix width (diameter)	23 Å	20 Å	18 Å
Phosphate-phosphate distance	5.9 Å	7.0 Å	5.9 Å
Dimension	Broad	Normal	Narrow

**FIGURE 25.5** Hairpin open and closed forms. (From Blicq, D., DNA hairpin, <http://xnet.rrc.mb.ca/davidb/dna.htm>.)

In its ssDNA form, DNA exists as a long single thread, or in many cases, it forms a *secondary structure*, where the strand loops around itself and forms hydrogen bonds with other bases on itself (called a *random coil*).

25.1.2.3 DNA Hairpins

DNA hairpins are a special *secondary structure* formed by an ssDNA, and contain a stem/neck double-stranded region, and an unhybridized loop region, as seen in Figure 25.5. Hairpins have been recognized as a useful tool in molecular computation because of three reasons: (1) Hairpins store energy in their unhybridized loop, and on hybridization, energy is released driving the reaction forward. (2) In their hairpin form, they are relatively unreactive with other DNA strands and act as excellent monomers until an external entity (usually another DNA strand) causes the stem region to open and react with other DNA complexes. Hence, they can persist with low leaks for a long amount of time. (3) A common way to create DNA complexes is to anneal them. DNA complexes usually contain a large number of strands, and multiple different structures can be formed because of varied interactions between different strands. In low concentrations, DNA hairpins usually form without error and are not involved in spurious structure formation. This is because their formation is not diffusion dependent, that is, the two ends of a hairpin hybridize with each other before two ends of different hairpins hybridize. This property is known as *locality* and is a strong motivation for the use of hairpins.

Hairpins [32] and metastable DNA hairpin complexes [85,102] have been used as fuel in chain reactions to form large polymers [20], in programming pathways in self-assembly [119], and in logic circuits [84]. A common technique to help open a DNA hairpin is via a process known as *toehold-mediated strand displacement*, which we shall discuss in more detail in Section 25.1.4.1.

25.1.3 Brief Overview of Chemical Reaction Networks in DNA Computing

Chemical reaction networks (CRNs) are becoming central tools in the study and practice of DNA computing and molecular programming. Their role is twofold—as a model for analyzing, quantifying, and understanding the behavior of certain DNA computing systems and as a specification/programming language for prescribing information processing (computational) behavior. The first of these roles is traditional and is analogous to the role played in biology by CRNs in describing biochemical processes and genetic reaction networks. The latter role—thinking of CRNs as a programming language—is unique to the field of DNA computing and is a consequence of the ability of DNA to act as an information processing medium and emulate (with certain restrictions) any CRN set down on paper. We will discuss both these roles briefly in the following paragraphs.

25.1.3.1 CRNs Model DNA Strand-Displacement Reaction Networks

Enzyme-free DNA computing devices can execute (1) Boolean circuits and linear threshold gate networks (the latter model neural networks) [68,69,83], (2) nucleic acid amplifiers [20,119,127], (3) finite state automata [30], and (4) molecular walkers [31,121]. All of these devices are examples of strand-displacement reaction networks (SDRNs). In a toehold-mediated strand-displacement reaction, an incoming DNA strand displaces a competing DNA strand hybridized to a DNA substrate strand. The incoming strand first binds to a toehold—a short single-stranded portion of the substrate—and then competitively displaces the outgoing strand from the substrate by a 1D random walk process. A cascade (network) of such strand-displacement reactions are called *SDRNs*.

The modular design characteristics of SDRNs allow them to be modelled as CRNs. In particular, the types and rates of reactions are limited. We can infer them from prior experience and/or predict them from thermodynamic parameters [129]. This allows us to predict the CRN model and verify its predictions experimentally.

25.1.3.2 CRNs as a Programming Language

In theory [95], SDRNs closely approximate the dynamic behavior of any CRN up to a time and concentration scaling. They illustrate how any CRN that we set down upon paper can be translated into a set of DNA molecules that when mixed together in the appropriate concentrations will emulate the behavior of the CRN. Certain CRNs seem hard to emulate in practice, and no successful SDRN implementations currently exist for these, but many others have been successfully implemented.

CRNs are more abstract than SDRNs and can be thought of as a higher-level programming language. The process of translating a CRN into its corresponding SDRN is then analogous to compiling a higher-level programming language down to a lower-level programming language. Programming in the CRN language has the advantages inherent in programming in higher-level languages vs. programming in lower-level languages.

How powerful is the CRN language? Quite powerful, it turns out. It is proven in [94] that a finite CRN obeying stochastic dynamics can achieve efficient Turing universal computation with arbitrarily small (nonzero) error. Error-free computation is impossible in this setting; only semilinear functions can be computed without errors [14].

25.1.4 DNA Reactions

In order to be able to efficiently compute with DNA, we should be aware of its properties and the types of reactions it can undergo. We classify this set of reactions into three types — DNA hybridization reactions, DNA enzyme reactions, and DNAzyme reactions. (1) DNA hybridization reactions are usually enzyme-free and isothermal and encapsulate strand-displacement reactions. (2) DNA enzyme reactions are powerful reactions, which can help cut and join the backbone of DNA strands, as well as synthesize new strands, and are often employed due to this versatility. Enzymatic reactions are often extremely rapid and extremely low error, hence making them attractive to use. (3) More recently, deoxyribozymes (DNAzymes) and aptamers have been discovered and used similar to enzymes to manipulate DNA reactions.

25.1.4.1 DNA Hybridization Reactions

A well-known example of DNA hybridization reactions is the Watson–Crick DNA hybridization between two complementary ssDNA strands as discussed in Section 25.1.2.2. Two ssDNA strands can attach to each other. However, they can also detach from one another, if the temperature is greater than the melting temperature of the strands (Figure 25.6). The *melting temperature* of a dsDNA is defined as the temperature at which 50% of the dsDNA has converted to single-stranded form.

25.1.4.1.1 Toehold-Mediated Strand Displacement

Yurke et al. reported an interesting DNA hybridization reaction through their DNA tweezer system [124]. As illustrated in Figure 25.7a, two ssDNA strands (B) and CB) are bound to one another, with one strand called the *incumbent strand* (strand B) completely bound, while the other CB has a few unbound bases. These bases (C) can together be called a *sticky end*, *overhang*, or a *toehold*. A third ssDNA, called

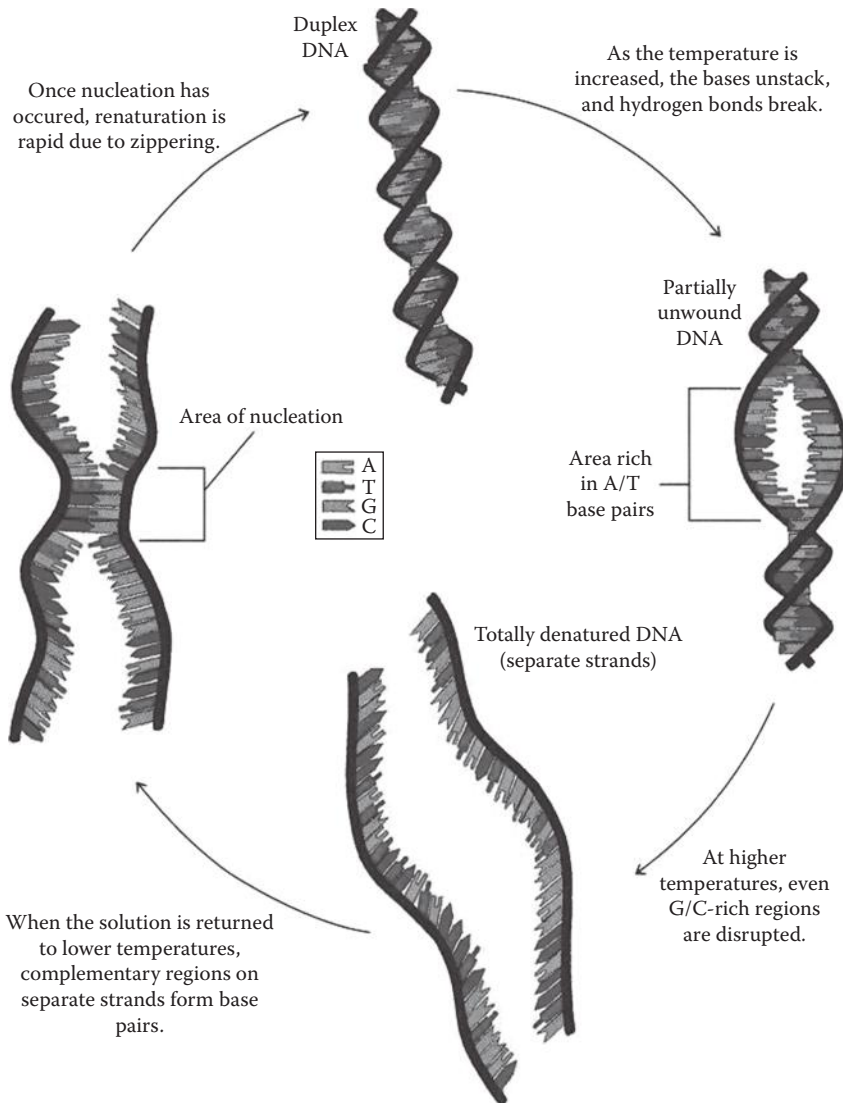

FIGURE 25.6 DNA denaturation renaturation. (From Moran, L.A. et al., *Biochemistry*, 2nd edn., Neil Patterson publishers, distributed by Prentice Hall Inc., 1994.)

FIGURE 25.7 (a) Toehold-mediated strand displacement and (b) toehold exchange. (From Iaki Sainz de Murieta and Alfonso Rodriguez-Patn, *Biosystems*, 109(2), 91, 2012.)

the *incoming strand* (strand BC), complementary to the ssDNA with the toehold (\overline{CB}), can hybridize to the toehold region (\overline{C}) and displace the incumbent strand (B). This process is termed *toehold-mediated strand displacement*. Typical toehold lengths used for toehold-mediated strand-displacement hybridization reactions range from 3 to 7 nucleotides. The rate constant of the toehold-mediated strand displacement ranges from $1 \text{ M}^{-1} \text{ s}^{-1}$ to $6 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$.

25.1.4.1.2 Toehold Exchange

Toehold exchange is an extension to toehold-mediated strand displacement, but it is extremely powerful. Zhang and Winfree [129] made the reaction in the previous section reversible, by introducing a small exit toehold. As seen in Figure 25.7b, toehold exchange proceeds in the same manner as toehold-mediated strand displacement. Strand B has been logically divided into two parts B^m and B_m , where B^m is a small segment (3–7 nt) long. The incoming strand is now shorter ($B_m C$). On toehold-mediated strand displacement, it does not completely dehybridize the incumbent strand ($B = B^m B_m$) and B^m of the incumbent bound. This segment floats away autonomously since its binding strength is too low to keep it in place at the current temperature (usually room temperature— 25°C).

Note that now, the incumbent strand has a toehold ($\overline{B^m}$), which it can attach to and, in the process, displace the strand $B_m C$. By simply shortening the incumbent strand, the process has been made reversible. This set of reactions, as we shall see in Section 25.3.1, are extremely useful in designing hybridization circuits.

25.1.4.2 DNA Enzyme Reactions

Enzymes are proteins that facilitate biochemical reactions. Enzymes are highly specific and usually catalyze their desired reactions. Theoretically, enzymes can be reused in a biochemical reaction, without being consumed by the reactants. They also provide high efficiency to their reactions. For example, one enzyme named catalase in liver can break down roughly five million molecules of hydrogen peroxide into oxygen and water in 5 min.

SmaI restriction enzyme—blunt ends

EcoRI restriction enzyme—sticky ends

Nb.BsmI nicking enzyme

T4 ligase enzyme

FIGURE 25.8 DNA enzymes.

In the field of DNA-based computation, scientists are currently working with a small subset of enzymes such as restriction enzymes, nicking enzymes, ligase enzymes, and polymerase enzymes. The purpose of restriction enzymes and nicking enzymes is to cleave the phosphodiester bond within a chain of nucleotides, whereas the purpose of ligase enzymes is to repair the phosphodiester bond as illustrated in Figure 25.8. In order for an enzyme to cleave or repair a specific location, the location has to have a recognition site that is designated for that particular enzyme. A recognition site (depicted as triangles in Figure 25.8) is normally a few nucleotides along the DNA double helix. For example, a *SmaI* restriction enzyme cleaves two phosphodiester bonds on both sides of a given DNA double helix to give an end result of two blunted ends of DNA double helices (Figure 25.8). Similarly, an *EcoRI* restriction enzyme cleaves two phosphodiester bonds on both sides of a given DNA double helix to give an end result of two separated overhang DNA helices (Figure 25.8). A *Nb.BsmI* nicking enzyme, on the other hand, cleaves a single phosphodiester bond on one side of a given DNA double helix. Furthermore, a broken phosphodiester bond can be repaired using a T4 ligase enzyme as illustrated in Figure 25.8. To amplify a particular DNA sequence, researchers often employ the polymerase chain reaction (PCR) technique. This technique involves the use of polymerase enzymes to catalyze the polymerization of nucleoside triphosphates (dNTPs) into a multiple copies of the target DNA sequence.

25.1.4.3 DNAzyme Reactions

Recently, researchers have been using deoxyribozymes (DNAzymes) and aptamers to catalyze DNA hybridization reactions. DNAzymes and aptamers are discovered by *in vitro* evolution search. They are both DNA-based sequences that possess enzymatic activities, which extend beyond Watson–Crick hybridization, and they have highly specific binding to target molecules. An example of the use of DNAzyme for DNA computation was demonstrated by Stojanovic et al. by building a molecular automaton using a network of DNAzymes [96].

25.1.5 Classes of Protocols and Computations

Molecular computations, specifically DNA computations, are generally conducted by the use of well-defined protocols that are reproducible. In the field of biochemistry, the term *protocol* denotes a precise method for the synthesis of materials such as preparing reagents, adding solutions and reagents to a test tube, and changing physical parameters (i.e., temperature), as well as separation of materials and read-out of data. Most computations fall into one of the following classes of protocols.

25.1.5.1 Autonomous vs. Nonautonomous Molecular Computations

The execution of a lengthy protocol may require a very considerable human effort. A particularly favorable class of protocols are those that are *autonomous*, requiring no further externally mediated operations after the solutions and reagents are added together. (Otherwise, the protocol is termed *nonautonomous*.)

25.1.5.2 Stepped Protocols

Stepped protocols [71] are a more general class of protocols that proceed by a sequential series of steps, where each step is autonomous, but between each consecutive step, there may be an externally mediated operation involving a single test tube.

Staged protocols [19] are an even more general class of protocols that proceed by a sequential series of stages involving multiple test tubes at the same time, where each stage is autonomous, but between stages, there may be a single externally mediated operation involving each test tube or pairs of the test tubes.

25.1.5.3 Local vs. Solution-Based Protocols

A reaction is *solution-based* if it occurs within a solution, and materials have to diffuse to each other in order to interact. Likewise, it is *local* if it occurs between materials that are attached to a surface, thereby reducing/eliminating the diffusion time.

25.1.5.4 Activatable Molecular Devices

A molecular device is *activatable* if it has two classes of states: *inactive*, where it generally cannot undergo state transitions until an activating event occurs, and *active*, where it can undergo state transitions. An activatable device usually is initialized inactive and transitions to an active state after an activation event.

25.2 Impact on Practice

Some of the practical applications of DNA computations and DNA nanoassemblies include the following:

1. *Detection of nucleic acid sequences*: For many diseases, the detection of the disease is done via the determination of a characteristic sequence t of DNA or RNA, where t has base length no more than 20 or so base pairs. This detection is conventionally done via the well-known PCR protocol, but this requires somewhat bulky and expensive device for repeated thermocycles and optical detection. The market for these detection protocols is over a billion dollars. DNA computation protocols may provide a much more cost-effective and portable means for detection. Section 25.3.2 describes various isothermal (requiring no thermal cycling) protocols for exquisite sensitive detection of DNA and RNA sequences.
2. *3D DNA nanoassemblies of proteins for x-ray crystallography structure determination*: Almost half of all proteins of interest to medicine cannot be crystallized, and so their 3D structure can be determined from conventional x-ray crystallography studies. An important application of DNA nanoassembly, proposed by Seeman [88], is the assembly of 3D DNA lattices that can hold a given protein at regular positions in the crystalline lattice, allowing for x-ray crystallography studies of an otherwise uncrystallizable protein. For further discussion of this application, see Section 25.3.6.5 discussion on 3D DNA nanoassemblies [130].

3. *3D DNA nanoassemblies for alignment of proteins for NMR structure determination*: Douglas and Shih [22] have proposed and demonstrated a novel method for improved nuclear magnetic resonance (NMR) studies of structure determination that makes use of long DNA nanoassemblies to partially align proteins.
4. *2D DNA nanoassemblies for molecular patterning*: DNA nanoassemblies can be used for programmed patterning of 2D molecular surfaces. This has applications to assembly of molecular electronic devices on molecular surfaces and 2D readout methods [47,76,118].
5. *DNA nanorobotic devices for molecular assembly lines*: Programmed control and sequencing of chemical reactions at the molecular scale have major applications in the chemical industry. DNA nanorobotic devices (see Section 25.3.4) have been demonstrated to execute a programmed sequence of chemical reactions at predetermined positions along a DNA nanostructure [33,57].

25.3 Research Issues

25.3.1 DNA Hybridization Circuits

The construction of circuits made out of DNA has been an area of interest since the advent of molecular computing. Having millions to billions of nanoscale DNA gates working in tandem, to accept an input and produce an unambiguous output, is a challenging task. There have been various designs to create logic gates and Boolean circuits using DNA motifs [1,44,64,65,67,69,80,81,83,84,97,98,113,128]. We examine a few such attempts at creating these circuits and the advantages and pitfalls associated with each. We classify the circuits into two types: DNA circuits contain a large number of DNA molecules, and each molecule reacts with a small subset of other molecules. Circuits in which molecules diffuse through solution, to find a molecule from this subset, are said to be *solution based*. On the other hand, DNA molecules can be attached to a surface, and these molecules only interact with other molecules within their reach. Such circuits are known as localized hybridization circuits.

25.3.1.1 Solution-Based DNA Hybridization Circuits

Qian and Winfree developed a scalable solution-based DNA hybridization circuit system. Their basic motif is a seesaw gate based on the toehold-exchange protocol as seen in Section 25.1.4 developed by [129]. The system consists of a set of seesaw gates. Each gate can accept an input (strand) and produce an output(strand). The input strands act catalytically; hence, a single input strand can help release multiple output strands from one (or more) seesaw gates. The output strands act as inputs for the next seesaw gates downstream in the circuit. Figure 25.9 shows the basic mode of operation of a seesaw gate motif.

As an example, the input strand consists of three domains, S2, T, and S5, and the output strand consists of S5, T, and S6. Note that the 5' end of the input and the 3' end of the output need to have the same set of domains, while the converse is not true (S2 and S6 can be different). These domains S2 and S6 can be used to help differentiate different input strands and different output strands that interact with the same gate. We now show how the authors use this difference to construct OR and AND gates.

25.3.1.1.1 Construction of AND-OR Gates

Having constructed the basic motif, the authors then constructed AND and OR gates using the same motif. In order to construct an OR gate, either one of the input strands (x_1 , x_2) should release the output strand. That is, the presence of either x_1 OR x_2 gives the output. Take the following construction: $x_1 = (S_{10} T S_5)$, $x_2 = (S_{10} T S_5)$. We can trivially see that either one of x_1 or x_2 will release the output strand. Hence, this gate is equivalent to an OR gate.

The construction of an AND gate is nontrivial. Only when both x_1 and x_2 are present should the output strand be released. The authors introduce a gate called the “*threshold gate*” as seen in Figure 25.9. The threshold gate can be thought of as a garbage collector that sucks a strand in and makes it unusable for further reactions. By varying the concentration of the threshold gate, both AND and OR gates can be constructed. This is seen in Figure 25.9.

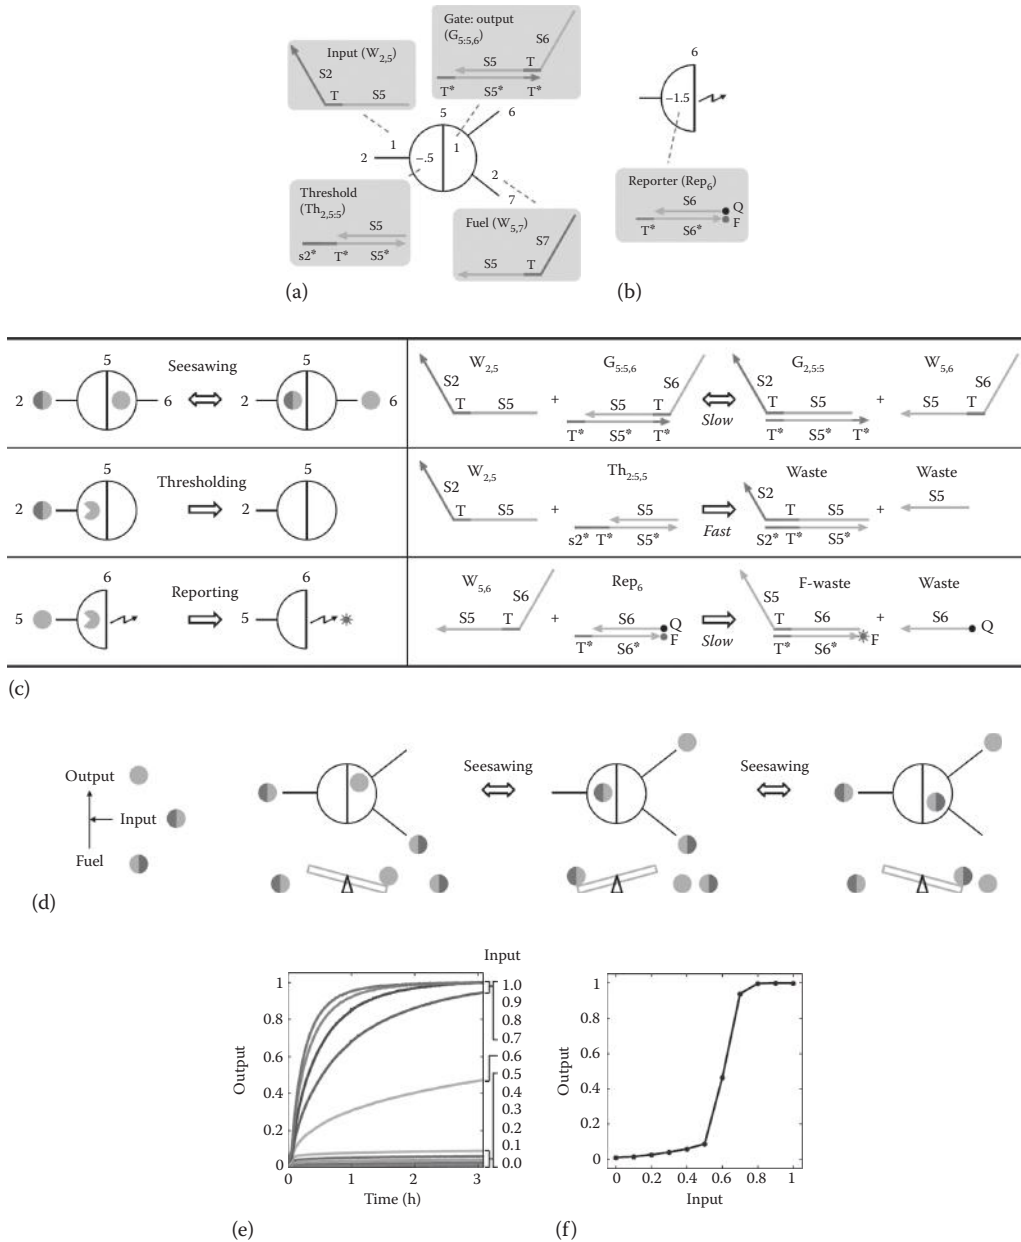

FIGURE 25.9 Components of a seesaw system. (From Qian, L. and Winfree, E., *Science*, 332(6034), 1196, 2011.)

25.3.1.1.2 A DNA Circuit That Computes the Square Root of $n \leq 15$

Using the AND and OR gate motifs, we can now construct any circuit by connecting a set of such gates sequentially. The authors construct a circuit that computes the square root of all numbers up to 15. It takes in 8 inputs, a 0 or a 1 for each bit. The output set of strands denote the set of bits that are set to 1 and hence encode the result.

The system described earlier is an example of how DNA can be used to do logical computation *in vitro*, and *detect* any input strands that are present in the vicinity. There are several disadvantages of this approach, with the primary one being that this methodology is slow, and as the depth of the circuit increases, the amount of time taken to perform a reliable computation increases linearly. Also, circuits such as these are susceptible to

erroneous reactions taking place between gates and strands that are not intended to happen, and this could lead to faulty outputs. In order to fix these problems, we discuss another set of circuits in the next section.

25.3.1.2 Localized DNA Hybridization Circuits

The solution-based systems described earlier demonstrate the enormous potential of DNA nanosystems. But most of the systems relied on diffusion-based hybridization to perform complex state changes/computation. At low concentrations and temperatures, diffusion can be quite slow and could impede the kinetics of these systems. At higher concentrations and temperature, unintended spurious interactions (often called *leaks*) could hijack the systems from its programmed trajectory. Localized hybridization networks are set of DNA strands attached to an addressable substrate. This localization increases the relative concentration of the reacting DNA strands thereby speeding up the kinetics. Diffusion-based systems possess global states encoded via concentration of various species and hence exhibit limited parallel ability. In contrast, localized hybridization systems allow for each copy of the localized hybridization network to operate independently of each other. Localized hybridization networks also allow one to reuse the same DNA sequence to perform different actions at distinct location on the addressable substrate, increasing the scalability of such systems by exploiting the limited sequence space. An advantage of localized hybridization computational circuit is sharper switching behavior as information is encoded over the state of a single molecule. This also eliminates the need for thresholding as computation is performed locally eliminating the need for a global consensus. These advantages are expounded in greater detail in Chandran et al. (2011). Quite recently, other articles such as Genot et al. (2011) and Aldaye et al. (2011), have also demonstrated that locality can be used successfully.

25.3.1.3 Design and Simulation Software

Computational tools are a growing necessity in order to design DNA strands for use in both simulations and experiments. Visual DSD from [42] is extremely useful in simulating DNA strand-displacement reactions. NUPACK [125] and MFOLD [132] help in design and analysis of sequences at the base level, in order to weed out wrong designs.

25.3.2 Strand-Displacement Reaction Network (SDRN)-Based DNA Detectors

The detection problem is the problem of designing a solution-based chemical molecular circuit (henceforth, the *detector*) for detecting the presence of an input molecular species by producing an output molecule (or molecules) in sufficient quantities so that it can be detected by a measuring instrument. The detector must be sensitive to small amounts of input, specific to the correct type of input, and robust to stochastic variability in the operation of the CRN. We might also ask that the detector function correctly over a wide range of concentrations, temperatures, and buffer conditions.

In this section, we will concentrate on the problem of detecting a short piece of DNA of known sequence. Various other molecules can often be transduced into a short DNA sequence by means of aptamer technology. This problem, interesting in its own right, will not be discussed in this chapter.

25.3.2.1 Advantages of SDRN Detectors

The canonical DNA detector is the PCR, an enzymatic detector that requires temperature cycling. Driven by exquisitely evolved enzymes and technological advances over the past 50 years, real-time PCR protocols are sensitive to as little as 2000 DNA molecules in an mL of solution. However, PCR is not often specific to single base mutations in input, requires temperature cycling, and works only in a narrow range of temperature and buffer conditions. Enzymatic detectors that seek to replace PCR have their own host of issues and rely on special enzymes.

In contrast, SDRN detectors are isothermal, easily modifiable to detect various sequences, can be made specific to single base mutations, and may work correctly over a wide range of temperature, concentration, and buffer conditions [126]. They can also function as a module (subroutine) within a larger SDRN performing a complex computation, for instance, an SDRN circuit that produces an output molecule only

in the presence of two types of inputs (AND logic) or one detecting either one of two types of inputs, but not both together (XOR logic) or any arbitrary Boolean predicate. The key limitation with current SDRN detectors is their lack of sensitivity to small amounts of input, but the hope is that this issue can be surmounted [29]. A sensitive SDRN detector could have applications in a variety of settings, including *in vivo*.

25.3.2.2 Leaks Limit Sensitivity of Detectors

A sensitive detector must necessarily amplify small input signal into sufficiently large output signal. This amplification must be conditional; in the presence of input, the amplification must be switched on and switched off in its absence. In terms of CRNs, this implies that detectors must have catalytic reaction pathways. Thermodynamics tells us that if a reaction proceeds in the presence of a catalyst, it must also occur in the absence of that catalyst, typically at a slower rate. These unplanned reactions are termed as *leaks*, and they limit the sensitivity of detectors [28]. Even in the absence of input, the detector produces output due to leak reactions. If the quantity of output produced (as a function of time) in the presence of input is sufficiently larger (detectable by measuring instrument) than the output produced (as a function of time) in the absence of input, the input is detectable. Otherwise, the detector is not sensitive to the input.

Identifying and mitigating leak reactions is the key to implementing sensitive detectors. For simple CRNs, the leak reactions may be easily guessed, since catalytic reactions are easily identified. What are the correct leak reactions when implementing more complex CRNs? Do the leak reactions depend on the particular technology we use to implement the CRN? Ref. [28] hypothesizes that the correct leak model for a CRN is the *saturation* (defined in [27]) of that CRN. Informally, the *saturation* of a CRN introduces some basis set of leak reactions that gets rid of all purely catalytic pathways. There may be many choices for the basis. The *rates* of these reactions depend on the type of technology we use to implement them, but their nature (up to a choice of basis) is determined purely by the connectivity of the CRN.

In SDRN detectors, having identified the leak reactions, knowledge of strand-displacement kinetics [129] allows us to guess the rates of these reactions, and hence we have an accurate model of the dynamic behavior of the SDRN detector before implementing them in the laboratory.

25.3.2.3 Overview of SDRN Detectors

Various successful implementations of SDRN detectors have been demonstrated. The hybridization chain reaction (HCR) of [20] triggers the formation of a linear nicked double-stranded polymer in the presence of an input DNA strand. The polymer units are two DNA strands initially trapped in a metastable hairpin form. The input triggers the opening of one the hairpins, which in turn triggers the other and a linear cascade of triggers results. The driving force for the reaction is the decrease in enthalpy due to the formation of additional hybridization bonds in the nicked double-stranded polymer as compared to the metastable hairpins. The system is described in Figure 25.10.

FIGURE 25.10 HCR by [20]. (a) Hairpins H1 and H2 are stable in the absence of initiator I. (b) I nucleates at the sticky end of H1 and undergoes an unbiased strand-displacement interaction to open the hairpin. (c) The newly exposed sticky end of H1 nucleates at the sticky end of H2 and opens the hairpin to expose a sticky end on H2 that is identical in sequence to I. Hence, each copy of I can propagate a chain reaction of hybridization events between alternating H1 and H2 hairpins to form a nicked double helix, amplifying the signal of initiator binding.

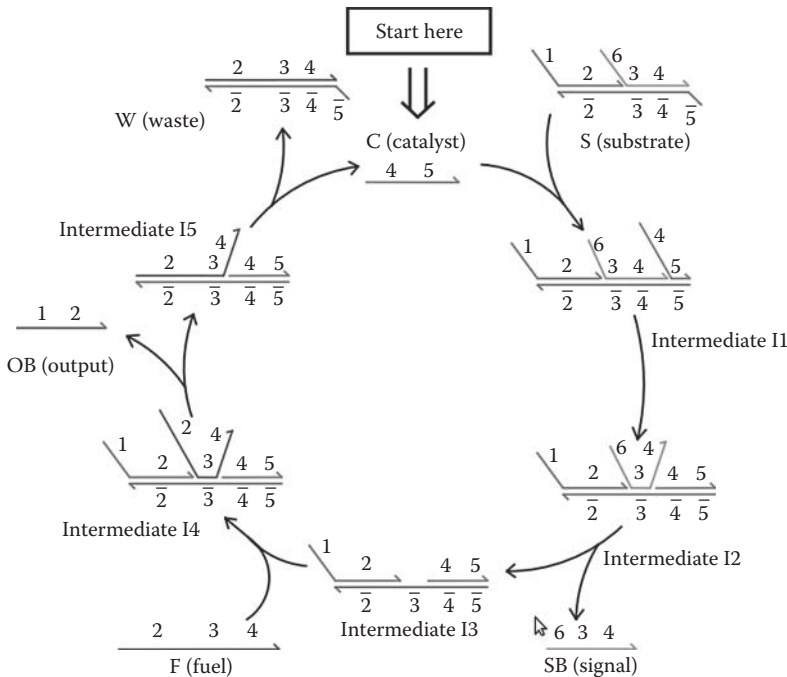

FIGURE 25.11 Entropy-driven catalyst by [127]. **C** (catalyst) first binds to the single-stranded toehold domain 5 on **S** to form the four-stranded intermediate **I1**, which then rearranges (by branch migration) to form **I2**. The binding between toehold domains 3 and 3 is too weak to keep **SB** attached, so **I2** spontaneously dissociates into **SB** and **I3**. Newly exposed 3 then facilitates the binding of **F**, resulting in **I4**, which then quickly rearranges to release **OB** and **I5**. Finally, **I5** rearranges so that **C** is attached only by the binding of 5 and 5, which spontaneously dissociates to leave **W** (waste) and regenerate **C**.

Reference [127] demonstrated an SDRN detector driven by entropy increase. The input DNA strand displaces the output from the DNA substrate via a toehold-mediated strand-displacement reaction. The input is released back into the solution by a fuel strand that displaces it from the substrate. The net effect is the fuel replacing an output molecule on the substrate, with the input acting catalytically. The direct displacement of output by fuel, in the absence of the input, is kinetically infeasible due to the lack of a toehold. This simple SDRN detector, like HCR, exhibits linear kinetics. However, when the output from one such SDRN detector is funnelled as input to a second such detector, the overall detector exhibits quadratic kinetics. Even an auto catalytic system where the output feeds back into the detector and a cross-catalytic system were demonstrated. These feedback systems exhibit exponential kinetics and hence detect input quickly. However, they suffer from higher leak rates, limiting sensitivity. The catalytic pathway is shown in Figure 25.11.

Reference [119] adapted a hairpin-based SDRN detector to allow it to exhibit exponential behavior. Their cross-catalytic system consists of two hairpins trapped in a metastable state. The hairpins are triggered by input and form a double-stranded complex with single-stranded overhangs and, in the process, release the input back into the solution. One of the single-stranded overhangs of the complex also acts as a catalytic trigger, resulting in exponential kinetics (Figure 25.12). The sensitivity of this SDRN detector is comparable to that obtained in [127].

25.3.3 DNA Replicators

Scientists have long tried to discover the origin of life. What was the sequence of steps that nature took, in order to create life as we now know it. Given that initially there was just matter, nature used energy from different sources and made autonomous self-replicating cellular machinery. With the discovery of

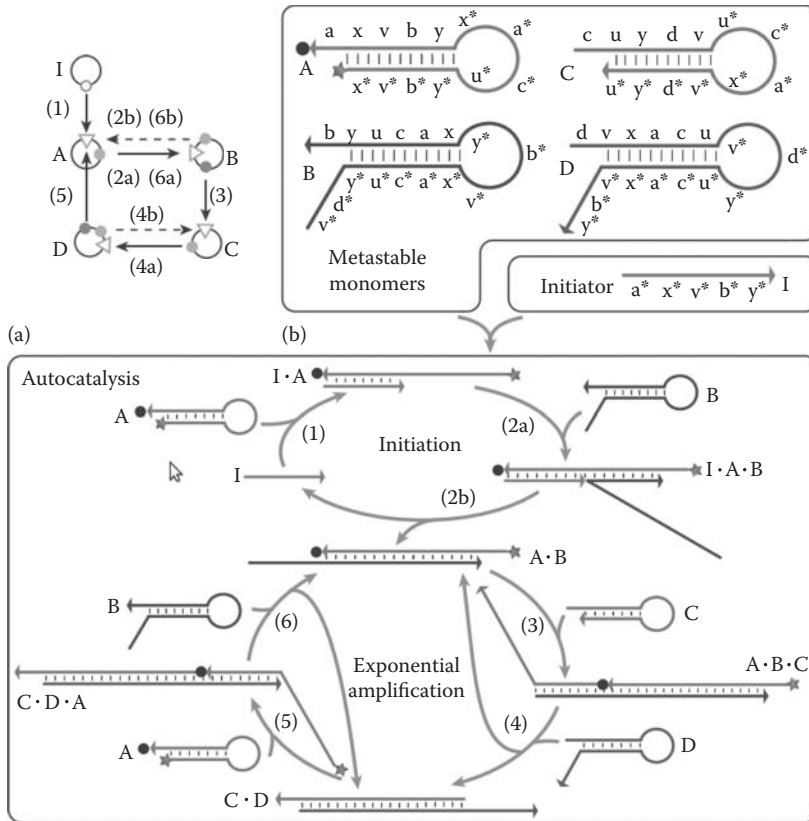

FIGURE 25.12 Hairpin-based cross-catalytic detector by [119] four hairpin species, A, B, C, and D, coexist metastably in the absence of initiator I (In b). The initiator catalyzes the assembly of hairpins A and B to form duplex ANB (steps 1–2, bottom), bringing the system to an exponential amplification stage powered by a cross-catalytic circuit: the duplex ANB has a single-stranded region that catalyzes the assembly of C and D to form CND (steps 3–4); duplex CND in turn has a single-stranded region that is identical to I and can thus catalyze A and B to form ANB (steps 5–6). Hence, ANB and CND form an autocatalytic set capable of catalyzing its own production.

the hereditary material DNA and RNA, it has been speculated that nucleic acids contain all the information required in order to completely define an organism and that the replication of these constituents is sufficient to ensure the replication of the entire organism.

Scientists at the Craig Venter Institute have created synthetic life, by artificially synthesizing a bacterial chromosome, with all the genes necessary for self-replication, and using it to boot up a cell and creating many copies of the same [26]. They ruled out the cause of self-replication being some external contaminant, by placing watermarks within the artificial DNA and re-sequencing the DNA from the cell copies, to prove their claim. However, this cell makes use of various biological molecules (enzymes) already engineered by nature to aid in the replication of an organism. How did organisms first gain the ability to self-replicate in the absence of these enzymes?

Attempts to answer this question have been made by the RNA world, who believe RNA was the first self-sustaining molecule, before DNA was chosen to be the information-bearing constituent of a cell. RNA, unlike DNA, is highly versatile and can perform ligation [24] and polymerization [39], which argue in favor of it being enough to self-replicate an organism. However, the hypothesis that nature accidentally created RNA is highly debated. Many believe that in a pre-RNA world, another molecule(s) was the hereditary material, which could transfer information to and from RNA. Recent research in synthetic molecules such as XNA and TNA is an attempt to resolve questions in this direction.

FIGURE 25.13 A seven-tile DNA replicator [107]. Replication of the seven-tile seed pattern in the first generation. In step 1, strands are annealed into tiles, all flanked by the same connectors, designated Y and Z. The initiator tile (19) contains a protected S-strand, paired with a cover strand, 6C. The B9 tiles contain the 4-hairpin markers for AFM imaging. In the presence of the seed (step 2), the strands assemble into a pattern mimicking the seed pattern. The magnetic dynabead (large gray circle) is prepared in step 3 and attached to the seed (step 4). This is followed by a wash step, the addition of linkers, and their annealing (steps 5–7). Heating the system to 37°C results in the separation of the daughter 7-tile complex and the seed (removed magnetically, using the dynabead).

What about in the absence of enzymes? An example of a nonenzymatic self-replicating system is by Zhang and Yurke [17]. As in other template-based self-replication proposals, their initial system consists of a templated structure. In order to replicate, they exploit the physical properties of DNA (persistence length), in order to cause fission in this structure, leading to two partial copies. A sequential addition of constituents leads to two complete structures being formed. Another theoretical model is by Chandran, Gopalkrishnan, and Reif, which they term meta-DNA [13]. This system consists of a template based on DNA nanotechnology, where a basic unit is a T-junction tile. Coupling multiple such tiles together forms a template, and they emulate a huge set of enzymatic operations, including polymerization, that can be done in this model.

There have been a few experimental models of self-replication in DNA nanotechnology as well. Scientists at NYU [107] use the BTX tile motif and have created an organism P (parent) made up of 7 such BTX tiles. Organism P acts as a template on which self-replication can be done. In order to self-replicate, a set of BTX tiles that represent the complement of P are added to the mix. This aids the formation of a daughter organism D, which in turn acts as a template again, and aids in the formation of a grandchild G, which is a duplicate of P, in terms of the set of tile motifs that both are made up of. This mechanism is depicted in Figure 25.13. In each replication step, a certain amount of error is introduced into the system, not unlike natural self-replication, where mutations are common. In this system, after two replications, about 31% of the original sequences are retained.

Another experimental demonstration of self-replication is by Schulman et al. [82], who attempt the problem of self-replication from a computer science perspective. They encode information in a set of DNA tiles and induce growth via self-assembly. They have a proofreading mechanism built in, in order to reduce the amount of errors in bit copying. Next, they induce scission in the tiles, that is, they break it apart by mechanical stress. These pieces of assemblies now act as separate growth fronts for self-replication, hereby starting a new cycle of replication. As compared to Seeman's model, about 76% of the original bits are propagated to the next set of organisms.

25.3.3.1 Conclusions and Open Problems

There have been several attempts to design enzyme free DNA/RNA-based replicators, but none are convincing enough to reliably say that life could have originated via a particular route. Indeed, there could be different pathways via which life came to exist as we know of it today, and building different systems will only bring us closer to discovering this. There are several characteristics of these systems, however, that one must appreciate. First, there is a distinction between self-replicating systems and self-reproducing systems, and life, we believe, might have originated from the former. Also, we must account for the environmental conditions in which these systems might have evolved in nature. DNA replicators are an attempt to designing such robust template-based self-replicating systems.

25.3.4 DNA Nanorobotic Devices

25.3.4.1 DNA Walkers

25.3.4.1.1 Introduction

Molecular motors exist in nature, and many motor proteins of the dynein, kinesin, and myosin families—that have been identified are known to support the tasks and functions that are essential to life. One of the goals of nanoscience is the ability to synthesize molecular motors that are programmable and capable of operating autonomously. Drawing inspiration from nature, many examples of such synthetic motors have been designed. DNA poses a relatively easy material to use as the building block for these motors, due to the fact that its components are well understood compared to other materials at the nanoscale [72].

Walkers are synthesized DNA systems that are able to move on a substrate. A major ambition for those designing and experimenting with DNA walkers is to be able to design autonomous systems that

can be easily controlled and programmed with specific functions. Autonomy in this case is defined as a system's ability to function in an environment without external intervention such that when the source of energy that drives it is depleted, the system halts [123].

Investigators have attempted to alter the method by which the walker moves, the substrate that the walker is moving on, or the fuel source that powers the walker in order to fully realize these two goals. In addition, investigators have also shown that walkers can perform specific tasks as proof of their viability and potential, such as transporting cargo [121], moving along different programmable pathways [52,72], assembling other structures [33], or performing controlled multistep chemical reactions [35]. One can divide the different classes of walkers in terms of (1) their degree of autonomy or (2) the type of fuel that powers these walkers or (3) both. We will start by looking at walkers with minimal autonomy, which respond to changes in their environment. Next, we will cover walkers powered by enzymes, followed by those that are driven by strand-displacement reactions, and finally we will address walkers that are considered autonomous as of this writing. In this section, the terms stators, anchorage sites, or footholds on a track have been used interchangeably, to denote a place where the walker can attach to, on a track or substrate.

25.3.4.1.2 Environmentally Driven Walkers

Nanomachines that function through the introduction of environmental alterations, such as variations to the pH of the solution, salt concentration, or the introduction of agents that cause synthetic DNA to change its conformation or shape, are considered nonautonomous, due to the fact that these nanomachines are heavily dependent on external intervention. Such environmental characteristics have been observed since the early 1970s (see [15,48,66] for some early examples) and later demonstrations of conformational changes based on the properties of the i-motif (see [46,48–51,58]). However, walkers that operate by means of environmental changes have only recently arisen.

Wang et al. [105] demonstrate the operation of a walker that switches back and forth between two sites on a track (Figure 25.14). Each site is made up of a single strand of DNA that is partially hybridized to the track, with a loose, dangling region (15 bp) that acts as the binding site for the walker. The sites are separated by 15 nt, and the first site is made up of an i-motif DNA strand, which collapses onto itself in an acidic environment (pH 5) and switches back to a loose conformation in an alkaline solution (pH 8; for more details, see [45]). Initially, when the walker is introduced, it hybridizes with the first site if the solution is alkaline. Once the solution becomes acidic, the strand of the first site forms a compact i-motif

FIGURE 25.14 A walker powered by the pH levels of its environment. (From Wang, C. et al., *Chem. Commun.*, 47(5), 1428, 2011.)

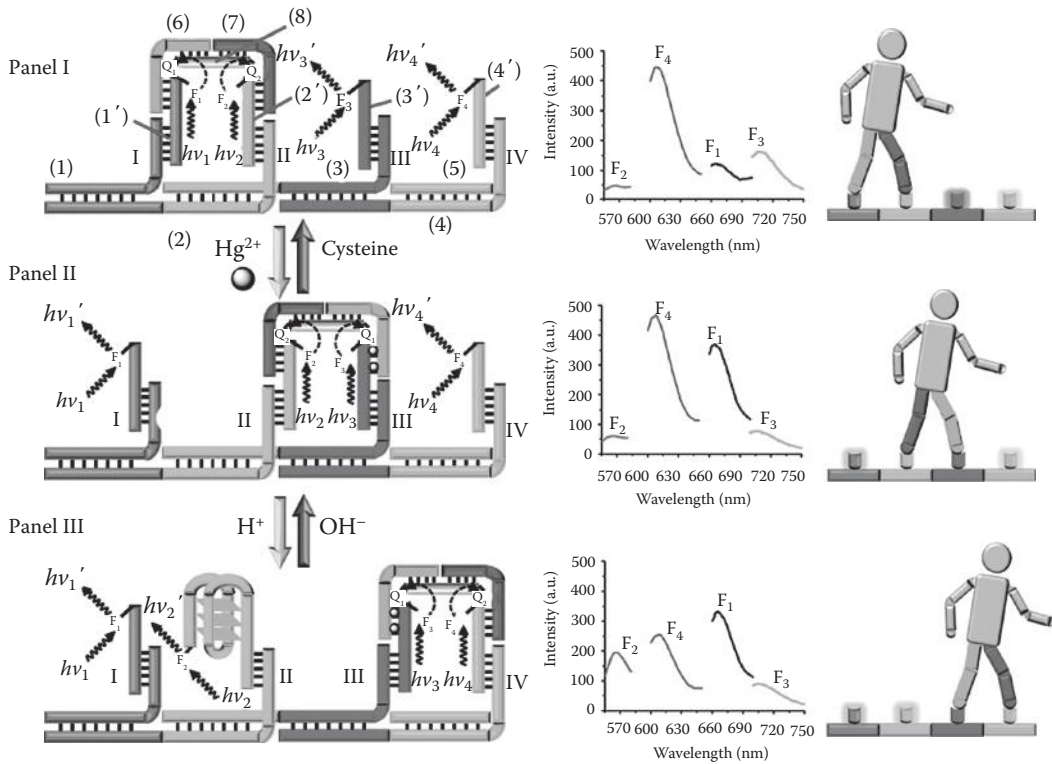

FIGURE 25.15 A walker that moves using both the i-motif, and Hg^{2+} and cysteine. (From Wang, Z.G. et al., *Nano Lett.*, 11(1), 304, January 2011.)

structure, which causes the walker to dissociate from the first site and hybridize with the second site. The limitation of this design is that the walker strand can only move back and forth between two sites, without progressing any further.

Another example is the bipedal walker and stepper by Wang et al. [109] (Figure 25.15). This walker operates using four footholds (I, II, III, IV), each having a partially complementary strand attached to the track, such that the noncomplementary site (1', 2', 3', 4') in Figure 25.15 acts as a sticky end for the walker to attach to. The sticky end of the second foothold is an i-motif. The walker is made up of two strands, each partially hybridized to a scaffold strand (8). Activation occurs by adding Hg^{2+} , which causes the formation of a thymine- Hg^{2+} -thymine bridge on the third site and moves the walker to the second and third footholds. If the acidity of the solution is increased (increasing H^+), the i-motif on the second foothold creates a compact structure, leading the walker to disassociate from it and attach to the fourth site, such that it is now bound to the third and fourth sticky ends. This walker can cycle back to its original state. Increasing alkalinity, which causes the i-motif to deprotonate and take on the conformation of a random coil, causes the walker to dissociate from the last site and hybridize with the second site. Adding cysteine causes the thymine- Hg^{2+} -thymine bonds to break from the third site and return to the original state of hybridization. The authors also describe an extension of this design to create a bipedal walker that moves on a circular track, with footholds attaching outwardly on the scaffold of the track.

25.3.4.1.3 Enzymatically Driven Walkers

Next we discuss walkers that operate via enzymatic reactions. The first such walker was introduced by Reif et al. [121], where a unidirectional walker was able to move from one site to another by the introduction of cleaving and ligating enzymes that targeted specific sites between the walker and the footholds at

FIGURE 25.16 A unidirectional walker powered by enzymatic reactions. (From Yin, P. et al., *Angew. Chem. Int. Ed.*, 116(37), 5014, 2004.)

each state of movement. The walker is composed of 6 nt that walk over three anchorage sites (A,B,C) on a track (see Figure 25.16; the asterisk denotes the current location of the walker). The anchorage sites are attached via a “hinge,” a 4 nt single strand of DNA, which adds flexibility to the sites. The walker starts off at the first anchorage site (A), and when Ligase (step I) is added, it causes the walker to ligate with the second anchorage (B), which creates a recognition site.

When the restriction enzyme (PflM I) is added, it cleaves the two anchorages such that the walker ends up on the second site. This cycle gets repeated in steps III (ligase) and IV (restriction enzyme BstAPI). Note that the restriction sites of PflM I and BstAPI are different, causing the walker to move in a unique direction. Other notable bidirectional walkers [7,100] are enzymatically driven, such as the walker by Bath et al. [7]. This walker uses a “burnt-bridge” mechanism [54], where random walks are biased in one direction, preventing the walker from moving backwards with a certain probability on a track with weak “bridges” or stators. The walker in this case cleaves the stator that it is hybridized to through a restriction enzyme, which moves the walker forward to hybridize with the next stator. Since the previous stator(s) is “burnt,” the walker is much less likely to hybridize with them; then it is to stay with the current stator, until another restriction enzyme cut catalyzes its next move.

FIGURE 25.17 Stepwise observation of a walker moving along a DNA origami substrate. (From Wickham, S.J. et al., *Nat. Nanotechnol.*, 6, 166, February 2011.)

Sekiguchi et al. [89] demonstrate another enzymatic walker. They designed a unidirectional walker which moves along a predetermined path composed of a pattern of footholds. The walker is composed of three legs, with additional parts that anneal and cleave the different stators on the track to move forward.

The last example is a walker by Wickham et al. [111] (based on their earlier walker [7]) where a walker of length 16 bp walks over 16 stators, each separated by approximately 6 nm in a track of approximately 100 nm on a rectangular DNA origami (Figure 25.17a). The walker is powered by a nicking enzyme, which can only act once the walker strand is hybridized to the stator strand (hence, the enzyme operates in a stepwise fashion). The movement of the walker was directly observed using real-time AFM as it traversed the origami stators. The walker is initially hybridized to the starting stator. The addition Once the walker forms a duplex with the stator, the nicking enzyme targets a specific site on the backbone of the stator, creating a nick in the DNA backbone 6 nt from the 5' end (Figure 25.17b). The nicked strand (6nt) dehybridizes and floats away, creating a toehold. The adjacent stator hybridizes to the walker via the toehold, and displaces the current stator via toehold mediated strand displacement, moving the walker to the adjacent stator. This process is repeated with each stator until the last stator is reached, which does not contain the nicking recognition site. This stops the walker from further movement. Hairpins were added as an AFM imaging reference parallel to the track. In addition, FRET experiments were run by having the walker carry a quencher with it that reacts with different fluorophores on the track to determine when the walkers reach specific points on their tracks.

25.3.4.1.4 Walkers Driven by Strand-Displacement Reactions

Strand-displacement reactions involve the use of a short, unhybridized portion (called a *toehold*) of a strand in a duplex to mediate the displacement of its complementary hybridized strand. These reactions can be designed to power walkers, as seen in the first demonstration by Seeman and Sherman [91], where a biped walker used set and unset strands to move along a three foothold track. Figure 25.18 shows a cartoon depicting individual steps of the walker. Figure 25.18a shows two sets of strands “Set 1A” and “Set 2B,” to keep the walker attached to the footholds. In Figure 25.18b, an unset strand “unset 2B” uses toehold-mediated strand displacement to unbind the “set 2B” strand from both the biped’s foot and the foothold strands. This creates a duplex waste product (Figure 25.18c), and causes the biped’s foot to dissociate from the foothold. In Figure 25.18d, strand “set 2C” is added, which causes one foot of the walker to hybridize to foothold 2C. In Figure 25.18e, “unset 1A” detaches the left foot, and in Figure 25.18f, “set 1B” attaches the left foot to foothold B. In this manner, the walker is propelled forward.

The walker by Shin and Pierce [92] is similar to Seeman’s walker, except that the trailing foot starts the motion forward along the track, while the leading foot keeps the walker attached to the track.

FIGURE 25.18 A biped DNA walker using set and unset strands to move at each step. (a) State 1A, 2B, (b) Starting unset, (c) State 1A, (d) State 1A, 2C, (e) State 2C, (f) State 1B, 2C. (From Sherman, W. and Seeman, N., *Nano Lett.*, 4, 1203, 2004.)

Other similar examples include Mao and Tian's circular biped walker [101], Bath et al. 's Brownian ratchet walker [31], and Dirks et al. 's autonomous cargo transporter [103].

Muscat et al. [61] demonstrated a more recent example, where the walker is composed of a cargo strand, powered forward by the introduction of a fuel strand (Figure 25.19). What distinguishes this walker is its usage of a combination of toehold hybridization and junction migration. In addition, the fuel strands are able to provide the walker with direction instructions.

Anchorage sites attached to a double-stranded track are made up of the domains $\overline{X}b\overline{c}$, where \overline{X} is unique to each site, while $\overline{b}\overline{c}$ are common to all. Note that $X = X_1 X_2$. A cargo strand abc can bind to anchorage site via hybridization with $\overline{b}\overline{c}$. The domain a is left to split (hence is called a split toehold) from the anchorage

FIGURE 25.19 A walker that is powered by split toehold hybridization and junction migration. (From Muscat, R.A., et al., *Nano Lett.*, 11(3), 982, March 2011.)

site and expose \bar{X} (an addressing domain that identifies the anchorage site). This exposure is key for the walker to function. Another split toehold (between toehold y and domain \bar{c}) is made at the second anchorage site, where the strand R_y (composed of Y_1, a, b and y) is partially complementary to the second anchorage site.

The fuel strand is made up of two main parts: one to hybridize with the first anchorage site and the other part to hybridize with the complementary strand of the second anchorage site (Figure 25.19a). The fuel strand starts by partially hybridizing to this identifying region first, which is called *split toehold hybridization* (Figure 25.19b). Afterwards, through junction migration, the fuel strand moves the cargo from the anchorage site onto its common binding domain (Figure 25.19c). Once that occurs, another split toehold hybridization reaction occurs, this time between y and \bar{c} and the now unsequestered complementary domains \bar{y} and the split toehold on the cargo strand c (Figure 25.19d). Through junction migration (Figure 25.19e), the cargo strand is finally moved onto the second anchorage site, and the fuel strand anchors R_y to the first anchorage site (Figure 25.19f).

Another example includes a transporter by Wang et al. [110], which is composed of two parts. The main nanostructure is composed of a 3-arm structure that has four footholds, three on the circumference and one at the center (Figure 25.20a). To each foothold, there is attached one strand each (A, B, C, A_x). This structure is named Module I. The second part of the system (Module II) consists of an arm that can transport a cargo strand (P_x) around the central axis in a circular fashion. Similar to the mechanism of set and unset strand displacement and unset strands seen earlier [91], the cargo strand is detached from the site; it is initially hybridized via the introduction of a fuel strand (Panel I, (Figure 25.20b))

FIGURE 25.20 A transporter that can move cargo along a circular track. (From Wang, Z.-G. et al., *Angew. Chem. Int. Ed.*, 51(18), 4322, 2012.)

complementary to that site. The arm is free to attach to the next site, B, (Panel II) until another fuel strand is introduced that essentially displaces the cargo strand from B to attach to C (Panel III). Anti-fuel strands can be introduced to reverse the sequence of movement. In order to ensure that the walker moves in the order specified, the duplexes that the cargo forms at each site were made energetically less stable than the previous site, starting from the first site A, to the last site C.

25.3.4.1.5 Autonomous, Programmable Walkers

The class of walkers described here are those that are considered programmable and autonomous. Reif and Sahu [72] introduced the theoretical design of an autonomous programmable RNA walker that acts

as a finite state machine. The machine is given instructions as input, and based on the previous input, it transitions to the next state on a 2D addressable lattice. The input instructions are fed as a sequence of hairpins, and DNazymes proceed to consume each instruction that the walker has already transitioned on, exposing the next instruction.

Another example is that of walkers that operate through multiple legs, or spiders in [64]. These spiders are comprised of a streptavidin core and DNazymes for legs which bind and cleave RNA sites on a substrate. The walker is biased and moves toward unvisited substrates. Dabby et al. [52] expanded on this work demonstrating a spider in Brownian motion on a preprogrammed pathway, in addition to making it respond to signals on the pathway which include stopping and turning.

One of the more recent examples given in [122] is an autonomous and controllable light-driven DNA walking device through the use of pyrene-assisted photolysis. The walker, a single strand, is thought of as having two legs, one on each end. The 3' end is the shorter leg (7 nt), while the 5' end has the longer leg (16 nt). Both the legs are linked together by pyrene (Figure 25.22—step 1). The anchorage segments are linked together by a weak disulfide bond (black dot). Using a fluorometer, a light source at 350 nm was used to initiate photolysis. The pyrene molecule cleaves the disulfide bond in the anchorage site, and as a result, the 7 nt segment on the anchorage site floats away. The short leg then hybridizes with the next anchorage site, and through toehold-mediated strand displacement, the long leg hybridizes to its complementary segment on the next anchorage site. This process is repeated up to step n , if there are n anchorage sites. To bias the direction of movement, a “burnt-bridge” mechanism was used.

However, this walker is difficult to control due to its autonomous movement. You et al. [123] altered this walker to make another light-powered DNA walker with reversible movement, depending on the

FIGURE 25.21 A reversible walker powered by (a) visible [122].

FIGURE 25.21 (continued) A reversible walker powered by (b) UV light irradiation. (From You, M. et al., *Angew. Chem. Int. Ed.*, 51(10), 2457, 2012.)

light's wavelength. In visible light, the walker moves forward, whereas UV light irradiation moves the walker backwards on a track. The anchorage site toeholds, also known as anchorage extender segments, have a different number of azobenzene molecules (one incorporated between every two bases of the toeholds). Azobenzene is a chiral molecule, and it switches its conformation from cis to trans when it is exposed to light wavelengths greater than 465 nm. The reverse is also true, namely, it switches back to cis in the presence of light with wavelength less than 465 nm.

The trans conformation of azobenzene stabilizes the double helix, while the cis conformation destabilizes it. Hence, in visible light, the walker moves from left to right towards the longer strand, which is the more stable duplex (Figure 25.21a). In UV light, however, azobenzene switches from trans to cis, destabilizing the helix. This causes the walker to reverse direction, preferring the more stable hybridization with the first site, again moving via toehold-mediated strand displacement (Figure 25.21b).

25.3.4.1.6 Discussions

DNA walkers are stepping stones to constructing DNA systems that have dynamic behavior, and are able to perform mechanical tasks at the nanoscale. By programming the directed movement of DNA molecules along a track, we can target the walker to deliver cargo reliably, send or receive information, and achieve nanoscale synthesis.

Multistep biosynthesis has been demonstrated by Liu et al. [35]. They designed a DNA walker that performs the synthesis of a linear product, in the order specified by the placement of the anchorage sites on the DNA track. At each step, the walker builds on the product, by attaching the cargo at the current site to that of the prior sites. At the final step a resulting synthesized product is obtained, not unlike mRNA translation.

25.3.5 DNA Dynamical Systems

The behavior of DNA complexes can be controlled via the action of DNA enzymes that act upon specific sequences of DNA strands [74], competitive DNA hybridization [131], or environmental changes such as pH or temperature [108]. One of the first applications of strand displacement to a DNA nanomachine was the molecular tweezer by [124]. The dynamic behavior of the tweezer is controllable, using strand displacement. Other types of devices include walkers [70,121] and molecular detectors [20], both in vitro and in vivo [59,104]. Delebèque et al. [18] also made nanostructures within a cell. Reference [33] made a molecular assembly line. These and many other devices have been constructed and studied.

25.3.6 DNA Tiling Assembly

25.3.6.1 Models of Tile Assembly

In this section, we give a brief review of the theoretical models of self-assembly. In DNA self-assembly, a tile is the basic unit of assembly, with the initial state consisting of a set of unordered tiles, and the final state consists of an assembly formed by some or all of these tiles sticking to one another. Theoretical models of tile assembly have been developed to study the computational properties of self-assembly. Tile assembly dates back to 1961, when Wang [106] proposed the Wang domino problem. In his tiling model, a tile is a square with a glue on each side. For two tiles to attach, their abutting glues should be the same. Retroflexion and rotation of tiles are not permitted. The problem statement is: "Given a finite set of tiles, can they tile the entire plane." An infinite number of copies of each tile type are provided. A more general problem is: "Does there exist an algorithm that can decide if a finite set of tiles can tile the whole plane." It has been proved that such an algorithm does not exist and that the tiling problem is undecidable [9,75]. The proof shows that any instance of the Turing halting problem can be reduced to

an instance of the Wang domino problem. Since the halting problem is not decidable, hence the Wang domino problem is not decidable either.

Rothemund and Winfree proposed the abstract tile assembly model (aTAM) in 2000 [78]. In aTAM, a tiling system is modelled as a quadruple $\langle T, s_0, \tau, g \rangle$. (1) T here is the tile set. As in the Wang model, a tile in aTAM is a square with a glue on each side. All glues are from a glue set Σ . Retroflexion and rotation of tiles are forbidden. (2) s_0 is a special tile called the *seed tile*. At the beginning of the assembly process, only the seed tile is fixed at a particular position and the other tiles are floating in the plane. Assembly begins from the seed tile. (3) τ is the temperature of the system. When a tile is at a position, it will be fixed at that position if and only if the accumulative glue strength between this tile and tiles around it is not less than τ . (4) g is the glue strength function. It defines the glue strength between two glues. An assembly that grows from the seed tile can grow infinitely large, or it may terminate. A configuration is *terminal* if it cannot grow anymore. This happens when there is no additional site for a tile to attach to at temperature τ . In Winfree's original definition [78], the aTAM is formally defined in 2D, but it can be extended to multidimensions. The 2D aTAM has been proved to be the Turing universal [117].

We begin by introducing some important definitions in aTAM. (1) The tile complexity of shapes [78]. The tile complexity of a shape is the minimum number of tile types that *uniquely* assemble that shape. (2) The time complexity of assembling a shape [3]. This models how fast a shape can be assembled. The assembly process of an aTAM system can be modelled by a continuous Markov process. The states of the Markov process are the different tile assembly configurations. To proceed from one state to another, a tile(s) attaches or detaches from the growing assembly. The rate of transition from state S_1 to state S_2 is dependent on the concentration of tile x if S_2 is formed by attaching x to S_1 . The time taken to reach the terminal state from the initial state is a random variable, and time complexity is defined as the expected value of this random variable.

One important problem in aTAM is the tile complexity and time complexity of assembling a fixed-shaped assembly. The fixed shape used by Winfree and Rothemund is an $N \times N$ square, where N is any positive integer. In other words, "What is the minimum number of tile types needed to construct an $N \times N$ square at temperature τ ?" and "What is the minimum expected time needed to construct an $N \times N$ square at temperature τ ?"

Rothemund and Winfree give a construction to show that the upper bound of tile complexity of assembling $N \times N$ square in a $\tau = 2$ system is $O(\log N)$ [78]. The basic idea of their construction is to use $O(\log N)$ tile types to build the frame of an $N \times N$ square and then use a constant number of tile types to fill the frame. The frame has two components: a counter of size $N \times \log N$ that grows toward the north and a diagonal of the $N \times N$ square that grows toward the northeast. They also proved a tile complexity lower bound $\Omega(\log N / \log \log N)$ for the same, using the Kolmogorov complexity. This lower bound is true for infinitely many N . The question is whether there exists a construction that can reach this lower bound to prove that it is tight.

In 2001, Adleman et al. [3] proved that the lower bound is indeed tight. Adleman et al. proposed a new construction of tile complexity $\Theta(\log N / \log \log N)$ that reaches the lower bound proved by Rothemund and Winfree. Their original construction is a $\tau = 3$ construction, but can be generalized to $\tau = 2$. The trick to improve the tile complexity was the technique by which they encoded a number. Rothemund and Winfree encoded N in base 2 (binary), and this technique led to the $O(\log N)$ tile complexity. In the new design by Adleman et al., they encoded the number in base $\Theta(\log N / \log \log N)$. This strategy reduced the tile complexity to $\Theta(\log N / \log \log N)$.

Adleman et al. also generalized Winfree's aTAM by incorporating time complexity to the original model. The construction of tile complexity $O(\log N)$ from Rothemund and Winfree was proved to have $\Theta(N \log N)$ time complexity. Adleman et al. gave a time complexity of $\Theta(N)$, which is optimal for assembling an $N \times N$ square.

Many variants of the aTAM have been developed. Winfree developed the kinetic tile assembly model (kTAM) [114] to model the kinetic properties of crystal growth. This model is based on four assumptions

that are essential to it. Aggarwal et al. [4] developed generalized models including the multiple temperature model, flexible glue model, and q-tile model. Sahu et al. [99] proposed the time-dependent glue strength model. In their model, the glue strength between two glues increases with time, until it reaches a maximum. The advantage of this model is that it can model catalysis and self-replication. Reif [71] proposed the stepwise assembly model in 1999. In this model, the assembly process is done by multiple steps. At each step, a separate assembly with a different tile sets and different temperature is created. Only the terminal product of one step is given as input to the next step. The terminal product of the final step is the terminal product of the whole system. We give more details of Reif's model in Section 25.3.6.6. In 2008, Demaine et al. proposed a generalized stepwise assembly model called the *staged assembly model* [19]. They also gave strategies to assemble shapes with $O(1)$ glues under their model. It has been proved that both the stepwise assembly model and the staged assembly model are the Turing universal at temperature 1 [6].

25.3.6.1.1 Theoretical Results of Self-Assembled Shapes

All constructions earlier try to store the information of the target shape in the tile set. This implies the need for a larger tile set to, assemble a target shape of a larger size. However, it is not feasible to synthesize a large number of tile types in practice. There are many constraints to implementing large tile sets such as the length of the pad, spurious reactions among pads of same tile, and sequence design.

An alternate strategy is encoding the information of target shapes in the concentrations of tile types. By this strategy, we can reduce the tile complexity of some self-assembled shapes to $O(1)$ [21,40]. Kao and Robert proposed a random assembly construction for approximate squares [40] by encoding the shape information in the tile concentration. By their construction, an $N \times N$ square can be assembled from a constant number of tile types with high approximation factor and high probability where N should be large enough. The question is whether there exists a construction of $O(1)$ tile complexity that assembles an exact $N \times N$ square with high probability. Doty published such a design in 2009 [21].

The problem of storing shape information in the tile concentration is that it is difficult to control the concentration precisely during the reaction process. Other methods to reduce the tile complexity include attempts by Reif in 1999, the stepwise assembly model [71]. Demaine proposed a generalized version of the stepwise assembly model called the *staged assembly model* [19]. The basic idea of these two models is assembling the target shape by multiple steps. This strategy can reduce the tile complexity efficiently [19,38]. The cost is stage complexity and bin(or tube) complexity [19,38].

25.3.6.2 Tile Assembly Experimental Methods

There are several DNA motifs that are used to design DNA tiles. These include DX and TX motifs [41,116] (Figures 25.23 and 25.24). DNA holliday junctions [25], and DNA origami [76]. These motifs are made stable by the incorporation of *crossover* junctions, where a DNA strand is initially bound to a strand, crosses over, and starts binding to another strand.

A motif attaches to a growing assembly via intermolecular contacts called *sticky ends*. These are complementary single-stranded DNA, which bind to each other once in close proximity. Arbitrarily complex tile

FIGURE 25.23 An example of a DX Tile. (From E. Winfree, F. Liu, L. Wenzler, and N. Seeman, Design and self-assembly of two-dimensional DNA crystals, *Nature*, 394:539–544, 1998.)

FIGURE 25.24 An example of a TX Tile. (From T. LaBean, H. Yan, J. Kopatsch, F. Liu, E. Winfree, J. Reif, and N. Seeman, Construction, analysis, ligation, and self-assembly of DNA triple crossover complexes, *Journal of the American Chemical Society*, 122(9):1848–1860, 2000.)

assemblies can be made using a small number of component tiles where each tile specifies an individual step of the computation. One of the first 1D experimental demonstrations after Adleman's travelling salesman [2] was the computation of a cumulative XOR function. The inputs were x_1, x_2, x_3, x_4 , and the outputs were y_1, y_2, y_3, y_4 where $y_i = y_{i-1} \text{ XOR } x_i$ and $y_1 = x_1$. A sample computation with input $x_1x_2x_3x_4 = 1110$ and output $y_1y_2y_3y_4 = 1011$ can be seen in Figure 25.25b in four steps by the self-assembly of DNA TX tiles [56]. Binary inputs are encoded in a DNA tile each, and the presence of a unique combination of input tiles results in the formation of a unique set of output tiles, seen in Figure 25.25a.

A more complex construction was the set of 2D DNA Sierpinski triangles made by Rothemund et al. [77]. They designed a 1D cellular automata, whose update rule computes a binary XOR, and the assembly results in a fractal pattern. A detailed design is in Figure 25.26. AFM images can be seen in Figure 25.27. These constructions give evidence that DNA can perform the Turing universal computation and has the ability to implement any algorithmically computable system.

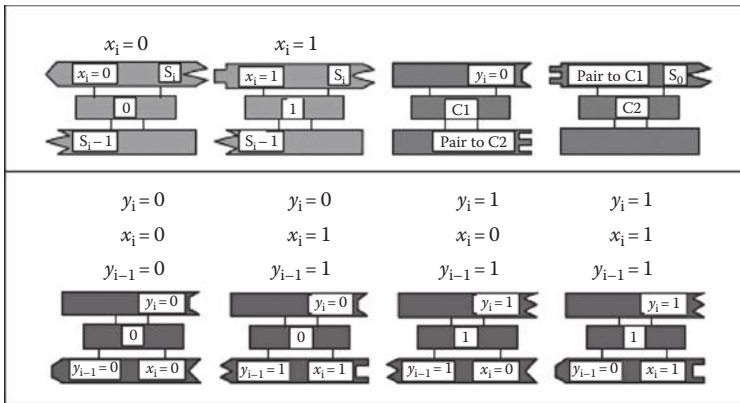

25.3.6.3 Tile Assembly Design and Simulation Software

Computer-aided design (CAD) softwares help molecular architects in the design of DNA-based tiles. To design the DNA sequences of these tiles, sequence symmetry minimization [87] is a common technique used to avoid spurious DNA strand interactions. Tools used in the design of such tiles are NanoEngineer [36], Tiamat [112], TileSoft [120], and GIDEON [10]. Another tool, caDNAno, developed by Douglas et al. [23], primarily designed for the use of DNA origami, can also be used for the same.

Simulating the behavior of DNA-based tiles yields useful theoretical results, which can help predict the kind of errors we should expect when using DNA tiles for computation or construction. Winfree wrote a simulator Xgrow [114] as part of simulating the kTAM (kinetic TAM) model, with extensions to it from [5]. Another simulator is ISU TAS, developed by Patitz at Iowa State University [63].

25.3.6.4 One-Dimensional DNA Tiling Assemblies

In this section, we will give a brief review of probabilistic linear tile assemble model (PLTAM) and results under this model [12]. Assembling linear structure of given length is an important problem in self-assembly both theoretically and experimentally. Many complex structures can be made from linear structures. One question is how big the smallest tile set that assembles linear structure of length N is. If the linear assembly process is deterministic, it can be proved that the smallest tile set to assemble linear structure of length N is of size N .

(a)

(b)

FIGURE 25.25 Calculation of cumulative XOR by self-assembly of DNA tiles. (a) Component tiles. The three helical domains are drawn as rectangles, flanked by sticky ends shown as geometrical shapes. The value of each tile is in the central rectangle. The meaning of each sticky end is also indicated. Shown are the two x tiles (top left), four y tiles (bottom row) and the initialization corner tiles C1 and C2 (top right). The y_i tiles are upside down from the x_i tiles. (b) The values of each tile are the same as in (a), and the sticky ends are the same. Note the complementarity of sticky-ended association at each molecular interface. The operations are designed to proceed from lower left to upper right, because the x_i and C1 and C2 tiles have longer sticky ends than the y_i tiles. (From Mao, C. et al., *Nature*, 407, 493, 2000.)

Chandran et al. proposed a probabilistic linear tile assembly model [12], where “probabilistic” means that given a tile type, there may be multiple tile types that can attach to its western or eastern pad and “linear” means that tiles in this model only have two pads: western pad and eastern pad. They also developed three schemes under PLTAM to assemble linear structure of expected length N with tile complexity $\Theta(\log N)$, $O(\log^2 N)$ and $O(\log^3 N)$. All schemes are for equimolar standard linear assembly system. A linear assembly system is standard if and only if it is halttable, east growing, diagonal, and uni-seeded where “halttable” means that the assembly process can stop, “east growing” means that the assembly process is from west to east, “diagonal” means that the glue strength between two glues is 0 if they are different and otherwise the strength is 1 if the glue is not null glue, and “uni-seeded” means that there is only one seed tile. It can be proved that standard systems can simulate a larger set of systems. The reason why they focus on equimolar system is that equimolar system is more practical.

FIGURE 25.26 The XOR cellular automaton and its implementation by tile-based self-assembly. (a) Left: Three time steps of its execution drawn as a spacetime history. Cells update synchronously according to XOR by the equation shown. Cells at even time steps are interleaved with those at odd time steps; arrows show propagation of information. Right: the Sierpinski triangle. (b) Translating the spacetime history into a tiling. For each possible input pair, a tile $T-xy$ that bears the inputs represented as shapes on the lower half of each side and the output as shapes duplicated on the top half of each side. (c) The four Sierpinski rule tiles, $T-00$, $T-11$, $T-01$, and $T-10$, represent the four entries of the truth table for XOR: $0 \text{ XOR } 0 \rightarrow 0$, $1 \text{ XOR } 1 \rightarrow 0$, $0 \text{ XOR } 1 \rightarrow 1$, and $1 \text{ XOR } 0 \rightarrow 1$. Lower binding domains on the sides of tiles match input from the layer below; upper binding domains provide output to both neighbors on the layer above. (d) Error-free growth results in the Sierpinski pattern. (From Rothmund, P. et al., *PLoS Biol.*, 2, 424, 2004.)

The basic trick of designing these three schemes is simulating some well-designed stochastic processes by linear tile sets. One issue is that all three schemes do not have a sharp tail bound of assembly length for a general N . What has been proved is that the $O(\log^3 N)$ scheme has sharp tail bound for infinite many N , and for large enough N , we can get sharp tail bound by dividing N into numerous identical chunks. Therefore, the open problem is whether there exists a scheme of $o(N)$ tile complexity with sharp tail bound of assembly length for general N .

25.3.6.5 Three-Dimensional DNA Tiling Assemblies

3D assemblies are a natural extension to the construction of 2D assemblies. Cook et al. [16] ask the question: *What is the number of tile types needed to create an $N \times N$ 2D square, using a 3D tile system?* In a 3D tile system, a Wang tile is replaced by a Wang cube, each cube having six faces and hence six glues. They give a construction showing that using $O(\log n)$ tile types (cubes in 3D) can be used to construct an $n \times n$ square, at temperature 1, as opposed to the temperature 2 result by Rothmund and Winfree [78].

Constructions have been done using 3D Wang assembly models that are used to solve NP-complete problems such as maximal clique [53]. The computational power of this system is the Turing universal as

FIGURE 25.27 AFM images of DNA sierpinski triangles. (a) A large templated crystal in a 5-tile reaction. A single 1 in the input row initiates a Sierpinski triangle. (b) A zoomed in region of (a) containing roughly 1000 tiles and 45 errors. (c) A close of up a Sierpinski triangle. Crosses in (b) and (c) indicate tiles that have been identified (by eye) to be incorrect with respect to the two tiles from which they receive their input. Scale bars are 100 nm [77]. (From Rothmund, P. et al., *PLoS Biol.*, 2, 424, 2004).

suggested by Winfree in [117], since it is a superset of the 2D tiling problem, but the additional computing power of this system at different temperatures has still to be ascertained.

25.3.6.6 Stepwise Tiling Assemblies

In this section, we will give a brief review of Reif's stepwise assembly model [71]. Reif's model reduces the tile complexity by dividing the assembly process into steps. It has been proved that this strategy can efficiently reduce tile complexity [19,38]. A tiling system under the stepwise assembly model is a quadruple $\langle T, s_0, g, \Phi \rangle$, where $T = T_1 \cup T_2 \dots \cup T_m$ and $\Phi = \{\tau_1, \tau_2, \dots, \tau_m\}$. The assembly process has m steps. In the first step, tiles in T_1 including s_0 assemble in tube 1 at temperature τ_1 for a long enough time. The terminal product of step 1 is delivered to tube 2. Add T_2 to tube 2 and let tiles (or supertiles) in tube 2 assemble at temperature τ_2 for a long enough time. This process continues until the step m is complete. The terminal product of step m is the terminal product of the whole system. Mañuch et al. proposed schemes of $O(1)$ tile complexity to assemble an $N \times N$ square [38]. Behsaz et al. proved that the stepwise assembly model is the Turing universal at temperature 1 [6]. Demaine et al. proposed the staged assembly model in 2008 [19]. It is a generalized version of the stepwise assembly model.

25.3.6.7 Activatable Tiles: Transition of State across Tiles

Experimental demonstration of the Turing universal tile-based algorithmic DNA self-assembly has been limited by significant assembly errors. An important class of errors, called *co-ordinated growth errors*, occur when an incorrect tile binds to a growing assembly even when some of its pads are mismatched with its neighbors. Activatable DNA tiles, introduced originally by [55], employ a protection/deprotection strategy to strictly enforce the direction of tiling assembly growth that prevents these errors, ensuring the robustness of the assembly process. Tiles are initially inactive, meaning that each tile's pads are protected and cannot bind with other tiles. After an activation event, the tile transitions to an active state and its pads are exposed, allowing further growth.

25.3.6.8 Error Correction in Tiling Assemblies

In this section, we give a brief review of error-correction techniques in self-assembly. Tile assembly has been beset with different types of errors. These are broadly classified into growth errors and nucleation errors. Growth errors happen when a tile incorrectly binds to a growing assembly and propagates this error by causing other incorrect tiles to attach. Nucleation errors happen when an assembly does not grow from the seed tile, but it randomly starts growing using other tiles from the tile set.

Errors in assembly are usually reduced by two approaches. (1) Reducing the errors by optimizing the reaction environment [114]. By this approach, the inherent error rate is reduced. (2) Reducing the errors by optimizing the tile set design [73,115]. However, this approach can only reduce the amount of errors in the assembled pattern and cannot improve the inherent error rate. Winfree proposed an error resilient scheme by the second approach called *proofreading tile sets* [115]. The basic idea of his scheme is using a $k \times k$ block of tiles to replace each tile in the original tile set. Although it does bring down the error from ϵ to ϵ^k , this scheme has two problems. (1) It amplifies the assembly size. (2) It can only reduce the errors in the output, while the errors inside the assembly pattern are dismissed.

Reif et al. proposed a compact error resilient scheme [73]. The basic idea of their scheme is adding proofreading portions to pads. Their scheme does not amplify the assembly size and can reduce the errors inside the assembly pattern. The problem of this scheme is that it is not suitable to general case.

25.4 Summary

DNA computing has matured since Adleman used it to solve a 7-node instance of the Hamiltonian path problem. Adleman's original aim was to leverage the inherent parallelism of DNA for computation and its high information density for storage. DNA computation started with solving a set of "hard" problems interesting to computer scientists but has since evolved to have other applications. Scientists have used DNA devices for a variety of uses, such as in biosensors for molecular detection, diagnostic applications, in nanofabrication, for structure determination, and as potential drug delivery devices.

It is important to analyze the power of any computational device. This is in order to be able to judge it against other devices with similar functionality and to get an estimate of the theoretical limits of any device. This is why CRNs (Section 25.1.3) are important to model the DNA strand-displacement techniques that are inherent to quite a few DNA devices.

DNA can be used to perform complex nanofabrication tasks. Both periodic structures such as lattices [34,86] and nonperiodic structures such as a smiley face and world map [76] have been constructed using DNA. These structures can be used as scaffolds to place gates, transistors, and routing elements at precise locations and thus create circuits from the bottom-up, as opposed to traditional top-down, lithographic techniques. However, as we discussed in Section 25.3.6.8, errors are inherent to scaffold construction, and even without errors, the size of the scaffolds that can be created pales in comparison to that achievable by silicon-based lithography. A parallel line of research is not in using DNA as a scaffold but in using DNA itself to construct the circuit elements. These designs are quite promising as discussed in Section 25.3.1. Using such devices, it would be possible to have medical diagnostic biochemical circuits, with applications similar to Benenson's DNA doctor [90].

DNA devices that are involved in detection have been a steady focus area among scientists. There exists a large set of techniques that has led to the construction of these devices. DNA machines typically respond to external stimuli such as pH, salt concentration, temperature, and other signalling molecules (DNA, proteins) that lead to a change in their state. This mechanical state change is detectable by techniques such as FRET and has led to the development of sensors. In addition, logical operations can be performed on DNA motifs, and coupled with sensors, complex biological systems can be designed as drug delivery systems.

The programmable self-assembly of DNA has also enabled us to construct biochemical circuits that can perform synthesis of complex molecules. For example, DNA-directed synthesis has been shown to

be achievable using a variant of DNA walker systems [33,35]. Being programmable, the synthesis of any oligomer can be controlled at every step, not unlike the central dogma that dictates protein synthesis.

One of Seeman's original goals of constructing lattices of DNA was to use it to determine the structure of other foreign (protein) molecules via x-ray crystallography [88]. Most lattices created with DNA have a lot of defects, hence not making DNA very suitable for this use. However, with the latest advances in structural DNA nanotechnology, that goal and others seem to be finally in sight.

Key Terms

Antiparallel: Each DNA strand has a 5' and 3' end. When two strands bind to each other, the 5' end of one strand is adjacent to the 3' end of the other strand.

Aptamer: DNA molecule that binds to a select target molecule such as other nucleic acids and proteins.

Base pairing: The binding of A (adenine) to T (thymine) or G (guanine) to C (cytosine).

DNAzyme: A molecule made of DNA that possesses enzymatic activity, not unlike that shown by protein enzymes.

Locality: The property of different reactants being in close proximity, due to structural or environmental constraints, causing them to react faster.

Nucleotide: A molecule made up of three components, a 5-carbon (pentose) sugar molecule, a nitrogenous base (one of A, T, G, C), and a phosphate group.

Random walk: A random walk in 1D is the path taken by an object, in either one of the two directions: left or right. At each step, the next direction is determined by an independent fair coin toss.

Secondary structure: The entire set of base pairs formed in a given set of DNA strands, where nucleotides in a pair may lie on either the same strand or on different strands.

Sensitivity: Probability of an actual target (strand) being correctly identified.

26.1 Introduction

Computational electromagnetics (CEM) is a natural extension of the analytic approach in solving the Maxwell equations. In spite of the fundamental difference between representing the solution in a continuum and in a discretized space, both approaches satisfy all pertaining theorems rigorously. The analytic approach to electromagnetics is elegant, and the results can describe the specific behavior as well as the general patterns of a physical phenomenon in a given regime. However, exact solutions to the Maxwell equations are usually unavailable. Some of the closed-form results that exist have restrictive underlying assumptions that limit their range of validity (Harrington 1961). Solutions of CEM generate only a point value for a specific simulation, but complexity of the physics or of the field configuration is no longer a limiting factor. The numerical accuracy of CEM is an issue to be addressed. Nevertheless, with the advent of high-performance computing systems, CEM is becoming a mainstay for engineering applications (Taflove 1992, Shang 2002).

In the tier-structured CEM discipline, the time-domain method or the frequency domain method is restricted mostly to Rayleigh and resonance regions where the characteristic electric length is of the same order in magnitude as the electromagnetic wavelength. In a high-frequency spectrum or the optical region, all practical applications are supported by the ray tracing of the shooting-and-bouncing (SBR) ray technique. This approximation is based on either physical optics, theory of diffraction, or a combination of both (Bowman et al. 1987). The SBR algorithm is naturally suitable for concurrent computing. Exceptionally high computational efficiency has been consistently demonstrated in the applications for broadband antenna design, ultraband and optical communication, and synthetic aperture radar imaging. In order for the time-domain method to effectively venture into the optical domain, a combination of spectral-like numerical algorithm and concurrent computing is essential.

CEM in the present context is focused on simulation methods for solving the Maxwell equations in the time domain. First of all, time dependence is the most general form of the Maxwell equations, and the dynamic electromagnetic field is not confined to a time-harmonic phenomenon. Therefore, CEM in the time domain has the widest range of engineering applications. In addition, several new numerical algorithms for solving the first-order hyperbolic partial-differential equations, as well as coordinate transformation techniques, were introduced recently to the CEM community. These finite-difference and finite-volume numerical algorithms were devised specifically to mimic the physics involving directional wave propagation. Meanwhile, very complex shapes associated with the field can be easily accommodated by incorporating a coordinate transformation technique. These methodologies have the potential to radically change future research in electromagnetics (Taflove 1992, Shang and Gaitonde 1995, Shang and Fithen 1996).

In order to use CEM effectively, it will be beneficial to understand the fundamentals of numerical simulation and its limitations. The inaccuracy incurred by a numerical simulation is attributable to the mathematical model for the physics, the numerical algorithm, and the computational accuracy. In general, differential equations in CEM consist of two categories: the first-order divergence–curl equations and the second-order curl–curl equations (Harrington 1961, 1968, Elliott 1966). In specific applications, further simplifications into the frequency domain or the Helmholtz equations and the potential formulation have been accomplished. Poor numerical approximations to physical phenomena can result, however, from solving overly simplified governing equations. Under these circumstances, no meaningful quantification of errors for the numerical procedure can be achieved. Physically incorrect values and inappropriate implementation of initial and/or boundary conditions are another major source of error. The placement of the far-field boundary and the type of initial or boundary conditions have also played an important role. These concerns are easily appreciated in the light of the fact that the governing equations are identical, but the different initial or boundary conditions generate different solutions (Shang 2009).

Numerical accuracy is also controlled by the algorithm and computing system adopted. The error induced by the discretization consists of the roundoff and the truncation error. The roundoff error is contributed by the computing system and is problem-size dependent. Since this error is random, it is the most difficult to evaluate. One anticipates that this type of error will be a concern for solution procedures involving large-scale matrix manipulation such as the method of moments and the implicit numerical algorithm for finite-difference or finite-volume methods. The truncation error for time-dependent calculations appears as dissipation and dispersion, which can be assessed and alleviated by mesh-system refinements.

Finally, numerical error can be the consequence of a specific formulation. The error becomes pronounced when a special phenomenon is investigated or when a discontinuous and distinctive stratification of the field is encountered, such as a wave propagating through the interface between media of different characteristic impedances, for which the solution is piecewise continuous. Only in a strongly conservative formulation can the discontinuous phenomenon be adequately resolved. Another example is encountered in radar cross-sectional simulation, where the scattered-field formulation has been shown to be superior to the total-field formulation.

The Maxwell equations in the time domain consist of a first-order divergence–curl system and are difficult to solve by conventional numerical methods. Nevertheless, the pioneering efforts by Yee and others have attained impressive achievements (Yee 1966, Taflove 1992). Recently, numerical techniques in CEM have been further enriched by development in the field of computational fluid dynamics (CFD). In CFD, the Euler equations, which are a subset of the Navier–Stokes equations, have the same classification in the partial-differential system as that of the time-dependent Maxwell equations. Both are hyperbolic systems and constitute initial-value problems (Sommerfeld 1949). For hyperbolic partial-differential equations, the solutions need not be analytic functions. More importantly, the initial values together with any possible discontinuities are continued along a time–space trajectory, which is commonly referred to as the characteristic. A series of numerical schemes have been devised in the CFD community to duplicate the directional information-propagation feature. These numerical procedures are collectively designated as the characteristic-based method, which in its most elementary form is identical to the Riemann problem (Roe 1986).

The characteristic-based method when applied to solve the Maxwell equations in the time domain has exhibited many attractive attributes. A synergism of the new numerical procedures and scalable parallel-computing capability will open up a new frontier in electromagnetics research. For this reason, a major portion of the present chapter will be focused on introducing the characteristic-based finite-volume and finite-difference methods (Shang 1995, Shang and Gaitonde 1995, Shang and Fithen 1996).

26.2 Governing Equations

The time-dependent Maxwell equations for the electromagnetic field can be written as (Harrington 1961, Elliott 1966)

$$\frac{\partial \mathbf{B}}{\partial t} + \nabla \times \mathbf{E} = 0 \quad (26.1)$$

$$\frac{\partial \mathbf{D}}{\partial t} - \nabla \times \mathbf{H} = -\mathbf{J} \quad (26.2)$$

$$\nabla \cdot \mathbf{B} = 0 \quad (26.3)$$

$$\nabla \cdot \mathbf{D} = \rho \quad (26.4)$$

The only conservation law for electric charge and current densities is

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \mathbf{J} = 0 \quad (26.5)$$

where ρ and \mathbf{J} are the charge and current density, respectively, and represent the source of the field. The constitutive relations between the magnetic flux density and intensity and between the electric displacement and field strength are $\mathbf{B} = \mu \mathbf{H}$ and $\mathbf{D} = \epsilon \mathbf{E}$. Equation 26.5 is often regarded as a fundamental law of electromagnetics, derived from the generalized Ampere's circuit law and Gauss's law. Since Equation 26.1 and 26.2 contain the information on the propagation of the electromagnetic field, they constitute the basic equations of CEM.

The previous partial-differential equations also can be expressed as a system of integral equations. The following expression is obtained by using Stokes' law and the divergence theorem to reduce the surface and volume integrals to a circuital line and surface integrals, respectively (Elliott 1966). These integral relationships hold only if the first derivatives of the electric displacement \mathbf{D} and the magnetic flux density \mathbf{B} are continuous throughout the control volume:

$$\oint \mathbf{E} \cdot d\mathbf{L} - \iint \frac{\partial \mathbf{B}}{\partial t} \cdot d\mathbf{S} \quad (26.6)$$

$$\oint \mathbf{H} \cdot d\mathbf{L} = \iint \left(\mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \right) \cdot d\mathbf{S} \quad (26.7)$$

$$\iint \mathbf{D} \cdot d\mathbf{S} = \iiint \rho dV \quad (26.8)$$

$$\iint \mathbf{B} \cdot d\mathbf{S} = 0 \quad (26.9)$$

The integral form of the Maxwell equations is rarely used in CEM. They are, however, invaluable as a validation tool for checking the global behavior of field computations.

The second-order curl–curl form of the Maxwell equations is derived by applying the curl operator to get

$$\nabla \times \nabla \times \mathbf{E} + \frac{1}{c^2} \frac{\partial^2 \mathbf{E}}{\partial t^2} = -\frac{\partial(\boldsymbol{\mu}\mathbf{J})}{\partial t} \quad (26.10)$$

$$\nabla \times \nabla \times \mathbf{B} + \frac{1}{c^2} \frac{\partial^2 \mathbf{B}}{\partial t^2} = \nabla \times (\boldsymbol{\mu}\mathbf{J}) \quad (26.11)$$

The outstanding feature of the curl–curl formulation of the Maxwell equations is that the electric and magnetic fields are decoupled. The second-order equations can be further simplified for harmonic fields. If the time-dependent behavior can be represented by a harmonic function $e^{i\omega t}$, the separation-of-variable technique will transform the Maxwell equations into the frequency domain (Harrington 1961, Elliott 1966). The resultant partial-differential equations in spatial variables become elliptic:

$$\nabla \times \nabla \times \mathbf{E} - k^2 \mathbf{E} = -i\omega(\boldsymbol{\mu}\mathbf{J}) \quad (26.12)$$

$$\nabla \times \nabla \times \mathbf{B} - k^2 \mathbf{B} = \nabla \times (\boldsymbol{\mu}\mathbf{J}) \quad (26.13)$$

where $k = \omega/c$ is the so-called propagation constant or the wave number and is the angular frequency of a component of a Fourier series or a Fourier integral (Harrington 1961, Elliott 1966). The previous equations are frequently the basis for finite-element approaches (Rahman et al. 1991).

In order to complete the description of the differential system, initial and/or boundary values are required. For Maxwell equations, only the source of the field and a few physical boundary conditions at the media interfaces are pertinent (Harrington 1961, Elliott 1966):

$$\mathbf{n} \times (\mathbf{E}_1 - \mathbf{E}_2) = \mathbf{0} \quad (26.14)$$

$$\mathbf{n} \times (\mathbf{H}_1 - \mathbf{H}_2) = \mathbf{J}_s \quad (26.15)$$

$$\mathbf{n} \times (\mathbf{D}_1 - \mathbf{D}_2) = \rho_s \quad (26.16)$$

$$\mathbf{n} \times (\mathbf{B}_1 - \mathbf{B}_2) = \mathbf{0} \quad (26.17)$$

where

The subscripts 1 and 2 refer to media on two sides of the interface

\mathbf{J}_s and ρ_s are the surface current and charge densities, respectively

Since all computing systems have finite memory, all CEM computations in the time domain must be conducted on a truncated computational domain. This intrinsic constraint requires a numerical far-field condition at the truncated boundary to mimic the behavior of an unbounded field. This numerical boundary unavoidably induces a reflected wave to contaminate the simulated field. In the past, absorbing boundary conditions at the far-field boundary have been developed from the radiation condition (Sommerfeld 1949, Enquist and Majda 1977, Mur 1981, Higdon 1986). In general, a progressive order-of-accuracy procedure can be used to implement the numerical boundary conditions with increasing accuracy (Enquist and Majda 1977, Higdon 1986).

The most popular approaches in the CEM community are the absorbing boundary condition or the perfectly matched-layer scheme (Mur 1981, Berenger 1994). The latter is actually derived from the characteristics or the domain of dependence of the hyperbolic partial-differential equation system. The detailed eigenvector and eigenvalue analyses of the characteristic formulation for the 3D Maxwell equations have been performed (Shang 1995). In this formulation, the flux vector of the governing equations is split according to the signs of the eigenvalue to honor the domain of dependence. The flux-vector splitting formulation is utilized in the present investigation.

On the other hand, the characteristic-based methods that satisfy the physical domain of influence requirement can specify the numerical boundary condition readily. For this formulation, the reflected wave can be suppressed by eliminating the undesirable incoming numerical data. Although the accuracy of the numerical far-field boundary condition depends on the coordinate system, in principle, this formulation under ideal circumstances can effectively suppress artificial wave reflections.

26.3 Characteristic-Based Formulation

The fundamental idea of the characteristic-based method for solving the hyperbolic system of equations is derived from the eigenvalue–eigenvector analyses of the governing equations. For Maxwell equations in the time domain, every eigenvalue is real, but not all of them are distinct (Shang 1995, Shang and Gaitonde 1995, Shang and Fithen 1996). In a time–space plane, the eigenvalue actually defines the slope of the characteristic or the phase velocity of the wave motion. All dependent variables within the time–space domain bounded by two intersecting characteristics are completely determined by the values along these characteristics and by their compatibility relationship. The direction of information propagation is also clearly described by these two characteristics (Sommerfeld 1949). In numerical simulation, the well-posedness requirement on initial or boundary conditions and the stability of a numerical approximation are also ultimately linked to the eigenvalues of the governing equation (Richtmyer and Morton 1967, Anderson et al. 1984). Therefore, characteristic-based methods have demonstrated superior numerical stability and accuracy to other schemes (Roe 1986, Shang 1995). However, characteristic-based algorithms also have an inherent limitation in that the governing equation can be diagonalized only in one spatial dimension at a time. The multidimensional equations are required to split into multiple 1D formulations. This limitation is not unusual for numerical algorithms, such as the approximate factored and the fractional-step schemes (Anderson et al. 1984, Shang 1995). A consequence of this restriction is that solutions of the characteristic-based procedure may exhibit some degree of sensitivity to the orientation of the coordinate selected. This numerical behavior is consistent with the concept of optimal coordinates.

In the characteristic formulation, data on the wave motion are first split according to the direction of phase velocity and then transmitted in each orientation. In each 1D time–space domain, the direction of the phase velocity degenerates into either a positive or a negative orientation. They are commonly referred to as the right-running and the left-running wave components (Sommerfeld 1949, Roe 1986). The sign of the eigenvalue is thus an indicator of the direction of signal transmission. The corresponding eigenvectors are the essential elements for diagonalizing the coefficient matrices and for formulating the approximate Riemann problem (Roe 1986). In essence, knowledge of eigenvalues and eigenvectors of the Maxwell equations in the time domain becomes the first prerequisite of the present formulation.

The system of governing equations cast in the flux-vector form in the Cartesian frame becomes (Shang 1995, Shang and Gaitonde 1995, Shang and Fithen 1996)

$$\frac{\partial U}{\partial t} + \frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial y} + \frac{\partial F_z}{\partial z} = -J \quad (26.18)$$

where U is the vector of dependent variables. The flux vectors are formed by the inner product of the coefficient matrix and the dependent variable, $F_x = C_x U$, $F_y = C_y U$, and $F_z = C_z U$, with

$$U = \{B_x, B_y, B_z, D_x, D_y, D_z\}^T \quad (26.19)$$

and

$$\begin{aligned} F_x &= \left\{ 0, \frac{-D_z}{\varepsilon}, \frac{D_y}{\varepsilon}, 0, \frac{B_z}{\mu}, \frac{-B_y}{\mu} \right\}^T \\ F_y &= \left\{ \frac{D_z}{\varepsilon}, 0, \frac{-D_x}{\varepsilon}, \frac{-B_z}{\mu}, 0, \frac{B_x}{\mu} \right\}^T \\ F_z &= \left\{ \frac{-D_y}{\varepsilon}, \frac{D_x}{\varepsilon}, 0, \frac{B_y}{\mu}, \frac{-B_x}{\mu}, 0 \right\}^T \end{aligned} \quad (26.20)$$

The coefficient matrices or the Jacobians of the flux vectors C_x , C_y , and C_z are (Shang 1995)

$$C_x = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & -\frac{1}{\varepsilon} \\ 0 & 0 & 0 & 0 & \frac{1}{\varepsilon} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{1}{\mu} & 0 & 0 & 0 \\ 0 & -\frac{1}{\mu} & 0 & 0 & 0 & 0 \end{bmatrix} \quad (26.21a)$$

$$C_y = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & \frac{1}{\varepsilon} \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -\frac{1}{\varepsilon} & 0 & 0 \\ 0 & 0 & -\frac{1}{\mu} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{1}{\mu} & 0 & 0 & 0 & 0 \end{bmatrix} \quad (26.21b)$$

$$C_z = \begin{bmatrix} 0 & 0 & 0 & 0 & -\frac{1}{\varepsilon} & 0 \\ 0 & 0 & 0 & \frac{1}{\varepsilon} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{1}{\mu} & 0 & 0 & 0 & 0 \\ -\frac{1}{\mu} & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \quad (26.21c)$$

where ϵ and μ are the permittivity and permeability, which relate the electric displacement to the electric field intensity and the magnetic flux density to the magnetic field intensity, respectively.

The eigenvalues of the coefficient matrices C_x , C_y , and C_z in the Cartesian frame are identical and contain multiplicities (Shang 1995, Shang and Gaitonde 1995). Care must be exercised to ensure that all associated eigenvectors

$$\lambda = \left\{ +\frac{1}{\sqrt{\epsilon\mu}}, -\frac{1}{\sqrt{\epsilon\mu}}, 0, +\frac{1}{\sqrt{\epsilon\mu}}, -\frac{1}{\sqrt{\epsilon\mu}}, 0 \right\} \quad (26.22a)$$

are linearly independent. The linearly independent eigenvectors associated with each eigenvalue are found by reducing the matrix equation, $(C - I\lambda)U = 0$, to the Jordan normal form (Shang 1995, Shang and Fithen 1996).

Since the coefficient matrices C_x , C_y , and C_z can be diagonalized, there exist nonsingular similar matrices S_x , S_y , and S_z such that

$$\begin{aligned} \Lambda_x &= S_x^{-1}C_xS_x \\ \Lambda_y &= S_y^{-1}C_yS_y \\ \Lambda_z &= S_z^{-1}C_zS_z \end{aligned} \quad (26.22b)$$

where the Λ_s are the *diagonalized* coefficient matrices. The columns of the similar matrices S_x , S_y , and S_z are simply the linearly independent eigenvectors of the coefficient matrices C_x , C_y , and C_z , respectively.

The fundamental relationship between the characteristic-based formulation and the Riemann problem can be best demonstrated in the Cartesian frame of reference. For the Maxwell equations in this frame of reference and for an isotropic medium, all the similar matrices are invariant with respect to temporal and spatial independent variables. In each time-space plane ($x-t$, $y-t$, and $z-t$), the 1D governing equation can be given just as in the $x-t$ plane:

$$\frac{\partial U}{\partial t} + C_x \frac{\partial U}{\partial x} = 0 \quad (26.23)$$

Substitute the diagonalized coefficient matrix to get

$$\frac{\partial U}{\partial t} + S_x \Lambda_x S_x^{-1} \frac{\partial U}{\partial x} = 0 \quad (26.24)$$

Since the similar matrix in the present consideration is invariant with respect to time and space, it can be brought into the differential operator. Multiplying the previous equation by the left-hand inverse of S_x , S_x^{-1} , we have

$$\frac{\partial S_x^{-1}U}{\partial t} + \Lambda_x \frac{\partial S_x^{-1}U}{\partial x} = 0 \quad (26.25)$$

One immediately recognizes the group of variables $S_x^{-1}U$ as the characteristics, and the system of equations is decoupled (Shang 1995). In scalar-variable form and with appropriate initial values, this is the Riemann problem (Sommerfeld 1949, Courant and Hilbert 1965). This differential system is specialized to study the breakup of a single discontinuity. The piecewise continuous solutions separated by the singular point are also invariant along the characteristics. Equally important, stable numerical operators can now be easily devised to solve the split equations according to the sign of the eigenvalue. In practice,

it has been found that if the multidimensional problem can be split into a sequence of 1D equations, this numerical technique is applicable to those 1D equations (Roe 1986, Shang 1995).

The gist of the characteristic-based formulation is also clearly revealed by the decomposition of the flux vector into positive and negative components corresponding to the sign of the eigenvalue:

$$\Lambda = \Lambda^+ + \Lambda^-, \quad F = F^+ + F^- \quad (26.26)$$

$$F^+ = S\Lambda^+S^{-1}, \quad F^- = S\Lambda^-S^{-1} \quad (26.27)$$

where the superscripts + and – denote the split vectors associated with positive and negative eigenvalues, respectively.

The characteristic-based algorithms have a deep-rooted theoretical basis for describing the wave dynamics. They also have however an inherent limitation in that the diagonalized formulation is achievable only in one dimension at a time. All multidimensional equations are required to be split into multiple 1D formulations. The approach yields accurate results so long as discontinuous waves remain aligned with the computational grid. This limitation is also the state-of-the-art constraint in solving partial-differential equations (Anderson et al. 1984, Roe 1986, Shang 1995).

26.4 Maxwell Equations in a Curvilinear Frame

In order to develop a versatile numerical tool for CEM in a wide range of applications, the Maxwell equations can be cast in a general curvilinear frame of reference (Shang and Gaitonde 1995, Shang and Fithen 1996). For efficient simulation of complex electromagnetic field configurations, the adoption of a general curvilinear mesh system becomes necessary. The system of equations in general curvilinear coordinates is derived by a coordinate transformation (Thompson 1982, Anderson et al. 1984). The mesh system in the transformed space can be obtained by numerous grid generation procedures (Thompson 1982). Computational advantages in the transformed space are also realizable. For a body-oriented coordinate system, the interface between two different media is easily defined by one of the coordinate surfaces. Along this coordinate parametric plane, all discretized nodes on the interface are precisely prescribed without the need for an interpolating procedure. The outward normal to the interface, which is essential for boundary-value implementation, can be computed easily by $n = \nabla S / \|\nabla S\|$. In the transformed space, computations are performed on a uniform mesh space, but the corresponding physical spacing can be highly clustered to enhance the numerical resolution.

As an illustration of the numerical advantage of solving the Maxwell equations on nonorthogonal curvilinear, body-oriented coordinates, a simulation of the scattered electromagnetic field from a reentry vehicle has been performed (Shang and Gaitonde 1995). The aerospace vehicle, X24C-10D, has a complex geometric shape (Figure 26.1). In addition to a blunt leading-edge spherical nose and a relatively flat delta-shaped underbody, the aft portion of the vehicle consists of five control

FIGURE 26.1 Radar-wave fringes on X24C-10D, grid $181 \times 59 \times 62$, TE excitation, $L/\lambda = 9.2$.

surfaces—a central fin, two middle fins, and two strakes. A body-oriented, single-block mesh system enveloping the configuration is adopted. The numerical grid system is generated by using a hyperbolic grid generator for the near-field mesh adjacent to the solid surface and a transfinite technique for the far field.

The two mesh systems are merged by the Poisson averaging technique (Thompson 1982, Shang and Gaitonde 1995). In this manner, the composite grid system is orthogonal in the near field but less restrictive in the far field. All solid surfaces of the X24C-10D are mapped onto a parametric surface in the transformed space, defined by $\eta = 0$. The entire computational domain is supported by a $181 \times 59 \times 162$ grid system, where the first coordinate index denotes the number of cross sections in the numerical domain. The second index describes the number of cells between the body surface and the far-field boundary, while the third index gives the cells used to circumscribe each cross-sectional plane. The electromagnetic excitation is introduced by a harmonic incident wave traveling along the x -coordinate. The fringe pattern of the scattered electromagnetic waves on the X24C-10D is presented in Figure 26.1 for a characteristic-length-to-wavelength ratio $L/\lambda = 9.2$. A salient feature of the scattered field is brought out by the surface curvature: the smaller the radius of surface curvature, the broader the diffraction pattern. The numerical result exhibits highly concentrated contours at the chine (the line of intersection between upper and lower vehicle surfaces) of the forebody and the leading edges of strakes and fins.

For the most general coordinate transformation of the Maxwell equations in the time domain, a one-to-one relationship between two sets of temporal and spatial independent variables is required. However, for most practical applications, the spatial coordinate transformation is sufficient:

$$\begin{aligned} \xi &= \xi(x, y, z) \\ \eta &= \eta(x, y, z) \\ \zeta &= \zeta(x, y, z) \end{aligned} \tag{26.28}$$

The governing equation in the strong conservation form is obtained by dividing the chain-rule differentiated equations by the Jacobian of coordinate transformation and by invoking metric identities (Anderson et al. 1984, Shang and Gaitonde 1995). The time-dependent Maxwell equations on a general curvilinear frame of reference and in the strong conservative form are

$$\frac{\partial U}{\partial t} + \frac{\partial F_\xi}{\partial \xi} + \frac{\partial F_\eta}{\partial \eta} + \frac{\partial F_\zeta}{\partial \zeta} = -J \tag{26.29}$$

where the dependent variables are now defined as

$$U = U(B_x V, B_y V, B_z V, D_x V, D_y V, D_z V) \tag{26.30}$$

Here, V is the Jacobian of the coordinate transformation and is also the inverse local cell volume. If the Jacobian has nonzero values in the computational domain, the correspondence between the physical and the transformed space is uniquely defined (Thompson 1982, Anderson et al. 1984). Since systematic procedures have been developed to ensure this property of coordinate transformations, detailed information on this point is not repeated here (Thompson 1982, Anderson et al. 1984). We have

$$V = \begin{bmatrix} \xi_x & \eta_x & \zeta_x \\ \xi_y & \eta_y & \zeta_y \\ \xi_z & \eta_z & \zeta_z \end{bmatrix} \tag{26.31}$$

and ξ_y , η_x , and ζ_x are the metrics of coordinate transformation and can be computed easily from the definition given by Equation 26.24. The flux-vector components in the transformed space have the following form:

$$F_\xi = \frac{1}{V} \begin{bmatrix} 0 & 0 & 0 & 0 & -\frac{\xi_z}{\epsilon} & \frac{\xi_y}{\epsilon} \\ 0 & 0 & 0 & \frac{\xi_z}{\epsilon} & 0 & -\frac{\xi_x}{\epsilon} \\ 0 & 0 & 0 & -\frac{\xi_y}{\epsilon} & \frac{\xi_x}{\epsilon} & 0 \\ 0 & \frac{\xi_z}{\mu} & -\frac{\xi_y}{\mu} & 0 & 0 & 0 \\ -\frac{\xi_z}{\mu} & 0 & \frac{\xi_x}{\mu} & 0 & 0 & 0 \\ \frac{\xi_y}{\mu} & -\frac{\xi_x}{\mu} & 0 & 0 & 0 & 0 \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (26.32)$$

$$F_\eta = \frac{1}{V} \begin{bmatrix} 0 & 0 & 0 & 0 & -\frac{\eta_z}{\epsilon} & \frac{\eta_y}{\epsilon} \\ 0 & 0 & 0 & \frac{\eta_z}{\epsilon} & 0 & -\frac{\eta_x}{\epsilon} \\ 0 & 0 & 0 & -\frac{\eta_y}{\epsilon} & \frac{\eta_x}{\epsilon} & 0 \\ 0 & \frac{\eta_z}{\mu} & -\frac{\eta_y}{\mu} & 0 & 0 & 0 \\ -\frac{\eta_z}{\mu} & 0 & \frac{\eta_x}{\mu} & 0 & 0 & 0 \\ \frac{\eta_y}{\mu} & -\frac{\eta_x}{\mu} & 0 & 0 & 0 & 0 \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (26.33)$$

$$F_\zeta = \frac{1}{V} \begin{bmatrix} 0 & 0 & 0 & 0 & -\frac{\zeta_z}{\epsilon} & \frac{\zeta_y}{\epsilon} \\ 0 & 0 & 0 & \frac{\zeta_z}{\epsilon} & 0 & -\frac{\zeta_x}{\epsilon} \\ 0 & 0 & 0 & -\frac{\zeta_y}{\epsilon} & \frac{\zeta_x}{\epsilon} & 0 \\ 0 & \frac{\zeta_z}{\mu} & -\frac{\zeta_y}{\mu} & 0 & 0 & 0 \\ -\frac{\zeta_z}{\mu} & 0 & \frac{\zeta_x}{\mu} & 0 & 0 & 0 \\ \frac{\zeta_y}{\mu} & -\frac{\zeta_x}{\mu} & 0 & 0 & 0 & 0 \end{bmatrix} \begin{Bmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{Bmatrix} \quad (26.34)$$

After the coordinate transformation, all coefficient matrices now contain metrics that are position dependent, and the system of equations in the most general frame of reference possesses

variable coefficients. This added complexity of the characteristic formulation of the Maxwell equations no longer permits the system of 1D equations to be decoupled into six scalar equations and reduced to the true Riemann problem (Shang 1995, Shang and Gaitonde 1995, Shang and Fithen 1996) like that on the Cartesian form.

26.5 Eigenvalues and Eigenvectors

As previously mentioned, eigenvalue and the eigenvector analyses are the prerequisites for characteristic-based algorithms. The analytic process to obtain the eigenvalues and the corresponding eigenvectors of the Maxwell equations in general curvilinear coordinates is identical to that in the Cartesian frame. In each of the temporal–spatial planes t – ξ , t – η , and t – ζ , the eigenvalues are easily found by solving the sixth-degree characteristic equation associated with the coefficient matrices (Sommerfeld 1949, Courant and Hilbert 1965):

$$\lambda_{\xi} = \left\{ -\frac{\alpha}{V\sqrt{\epsilon\mu}}, -\frac{\alpha}{V\sqrt{\epsilon\mu}}, \frac{\alpha}{V\sqrt{\epsilon\mu}}, \frac{\alpha}{V\sqrt{\epsilon\mu}}, 0, 0 \right\} \quad (26.35)$$

$$\lambda_{\eta} = \left\{ -\frac{\beta}{V\sqrt{\epsilon\mu}}, -\frac{\beta}{V\sqrt{\epsilon\mu}}, \frac{\beta}{V\sqrt{\epsilon\mu}}, \frac{\beta}{V\sqrt{\epsilon\mu}}, 0, 0 \right\} \quad (26.36)$$

$$\lambda_{\zeta} = \left\{ -\frac{\gamma}{V\sqrt{\epsilon\mu}}, -\frac{\gamma}{V\sqrt{\epsilon\mu}}, \frac{\gamma}{V\sqrt{\epsilon\mu}}, \frac{\gamma}{V\sqrt{\epsilon\mu}}, 0, 0 \right\} \quad (26.37)$$

where

$$\alpha = \sqrt{\xi_x^2 + \xi_y^2 + \xi_z^2}, \quad \beta = \sqrt{\eta_x^2 + \eta_y^2 + \eta_z^2}, \quad \text{and} \quad \gamma = \sqrt{\zeta_x^2 + \zeta_y^2 + \zeta_z^2}$$

One recognizes that the eigenvalues in each 1D time–space plane contain multiplicities, and hence the eigenvectors do not necessarily have unique elements (Courant and Hilbert 1965, Shang 1995). Nevertheless, linearly independent eigenvectors associated with each eigenvalue still have been found by reducing the coefficient matrix to the Jordan normal form (Shang 1995, Shang and Fithen 1996). For reasons of wide applicability and internal consistency, the eigenvectors are selected in such a fashion that the similar matrices of diagonalization reduce to the same form as in the Cartesian frame. Furthermore, in order to accommodate a wide range of electromagnetic field configurations such as antennas, waveguides, and scatterers, the eigenvalues are no longer identical in the three time–space planes. This complexity of formulation is essential to facilitate boundary-condition implementation on the interfaces of media with different characteristic impedances.

From the eigenvector analysis, the similarity transformation matrices for diagonalization in each time–space plane are formed by using eigenvectors as the column arrays as shown in the following equations. For example, the first column of the similar matrix of diagonalization

$$\left[-\sqrt{\frac{\mu}{\epsilon}} \frac{\xi_y}{\alpha}, \sqrt{\frac{\mu}{\epsilon}} \frac{(\xi_x^2 + \xi_z^2)}{\alpha\xi_x}, \sqrt{\frac{\mu}{\epsilon}} \frac{\xi_y\xi_z}{\alpha\xi_x}, \frac{\xi_y}{\xi_x}, 0, 1 \right]$$

in the t - ξ plane is the eigenvector corresponding to the eigenvalue $\lambda_\xi = -\alpha/V\sqrt{\epsilon\mu}$. We have

$$S_\xi = \begin{pmatrix} -\sqrt{\frac{\mu}{\epsilon}} \frac{\xi_y}{\alpha} & \sqrt{\frac{\mu}{\epsilon}} \frac{\xi_z}{\alpha} & \sqrt{\frac{\mu}{\epsilon}} \frac{\xi_y}{\alpha} & -\sqrt{\frac{\mu}{\epsilon}} \frac{\xi_z}{\alpha} & 1 & 0 \\ \sqrt{\frac{\mu}{\epsilon}} \frac{(\xi_x^2 + \xi_z^2)}{\alpha \xi_x} & \sqrt{\frac{\mu}{\epsilon}} \frac{\xi_y \xi_z}{\alpha \xi_x} & -\sqrt{\frac{\mu}{\epsilon}} \frac{(\xi_x^2 + \xi_z^2)}{\alpha \xi_x} & \sqrt{\frac{\mu}{\epsilon}} \frac{\xi_y \xi_z}{\alpha \xi_x} & \frac{\xi_y}{\xi_x} & 0 \\ -\sqrt{\frac{\mu}{\epsilon}} \frac{\xi_y \xi_z}{\alpha \xi_x} & -\sqrt{\frac{\mu}{\epsilon}} \frac{(\xi_x^2 + \xi_y^2)}{\alpha \xi_x} & \sqrt{\frac{\mu}{\epsilon}} \frac{\xi_y \xi_z}{\alpha \xi_x} & \sqrt{\frac{\mu}{\epsilon}} \frac{(\xi_x^2 + \xi_y^2)}{\alpha \xi_x} & \frac{\xi_z}{\xi_x} & 0 \\ -\frac{\xi_z}{\xi_x} & -\frac{\xi_y}{\xi_x} & -\frac{\xi_z}{\xi_x} & -\frac{\xi_y}{\xi_x} & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & \frac{\xi_y}{\xi_x} \\ 1 & 0 & 1 & 0 & 0 & \frac{\xi_z}{\xi_x} \end{pmatrix} \quad (26.38)$$

$$S_\eta = \begin{pmatrix} -\sqrt{\frac{\mu}{\epsilon}} \frac{(\eta_y^2 + \xi_z^2)}{\beta \eta_y} & -\sqrt{\frac{\mu}{\epsilon}} \frac{\eta_x \eta_z}{\beta \eta_y} & \sqrt{\frac{\mu}{\epsilon}} \frac{(\eta_y^2 + \xi_z^2)}{\beta \eta_y} & \sqrt{\frac{\mu}{\epsilon}} \frac{\eta_x \eta_z}{\beta \eta_y} & \frac{\eta_x}{\eta_y} & 0 \\ \sqrt{\frac{\mu}{\epsilon}} \frac{\eta_x}{\beta} & -\sqrt{\frac{\mu}{\epsilon}} \frac{\eta_z}{\beta \eta_y} & -\sqrt{\frac{\mu}{\epsilon}} \frac{\eta_x}{\beta} & \sqrt{\frac{\mu}{\epsilon}} \frac{\eta_z}{\beta \eta_y} & 1 & 0 \\ -\sqrt{\frac{\mu}{\epsilon}} \frac{\eta_x \eta_z}{\alpha \eta_y} & \sqrt{\frac{\mu}{\epsilon}} \frac{(\eta_x^2 + \xi_y^2)}{\alpha \eta_y} & \sqrt{\frac{\mu}{\epsilon}} \frac{\eta_x \eta_z}{\alpha \eta_y} & -\sqrt{\frac{\mu}{\epsilon}} \frac{(\eta_y^2 + \xi_y^2)}{\beta \eta_y} & \frac{\eta_z}{\eta_y} & 0 \\ 0 & 1 & 0 & 1 & 0 & \frac{\eta_x}{\eta_y} \\ -\frac{\eta_z}{\eta_y} & -\frac{\eta_x}{\eta_y} & -\frac{\eta_x}{\eta_y} & -\frac{\eta_x}{\eta_y} & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & \frac{\eta_z}{\eta_y} \end{pmatrix} \quad (26.39)$$

$$S_\zeta = \begin{pmatrix} \sqrt{\frac{\mu}{\epsilon}} \frac{(\zeta_y^2 + \zeta_z^2)}{\gamma \zeta_z} & \sqrt{\frac{\mu}{\epsilon}} \frac{\zeta_x \zeta_y}{\gamma \zeta_z} & -\sqrt{\frac{\mu}{\epsilon}} \frac{(\zeta_y^2 + \zeta_z^2)}{\gamma \zeta_z} & -\sqrt{\frac{\mu}{\epsilon}} \frac{\zeta_x \zeta_y}{\gamma \zeta_z} & \frac{\zeta_x}{\zeta_z} & 0 \\ -\sqrt{\frac{\mu}{\epsilon}} \frac{\zeta_x \zeta_y}{\gamma \zeta_z} & -\sqrt{\frac{\mu}{\epsilon}} \frac{(\zeta_x^2 + \zeta_z^2)}{\gamma \zeta_z} & \sqrt{\frac{\mu}{\epsilon}} \frac{\zeta_x \zeta_y}{\gamma \zeta_z} & \sqrt{\frac{\mu}{\epsilon}} \frac{(\zeta_x^2 + \zeta_z^2)}{\gamma \zeta_z} & \frac{\zeta_y}{\zeta_z} & 0 \\ -\sqrt{\frac{\mu}{\epsilon}} \frac{\zeta_x}{\gamma} & \sqrt{\frac{\mu}{\epsilon}} \frac{\zeta_y}{\gamma} & \sqrt{\frac{\mu}{\epsilon}} \frac{\zeta_x}{\gamma} & -\sqrt{\frac{\mu}{\epsilon}} \frac{\zeta_y}{\gamma} & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & \frac{\zeta_x}{\zeta_z} \\ 1 & 0 & 1 & 0 & 0 & \frac{\zeta_y}{\zeta_z} \\ -\frac{\zeta_y}{\zeta_z} & -\frac{\zeta_x}{\zeta_z} & -\frac{\zeta_y}{\zeta_z} & -\frac{\zeta_x}{\zeta_z} & 0 & 1 \end{pmatrix} \quad (26.40)$$

Since the similar matrices of diagonalization, S_{ξ} , S_{η} , and S_{ζ} , are nonsingular, the left-hand inverse matrices S_{ξ}^{-1} , S_{η}^{-1} , and S_{ζ}^{-1} are easily found. Although these left-hand inverse matrices are essential to the diagonalization process, they provide little insight for the following flux-vector splitting procedure. The rather involved results are omitted here, but they can be found in Shang and Fithen (1996).

26.6 Flux-Vector Splitting

An efficient flux-vector splitting algorithm for solving the Euler equations was developed by Steger and Warming (1987). The basic concept is equally applicable to any hyperbolic differential system for which the solution need not be analytic (Sommerfeld 1949, Courant and Hilbert 1965). In most CEM applications, discontinuous behavior of the solution is associated only with the wave across an interface between different media, a piecewise continuous solution. Even if a jump condition exists, the magnitude of the finite jump across the interface is much less drastic than the shock waves encountered in supersonic flows. Nevertheless, the salient feature of the piecewise continuous solution domains of the hyperbolic partial-differential equation stands out: the coefficient matrices of the time-dependent, 3D Maxwell equations cast in the general curvilinear frame of reference contain metrics of coordinate transformation. Therefore, the equation system no longer has constant coefficients even in an isotropic and homogeneous medium. Under this circumstance, eigenvalues can change sign at any given field location due to the metric variations of the coordinate transformation. Numerical oscillations have appeared in results calculated using the flux-vector splitting technique when eigenvalues change sign. A refined flux-difference splitting algorithm has been developed to resolve fields with jump conditions (Van Leer 1982, Anderson et al. 1985). The newer flux-difference splitting algorithm is particularly effective at locations where the eigenvalues vanish. Perhaps more crucial for electromagnetics, the polarization of the medium, making the basic equations become nonlinear, occurs only in the extremely high-frequency range (Harrington 1961, Elliott 1966). In general, the governing equations are linear; at most, the coefficients of the differential system are dependent on physical location and phase velocity. For this reason, the difference between the flux-vector splitting (Steger and Warming 1987) and flux-difference splitting (Van Leer 1982, Anderson et al. 1985) schemes, when applied to the time-dependent Maxwell equations, is not of great importance.

The basic idea of the flux-vector splitting of Steger and Warming is to process data according to the direction of information propagation. Since diagonalization is achievable only in each time-space plane, the direction of wave propagation degenerates into either the positive or the negative orientation. This designation is consistent with the notion of the right-running and the left-running wave components. The flux vectors are computed from the point value, including the metrics at the node of interest. This formulation for solving hyperbolic partial-differential equations not only ensures the well posedness of the differential system but also enhances the stability of the numerical procedure (Richtmyer and Morton 1967, Anderson et al. 1984, Roe 1986, Shang 1995). Specifically, the flux vectors F_{ξ} , F_{η} , and F_{ζ} will be split according to the sign of their corresponding eigenvalues. The split fluxes are differenced by an upwind algorithm to allow for the zone of dependence of an initial-value problem (Roe 1986, Shang 1995, Shang and Gaitonde 1995, Shang and Fithen 1996).

From the previous analysis, it is clear that the eigenvalues contain multiplicities, and hence the split flux of the 3D Maxwell equations is not unique (Shang and Gaitonde 1995, Shang and Fithen 1996). All flux vectors in each time-space plane are split according to the signs of the local eigenvalues:

$$\begin{aligned} F_{\xi} &= F_{\xi}^{+} + F_{\xi}^{-} \\ F_{\eta} &= F_{\eta}^{+} + F_{\eta}^{-} \\ F_{\zeta} &= F_{\zeta}^{+} + F_{\zeta}^{-} \end{aligned} \tag{26.41}$$

The flux-vector components associated with the positive and negative eigenvalues are obtainable by a straightforward matrix multiplication:

$$\begin{aligned}
 F_{\xi}^+ &= S_{\xi} \lambda_{\xi}^+ S_{\xi}^{-1} U \\
 F_{\xi}^- &= S_{\xi} \lambda_{\xi}^- S_{\xi}^{-1} U \\
 F_{\eta}^+ &= S_{\eta} \lambda_{\eta}^+ S_{\eta}^{-1} U \\
 F_{\eta}^- &= S_{\eta} \lambda_{\eta}^- S_{\eta}^{-1} U \\
 F_{\zeta}^+ &= S_{\zeta} \lambda_{\zeta}^+ S_{\zeta}^{-1} U \\
 F_{\zeta}^- &= S_{\zeta} \lambda_{\zeta}^- S_{\zeta}^{-1} U
 \end{aligned} \tag{26.42}$$

It is also important to recognize that even if the split flux vectors in each time–space plane are no unique, the sum of the split components must be unambiguously identical to the flux vector of the governing Equation 26.29. This fact is easily verifiable by performing the addition of the split matrices to reach the identities in Equation 26.32 through 26.34. In addition, if one sets the diagonal elements of metrics, $\xi_x, \eta_y,$ and $\zeta_z,$ equal to unity and the off-diagonal elements equal to zero, the coefficient matrices will recover the Cartesian form:

$$\begin{aligned}
 F_{\epsilon}^+ &= \frac{1}{2V} \begin{pmatrix} \frac{\xi_y^2 + \xi_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_x \xi_y}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_x \xi_z}{\alpha\sqrt{\epsilon\mu}} & 0 & \frac{-\xi_z}{\epsilon} & \frac{\xi_y}{\epsilon} \\ \frac{-\xi_x \xi_y}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_x^2 + \xi_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_y \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_z}{\epsilon} & 0 & \frac{-\xi_x}{\epsilon} \\ \frac{-\xi_x \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_y \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_x^2 + \xi_y^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_y}{\epsilon} & \frac{\xi_x}{\epsilon} & 0 \\ 0 & \frac{\xi_z}{\mu} & \frac{-\xi_y}{\mu} & \frac{\xi_y^2 + \xi_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_x \xi_y}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_x \xi_z}{\alpha\sqrt{\epsilon\mu}} \\ \frac{-\xi_z}{\mu} & 0 & \frac{\xi_x}{\mu} & \frac{-\xi_x \xi_y}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_x^2 + \xi_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_y \xi_z}{\alpha\sqrt{\epsilon\mu}} \\ \frac{\xi_y}{\mu} & \frac{-\xi_x}{\mu} & 0 & \frac{-\xi_x \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_y \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_x^2 + \xi_y^2}{\alpha\sqrt{\epsilon\mu}} \end{pmatrix} \begin{matrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{matrix} \\
 F_{\epsilon}^- &= \frac{1}{2V} \begin{pmatrix} \frac{-(\xi_y^2 + \xi_z^2)}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_x \xi_y}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_x \xi_z}{\alpha\sqrt{\epsilon\mu}} & 0 & \frac{-\xi_z}{\epsilon} & \frac{\xi_y}{\epsilon} \\ \frac{\xi_x \xi_y}{\alpha\sqrt{\epsilon\mu}} & \frac{-(\xi_x^2 + \xi_z^2)}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_y \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_z}{\epsilon} & 0 & \frac{-\xi_x}{\epsilon} \\ \frac{\xi_x \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_y \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{-(\xi_x^2 + \xi_y^2)}{\alpha\sqrt{\epsilon\mu}} & \frac{-\xi_y}{\epsilon} & \frac{\xi_x}{\epsilon} & 0 \\ 0 & \frac{\xi_z}{\mu} & \frac{-\xi_y}{\mu} & \frac{-(\xi_y^2 + \xi_z^2)}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_x \xi_y}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_x \xi_z}{\alpha\sqrt{\epsilon\mu}} \\ \frac{-\xi_z}{\mu} & 0 & \frac{\xi_x}{\mu} & \frac{\xi_x \xi_y}{\alpha\sqrt{\epsilon\mu}} & \frac{-(\xi_x^2 + \xi_z^2)}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_y \xi_z}{\alpha\sqrt{\epsilon\mu}} \\ \frac{\xi_y}{\mu} & \frac{-\xi_x}{\mu} & 0 & \frac{\xi_x \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\xi_y \xi_z}{\alpha\sqrt{\epsilon\mu}} & \frac{-(\xi_y^2 + \xi_z^2)}{\alpha\sqrt{\epsilon\mu}} \end{pmatrix} \begin{matrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{matrix}
 \end{aligned} \tag{26.44}$$

$$F_{\eta}^+ = \frac{1}{2V} \begin{pmatrix} \frac{\eta_y^2 + \eta_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\eta_x\eta_y}{\alpha\sqrt{\epsilon\mu}} & \frac{-\eta_x\eta_z}{\alpha\sqrt{\epsilon\mu}} & 0 & \frac{-\eta_z}{\epsilon} & \frac{\eta_y}{\epsilon} \\ \frac{-\eta_x\eta_y}{\alpha\sqrt{\epsilon\mu}} & \frac{\eta_x^2 + \eta_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\eta_y\eta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\eta_z}{\epsilon} & 0 & \frac{-\eta_x}{\epsilon} \\ \frac{-\eta_x\eta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{-\eta_y\eta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\eta_x^2 + \eta_y^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\eta_y}{\epsilon} & \frac{\eta_x}{\epsilon} & 0 \\ 0 & \frac{\eta_z}{\mu} & \frac{-\eta_y}{\mu} & \frac{\eta_y^2 + \eta_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\eta_x\eta_y}{\alpha\sqrt{\epsilon\mu}} & \frac{-\eta_x\eta_z}{\alpha\sqrt{\epsilon\mu}} \\ \frac{-\eta_z}{\mu} & 0 & \frac{\eta_x}{\mu} & \frac{-\eta_x\eta_y}{\alpha\sqrt{\epsilon\mu}} & \frac{\eta_x^2 + \eta_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\eta_y\eta_z}{\alpha\sqrt{\epsilon\mu}} \\ \frac{\eta_y}{\mu} & \frac{-\eta_x}{\mu} & 0 & \frac{-\eta_x\eta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{-\eta_y\eta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\eta_x^2 + \eta_y^2}{\alpha\sqrt{\epsilon\mu}} \end{pmatrix} \begin{pmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{pmatrix} \quad (26.45)$$

$$F_{\zeta}^+ = \frac{1}{2V} \begin{pmatrix} \frac{\zeta_y^2 + \zeta_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\zeta_x\zeta_y}{\alpha\sqrt{\epsilon\mu}} & \frac{-\zeta_x\zeta_z}{\alpha\sqrt{\epsilon\mu}} & 0 & \frac{-\zeta_z}{\epsilon} & \frac{\zeta_y}{\epsilon} \\ \frac{-\zeta_x\zeta_y}{\alpha\sqrt{\epsilon\mu}} & \frac{\zeta_x^2 + \zeta_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\zeta_y\zeta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\zeta_z}{\epsilon} & 0 & \frac{-\zeta_x}{\epsilon} \\ \frac{-\zeta_x\zeta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{-\zeta_y\zeta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\zeta_x^2 + \zeta_y^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\zeta_y}{\epsilon} & \frac{\zeta_x}{\epsilon} & 0 \\ 0 & \frac{\zeta_z}{\mu} & \frac{-\zeta_y}{\mu} & \frac{\zeta_y^2 + \zeta_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\zeta_x\zeta_y}{\alpha\sqrt{\epsilon\mu}} & \frac{-\zeta_x\zeta_z}{\alpha\sqrt{\epsilon\mu}} \\ \frac{-\zeta_z}{\mu} & 0 & \frac{\zeta_x}{\mu} & \frac{-\zeta_x\zeta_y}{\alpha\sqrt{\epsilon\mu}} & \frac{\zeta_x^2 + \zeta_z^2}{\alpha\sqrt{\epsilon\mu}} & \frac{-\zeta_x\zeta_z}{\alpha\sqrt{\epsilon\mu}} \\ \frac{\zeta_y}{\mu} & \frac{-\zeta_x}{\mu} & 0 & \frac{-\zeta_x\zeta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{-\zeta_x\zeta_z}{\alpha\sqrt{\epsilon\mu}} & \frac{\zeta_x^2 + \zeta_y^2}{\alpha\sqrt{\epsilon\mu}} \end{pmatrix} \begin{pmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{pmatrix} \quad (26.47)$$

$$F_{\zeta}^{-} = \frac{1}{2V} \begin{pmatrix} -(\zeta_y^2 + \zeta_z^2) & \zeta_x \zeta_y & \zeta_x \zeta_z & 0 & -\zeta_z & \zeta_y \\ \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} & 0 & \epsilon & \epsilon \\ \zeta_x \zeta_y & -(\zeta_x^2 + \zeta_z^2) & \zeta_y \zeta_z & \zeta_z & 0 & -\zeta_x \\ \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} & \epsilon & \epsilon & \epsilon \\ \zeta_x \zeta_z & \zeta_y \zeta_z & -(\zeta_x^2 + \zeta_y^2) & -\zeta_y & \zeta_x & 0 \\ \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} & \epsilon & \epsilon & 0 \\ 0 & \zeta_z & -\zeta_y & -(\zeta_y^2 + \zeta_z^2) & \zeta_x \zeta_y & \zeta_x \zeta_z \\ \mu & \mu & \mu & \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} \\ -\zeta_z & 0 & \zeta_x & \zeta_x \zeta_y & -(\zeta_x^2 + \zeta_z^2) & \zeta_x \zeta_z \\ \mu & \mu & \mu & \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} \\ \zeta_y & -\zeta_x & 0 & \zeta_x \zeta_z & \zeta_x \zeta_z & -(\zeta_x^2 + \zeta_y^2) \\ \mu & \mu & 0 & \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} & \alpha\sqrt{\epsilon\mu} \end{pmatrix} \begin{pmatrix} B_x \\ B_y \\ B_z \\ D_x \\ D_y \\ D_z \end{pmatrix} \quad (26.48)$$

26.7 Finite-Difference Approximation

Once the detailed split fluxes are known, the formulation of the finite-difference approximation is straightforward. From the sign of an eigenvalue, the stencil of a spatially second- or higher-order-accurate windward differencing can be easily constructed to form multiple 1D difference operators (Richtmyer and Morton 1967, Anderson et al. 1984, Shang 1995). In this regard, the forward difference and the backward difference approximations are used for the negative and the positive eigenvalues, respectively. The split flux vectors are evaluated at each discretized point of the field according to the signs of the eigenvalues.

For the present purpose, a second-order accurate procedure is given:

$$\text{If } \lambda < 0 \quad \Delta U_i = \frac{-3U_i + 4U_{i+1} - U_{i+2}}{2} \quad (26.49)$$

$$\text{If } \lambda > 0 \quad \Delta U_i = \frac{3U_i - 4U_{i+1} + U_{i+2}}{2}$$

The necessary metrics of the coordinate transformation are calculated by central differencing, except at the edges of computational domain, where one-sided differences are used. Although the fractional-step or the time-splitting algorithm (Richtmyer and Morton 1967, Anderson et al. 1984, Shang 1995) has demonstrated greater efficiency in data storage and a higher data-processing rate than predictor-corrector time integration procedures (Shang 1995, Shang and Gaitonde 1995, Shang and Fithen 1996), it is limited to second-order accuracy in time. With respect to the fractional-step method, the temporal second-order result is obtained by a sequence of symmetrically cyclic operators (Richtmyer and Morton 1967, Shang 1995):

$$U_i^{n+1} = L_{\xi} L_{\eta} L_{\zeta} L_{\mu} L_{\xi} U_i^n \quad (26.50)$$

where L_{ξ} , L_{η} , and L_{ζ} are the difference operators for 1D equations in the ξ , η , and ζ coordinates, respectively.

In general, second-order and higher temporal resolution is achievable through multiple-time-step schemes (Richtmyer and Morton 1967, Anderson et al. 1984). However, one-step schemes are more attractive because they have less memory requirements and do not need special start-up procedures

(Shang and Gaitonde 1995, Shang and Fithen 1996). For future higher-order accurate solution development potential, the Runge–Kutta family of single-step, multistage procedure is recommended. This choice is also consistent with the accompanying characteristic-based finite-volume method (Shang and Gaitonde 1995).

In the present effort, the two-stage, formally second-order accurate scheme is used:

$$\begin{aligned}
 U^0 &= U_i^n \\
 U^1 &= U^0 - \Delta U(U^0) \\
 U^2 &= 0.5[\Delta U(U^1 + \Delta U(U^0))] \\
 U_i^{n+1} &= U^2
 \end{aligned} \tag{26.51}$$

where ΔU comprises the incremental values of dependent variables during each temporal sweep. The resultant characteristic-based finite-difference scheme for solving the 3D Maxwell equations in the time domain is second-order accurate in both time and space.

The most significant feature of the flux-vector splitting scheme lies in its ability to easily suppress reflected waves from the truncated computational domain. In wave motion, the compatibility condition at any point in space is described by the split flux vector (Shang 1995, Shang and Gaitonde 1995, Shang and Fithen 1996). In the present formulation, an approximated no-reflection condition can be achieved by setting the incoming flux component equal to zero:

$$\text{either } \lim_{r \rightarrow \infty} F^+(\xi, \eta, \zeta) = 0 \quad \text{or} \quad \lim_{r \rightarrow \infty} F^-(\xi, \eta, \zeta) = 0 \tag{26.52}$$

The 1D compatibility condition is exact when the wave motion is aligned with one of the coordinates (Shang 1995). This unique attribute of the characteristic-based numerical procedure in removing a fundamental dilemma in CEM will be demonstrated in detail later.

26.8 Finite-Volume Approximation

The finite-volume approximation solves the governing equation by discretizing the physical space into contiguous cells and balancing the flux vectors on the cell surfaces. Thus, in discretized form, the integration procedure reduces to evaluation of the sum of all fluxes aligned with surface-area vectors:

$$\frac{\Delta U}{\Delta t} + \frac{\Delta F}{\Delta \xi} + \frac{\Delta G}{\Delta \eta} + \frac{\Delta H}{\Delta \zeta} - J = 0 \tag{26.53}$$

In the present approach, the continuous differential operators have been replaced by discrete operators. In essence, the numerical procedure needs only to evaluate the sum of all flux vectors aligned with surface-area vectors (Van Leer 1982, Anderson et al. 1985, Shang and Gaitonde 1995, Shang and Fithen 1996). Only one of the vectors is required to coincide with the outward normal to the cell surface, and the rest of the orthogonal triad can be made to lie on the same surface. The metrics, or more appropriately the direction cosines, on the cell surface are uniquely determined by the nodes and edges of the elementary volume. This feature is distinct from the finite-difference approximation. The shape of the cell under consideration and the stretching ratio of neighbor cells can lead to a significant deterioration of the accuracy of finite-volume schemes (Leonard 1988).

The most outstanding aspect of finite-volume schemes is the elegance of its flux-splitting process. The flux-difference splitting for Equation 26.25 is greatly facilitated by a locally orthogonal system in

the transformed space (Van Leer 1982, Anderson et al. 1985). In this new frame of reference, eigenvalues and eigenvectors as well as metrics of the coordinate transformation between two orthogonal systems are well known (Shang 1995, Shang and Gaitonde 1995). The inverse transformation is simply the transpose of the forward mapping. In particular, the flux vectors in the transformed space have the same functional form as that in the Cartesian frame. The difference between the flux vectors in the transformed and the Cartesian coordinates is a known quantity and is given by the product of the surface outward normal and the cell volume, $V(\nabla S/\|\nabla S\|)$ (Shang and Gaitonde 1995). Therefore, the flux vectors can be split in the transformed space according to the signs of the eigenvalues but without detailed knowledge of the associated eigenvectors in the transformed space. This feature of the finite-volume approach provides a tremendous advantage over the finite-difference approximation in solving complex problems in physics.

The present formulation adopts Van Leer's kappa scheme in which solution vectors are reconstructed on the cell surface from the piecewise data of neighboring cells (Van Leer 1982, Anderson et al. 1985). The spatial accuracy of this scheme spans a range from first-order to third-order upwind-biased approximations:

$$U_{i+(1/2)}^+ = U_i + \frac{\varphi}{4}[(1 - \kappa)\nabla + (1 + \kappa)\Delta]U_i \quad (26.54)$$

$$U_{i+(1/2)}^- = U_i - \frac{\varphi}{4}[(1 + \kappa)\nabla + (1 - \kappa)\Delta]U_i$$

where $\Delta U_i = U_i - U_{i-1}$ and $\nabla U_i = U_{i+1} - U_i$ are the forward and backward differencing discretizations. The parameters φ and κ control the accuracy of the numerical results. For $\varphi = 1$, $\kappa = -1$, a two-point windward scheme is obtained. This method has an odd-order leading truncation-error term; the dispersive error is expected to dominate. If $\kappa = 1/3$, a third-order upwind-biased scheme will emerge. In fact both upwind procedures have discernible leading phase error. This behavior is a consequence of using the two-stage time integration algorithm, and the dispersive error can be alleviated by increasing the temporal resolution. For $\varphi = 1$, $\kappa = 0$, the formulation recovers the Fromm scheme (Van Leer 1982, Anderson et al. 1985). If $\kappa = 1$, the formulation yields the spatially central scheme. Since the fourth-order dissipative term is suppressed, the central scheme is susceptible to parasitic odd-even point decoupling (Anderson et al. 1984, 1985).

The time integration is carried out by the same two-stage Runge-Kutta method as in the present finite-difference procedure (Shang 1995, Shang and Gaitonde 1995). The finite-volume procedure is therefore second-order accurate in time and up to third-order accurate in space (Shang and Gaitonde 1995, Shang and Fithen 1996). For the present purpose, only the second-order upwinding and the third-order upwind-biased options are exercised. The second-order windward schemes in the form of the flux-vector splitting finite-difference and the flux-difference splitting finite-volume schemes are formally equivalent (Van Leer 1982, Anderson et al. 1985, Leonard 1988, Shang and Gaitonde 1995, Shang and Fithen 1996).

26.9 Summary and Research Issues

The technical merits of the characteristic-based methods for solving the time-dependent, 3D Maxwell equations can best be illustrated by the following two illustrations. In Figure 26.2, the exact electric field of a traveling wave is compared with numerical results. The numerical results were generated at the maximum allowable time-step size defined by the Courant-Friedrichs-Lewy (CFL) number of 2 ($\lambda\Delta x/\Delta t = 2$) (Richtmyer and Morton 1967, Anderson et al. 1984). The numerical solutions presented are at instants when a right-running wave reaches the midpoint of the computational domain and exits the numerical boundary, respectively. For this 1D simulation, the characteristic-based scheme using the

FIGURE 26.2 Perfect-shift property of a 1D wave computation, CFL = 2.

single-step upwind explicit algorithm exhibits the shift property, which indicates a perfect translation of the initial value in space (Anderson et al. 1984). As the impulse wave moves through the initially quiescent environment, the numerical result duplicates the exact solution at each and every discretized point, including the discontinuous incoming wave front. Although this highly desirable property of a numerical solution is achievable only under very restrictive conditions and is not preserved for multi-dimensional problems (Richtmyer and Morton 1967, Anderson et al. 1984), the ability to simulate the nonanalytic solution behavior in the limit is clearly illustrated.

In Figure 26.3, another outstanding feature of the characteristic-based method is highlighted by simulating the oscillating electric dipole. For the radiating electric dipole, the depicted temporal calculations are sampled at the instant when the initial pulse has traveled a distance of 2.24 wavelengths

FIGURE 26.3 Instantaneous distributions of oscillating-dipole electric field.

from the dipole. The numerical results are generated on a $48 \times 48 \times 96$ mesh system with the second-order scheme. Under that condition, each wavelength is resolved by 15-mesh points, and the difference between numerical results by the finite-volume and the finite-difference method is negligible. However, on an irregular mesh like the present spherical polar system, the finite-volume procedure has shown a greater numerical error than the finite-difference procedure on highly stretched grid systems (Anderson et al. 1985, Shang and Fithen 1996). Under the present computational conditions, both numerical procedures yield uniformly excellent comparison with the theoretical result. Significant error appeared only in the immediate region of the coordinate origin. At that location, the solution has a singularity that behaves as the inverse cube of the radial distance. The most interesting numerical behavior, however, is revealed in the truncated far field. The no-reflection condition at the numerical boundary is observed to be satisfied within the order of the truncation error. For a spherically symmetric radiating field, the orientation of the wave is aligned with the radial coordinate, and the suppression of the reflected wave within the numerical domain is the best achievable by the characteristic formulation.

The corresponding magnetic field intensity computed by both the second-order accurate finite-difference and the finite-volume procedure is given in Figure 26.4. Again, the difference in solution between the two distinct numerical procedures is indiscernible. For the oscillating electric dipole, only the x - and y -components of the magnetic field exist. Numerical results attain excellent agreement with theoretical values (Shang and Gaitonde 1995, Shang and Fithen 1996). The third-order accurate finite-volume scheme also produces a similar result on the same mesh but at a greater allowable time-step size (a CFL value of 0.87 is used vs. 0.5 for the second-order method). A numerically more efficient and higher-order accurate simulation is obtainable in theory. However, at present, the third-order windward-biased algorithm cannot reinforce rigorously the zone-of-dependence requirement; therefore, the reflected-wave suppression is incomplete in the truncated numerical domain. For this reason, the third-order accurate results are not included here.

Numerical accuracy and efficiency are closely related issues in CEM. A high-accuracy requirement of a simulation is supportable only by efficient numerical procedures. The inaccuracies incurred by numerical simulations are attributable to the mathematical formulation of the problem, to the algorithm, to the

FIGURE 26.4 Instantaneous distributions of oscillating-dipole magnetic field.

numerical procedure, and to computational inaccuracy. A basic approach to relieve the accuracy limitation must be derived from using high-order schemes or spectral methods. The numerical efficiency of CEM can be enhanced substantially by using scalable multicomputers (Shang et al. 1993). The effective use of a distributed-memory, message-passing homogeneous multicomputer still requires a judicious trade-off between a balanced work load and interprocessor communication. A characteristic-based finite-volume computer program has been successfully mapped onto distributed-memory systems by a rudimentary domain decomposition strategy. For example, a square waveguide, at five different frequencies up to the cutoff, was simulated.

Figure 26.5 displays the x -component of the magnetic field intensity within the waveguide. The simulated transverse electric mode, $TE_{1,1}$, $E_x = 0$, which has a half period of π along the x - and y -coordinates, is generated on a $(24 \times 24 \times 128)$ mesh system. Since the entire field is described by simple harmonic functions, the remaining field components are similar, and only half the solution domain along the z -coordinate is presented to minimize repetition. In short, the agreement between the closed-form and numerical solutions is excellent at each frequency. In addition, the numerical simulations duplicate the physical phenomenon at the cutoff frequency, below which there is no phase shift along the waveguide and the wave motion ceases (Harrington 1961, Elliott 1966). For simple harmonic wave motion in an isotropic medium, the numerical accuracy can be quantified. At a grid-point density of 12 nodes per wavelength, the L_2 norm (Richtmyer and Morton 1967) has a nearly uniform magnitude of order 10^{-4} . The numerical results are fully validated by comparison with theory. However, further efforts are still required to substantially improve the parallel and scalable numerical efficiency. In fact, this is the most promising area in CEM research.

The pioneering efforts in CEM usually employed the total-field formulation on staggered-mesh systems (Yee 1966, Taflove 1992). That particular combination of numerical algorithm and procedure has been proven to be very effective. In earlier RCS calculations using the present numerical procedure,

FIGURE 26.5 Cutoff frequency of a square waveguide, $TE_{1,1}$.

the total-field formulation was also utilized (Shang 1995, Shang and Gaitonde 1995). However, for 3D scatterer simulation, the numerical accuracy requirement for RCS evaluations becomes extremely stringent. In the total-field formulation, the dynamic range of the field variables has a substantial difference from the exposed and the shadow region, and the incident wave must also traverse the entire computation domain.

Both requirements impose severe demands on the numerical accuracy of simulation. In addition, the total field often contains only the residual of partial cancelations of the incident and the diffracted waves. The far-field electromagnetic energy distribution becomes a secular problem—a small difference between two variables of large magnitude. An alternative approach via the scattered-field formulation for RCS calculations appears to be very attractive. Particularly in this formulation, the numerical dissipation of the incident wave that must propagate from the far-field boundary to the scatterer is completely eliminated from the computations. In short, the incident field can be directly specified on the scatterer’s surface. The numerical advantage over the total-field formulation is substantial.

The total-field formulation can be cast in the scattered-field form by replacing the total field with scattered-field variables (Harrington 1961, Elliott 1966):

$$U_s = U_t - U_i \tag{26.55}$$

Since the incident field U_i must satisfy the Maxwell equations identically, the equations of the scattered field remain unaltered from the total-field formulation. Thus, the scattered-field formulation can be considered as a dependent-variable transform of the total-field equations. In the present approach, both formulations are solved by a characteristic-based finite-volume scheme.

The comparison of horizontal polarized RCS of a perfect electrically conducting (PEC) sphere, $\sigma(\theta, 0, 0)$, from the total-field and scattered-field formulations at $ka = 5.3$ (where $k =$ wave number and $a =$ diameter of the sphere) is presented in Figure 26.6. The validating datum is the exact solution for the scattering of a plane electromagnetic wave by a PEC sphere, which is commonly referred to as the Mie series (Elliott 1966). Both numerical results are generated under identical computational conditions. The location of the truncated far-field boundary is prescribed at 2.5 wavelengths from the center of the PEC sphere. Numerical results of the total-field formulation reveal far greater error than for the

FIGURE 26.6 Comparison of total-field and scattered-field RCS calculations of $\sigma(\theta, 0^\circ)$, $ka = 5.3$.

scattered-field formulation. The additional source of error is incurred when the incident wave must propagate from the far-field boundary to the scatterer. In the scattered-field formulation, the incident field data are described precisely by the boundary condition on the scatterer surface. Since the far-field electromagnetic energy distribution is derived from the near-field parameters (Sommerfeld 1949, Taflove 1992, Shang and Gaitonde 1995), the advantage of describing the data incident on a scatterer without error is tremendous. Numerical errors of the total-field calculations are evident in the exaggerated peaks and troughs over the entire viewing-angle displacement.

In Figure 26.7, the vertically polarized RCS $\sigma(\theta, 90.0^\circ)$ of the $ka = 5.3$ case substantiates the previous observation. In fact, the numerical error of the total-field calculation is excessive in comparison with the result of the scattered-field formulation. Since the results are not obtained for the optimal far-field placement for RCS computation, the results of the scattered-field formulation overpredict the theoretical values by 2.7%. The deviation of the total-field result from the theory, however, exceeds 25.6% and becomes unacceptable. In addition, computations by the total-field formulation exhibit a strong sensitivity to placement of the far-field boundary. A small perturbation of the far-field boundary placement leads to a drastic change in the RCS prediction: a feature resembling the ill-posedness condition, which is highly undesirable for numerical simulation. Since there is very little difference in computer coding for the two formulations, the difference in computing time required for an identical simulation is insignificant. On the Cray C90, 1,505.3 s at a data-processing rate of 528.8 Mflops and an average vector length of 62.9 is needed to complete a sampling period. At present, the most efficient calculation on a distributed-memory system, Cray T3-D, has reduced the processing time to 1204.2 s using 76 computing nodes.

More recent progress of CEM in the time domain can be illustrated in three aspects: the vastly increased data processing on multicomputers, the modeling and simulation of increasingly complex scatters, and the removing the fundamental limitation in conducting wave propagation in a finite computational domain without reflection.

Just a few years ago, an order of tenfold speedup and immense increase in memory size by parallel-computing system permitted an RCS calculation of a PEC sphere at a wave number beyond 100, ($ka = 50.0$). The calculation is carried on a $(91 \times 241 \times 384)$ mesh system, and the bistatic RCS was sampled for the elapse time of three periods. The RCS computation requires 2887.6 s on an IBM SP 256 node system, which is the first generation commercially available of massive parallel-computing system. The calculated horizontal polarized bistatic RCS distribution $\sigma(\theta, 90^\circ)$ is presented in Figure 26.8 to exhibit an excellent agreement with the theoretical results by the Mie series over a dynamic range of six decades

FIGURE 26.7 Comparison of total-field and scattered-field RCS calculations of $\sigma(\theta, 90^\circ)$, $ka = 5.3$.

(Bowman et al. 1987). Today, the speedup of modern concurrent computers increases almost exponentially to expand the predictable frequency range of incident wave approaching the lower optical regime.

In 1999, the time-domain computational procedure using the structured, overset grid generation process has applied to a scattering simulation of a full-scale B1-B aircraft. This particular simulation is intended to demonstrate the range of practical application of time-domain methods and to seek an alternative grid topology for the discretized field approximation. Two separate multiblock grids for the fore and aft portion of the B1-B are constructed according to the distinct geometric features of the aircraft. A widely used grid generation package from the CFD community is adopted for the process (Shang 2009). The two major multiblock grid systems are overlapped to allow the information exchange between the two systems during the data processing. The level of effort required to generate this overall grid system is substantial; nearly nine months of man-hour has been devoted from the time of the available computer-aided design (CAD) model of the aircraft until a workable grid is completed. The overset grid system was used to produce the electromagnetic scattering field at 100 MHz that consists of a total of 711 grid blocks with 383 and 328 blocks distributed between the fore and aft grid systems, respectively. The fringe pattern on the B1-B aircraft is displayed by Figure 26.9. A total of 34.5 million

FIGURE 26.9 Radar fringe pattern on B1-B aircraft, $f = 100$ MHz.

grid cells were used and with 23.5 million cells are concentrated in describing the fore body of this aircraft including the complex engine nacelles with the air breathing inlet. The aft body configuration is equally challenging with rudder and elevator assembly. The numerical simulation requires then the unprecedented problem size of more than 192,000,000 unknowns. On a 258-node SGI Origin 2000 system, which is another first-generation parallel computer, the data-processing rate is estimated to be about 24.32 Gflops (giga floating point per second). This speedup benchmark in data-processing rate by parallel computing is easily surpassed by the new generation of multicomputer.

Meanwhile, the progress in the technique of grid generation is shifting to the unstructured grid approach, which represents the most general grid connectivity. Basically, the discretized field points are constructed by a group of contiguous tetrahedrons from the solid surface of a complex electric objective extending to far field. This coordinate transforming process requires an explicit connectivity of adjacent grid points. The identical need also exists for the mapping of a numerical procedure to multicomputers by the domain decomposition approach. The explicit connectivity of adjacent grid cells or data blocks for grid generation is also optimal for load balancing and limiting interprocessor communication for concurrent computing to become the most attractive approach for simulating the complex scatter configuration (Shang 2009).

The fundamental challenge for CEM is that the hyperbolic differential system must be solved on a truncated physical domain due to a finite size of computer memory. The limitation was remedied earlier by the absorbing far-field boundary condition of Enquist and Majda (1977) and later by the perfectly matching layer (PML) of Berenge (1992). Both approaches alleviate the wave reflection from the far-field computational domain by numerical dissipation. In the middle 1990s, Shang and Fithen (1996) and Shang and Gaitonde (1995) formally derived the 3D characteristic formulation for the time-dependent Maxwell equation on a generalized curvilinear coordinates. In the characteristic-based formulation, the no-reflection far-field boundary condition is readily achievable by imposed vanishing incoming flux-vector component at the computational domain.

The effectiveness of the characteristic formulation is demonstrated by the numerical simulation of the near-field, microwave radiation from a rectangular pyramidal horn shown in Figure 26.10. In this figure, the transmit wave is the principal transverse electric mode, $TE_{1,0}$, at a frequency of 12.56 GHz with

FIGURE 26.10 Near-field wave pattern of a pyramidal antenna, $TE_{1,0}$ = 12.56 GHz.

a wavelength of 2.398 cm, and the aperture of the antenna has a dimension of 3.05 by 3.64 wavelength. The far-field boundary condition for this numerical simulation is placed just at a few wavelengths from the exit of the antenna. The graph is presented at the time frame when the transmitting wave front has just passed through the computational outer domain. The contour of electric intensity exhibits no detectable distortion of any reflected waves from the computational boundary.

In summary, recent progress in solving the 3D Maxwell equations in the time domain has opened a new frontier in electromagnetics, plasmadynamics, and optics, as well as the interface between electrodynamics and quantum mechanics (Taflove 1992). The progress in microchip and interconnect network technology has led to a host of high-performance distributed-memory, message-passing parallel computer systems. The synergism of efficient and accurate numerical algorithms for solving the Maxwell equations in the time domain with high-performance multicomputers will propel the new interdisciplinary simulation technique to practical and productive applications.

Nomenclature

B	magnetic flux density
C	coefficient matrix of flux-vector formulation
D	electric displacement
E	electric field strength
F	flux-vector component
H	magnetic flux intensity
i, j, k	index of discretization
J	electric current density
N	index of temporal level of solution
S	similarity matrix of diagonalization
t	time
U	dependent variables
V	elementary cell volume
x, y, z	Cartesian coordinates
Δ	forward difference operator
λ	eigenvalue
ξ, η, ζ	transformed coordinates
∇	gradient, backward difference operator

27.1 Introduction

The use of computer-based methods for the prediction of fluid flows has seen tremendous growth in the past half century. Fluid dynamics has been one of the earliest, and most active, fields for the application of numerical techniques. This is due to the essential nonlinearity of most fluid flow problems of practical interest—which makes analytical, or closed-form, solutions virtually impossible to obtain—combined with the geometrical complexity of these problems. In fact, the history of computational fluid dynamics (CFD) can be traced back virtually to the birth of the digital computer itself, with the pioneering work of John von Neumann and others in this area. Von Neumann was interested in using the computer not only to solve engineering problems but to understand the fundamental nature of fluid flows themselves. This is possible because the complexity of fluid flows arises, in many instances, not from complicated or poorly understood formulations but from the nonlinearity of partial differential equations that have been known for more than a century. A famous paragraph, written by von Neumann in 1946, serves to illustrate this point. He wrote [16]:

“Indeed, to a great extent, experimentation in fluid mechanics is carried out under conditions where the underlying physical principles are not in doubt, where the quantities to be observed are completely determined by known equations. The purpose of the experiment is not to verify a proposed theory but to replace a computation from an unquestioned theory by direct measurements. Thus, wind tunnels are, for example, used at present, at least in part, as computing devices of the so-called analogy type ... to integrate the non-linear partial differential equations of fluid dynamics.”

This chapter article provides some of the basic background in fluid dynamics required to understand the issues involved in numerical solution of fluid flow problems, then outlines the approaches that have been successful in attacking problems of practical interest, and identifies areas of current research.

27.2 Underlying Principles

In this section, we will provide the background in fluid dynamics required to understand the principles involved in the numerical solution of the governing equations. The formulation of the equations in generalized, curvilinear coordinates and the geometrical issues involved in the construction of suitable grids will also be discussed.

27.2.1 Fluid Dynamical Background

As can be inferred from the quotation of von Neumann presented in the introduction, fluid dynamics is fortunate to have a generally accepted mathematical framework for describing most problems of practical interest. Such diverse problems as the high-speed flow past an aircraft wing, the motions of the atmosphere responsible for our weather, and the unsteady air currents produced by the flapping wings of a housefly, all can be described as solutions to a set of partial differential equations known as the Navier–Stokes equations. These equations express the physical laws corresponding to conservation of mass, Newton’s second law of motion relating the acceleration of fluid elements to the imposed forces, and conservation of energy, under the assumption that the stresses in the fluid are linearly related to the local rates of strain of the fluid elements. This latter assumption is generally regarded as an excellent approximation for everyday fluids such as water and air—the two most common fluids of engineering and scientific interest.

We will describe the equations for problems in two space dimensions, for the sake of economy of notation; here, and elsewhere, the extension to problems in three dimensions will be straightforward unless otherwise noted. The Navier–Stokes equations can be written in the form

$$\frac{\partial \mathbf{w}}{\partial t} + \frac{\partial \mathbf{f}}{\partial x} + \frac{\partial \mathbf{g}}{\partial y} = \frac{\partial \mathbf{R}}{\partial x} + \frac{\partial \mathbf{S}}{\partial y} \quad (27.1)$$

where \mathbf{w} is the vector of conserved quantities

$$\mathbf{w} = \{\rho, \rho u, \rho v, e\}^T \quad (27.2)$$

where

ρ is the fluid density

u and v are the fluid velocity components in the x and y directions, respectively

e is the total energy per unit volume

The inviscid flux vectors \mathbf{f} and \mathbf{g} are given by

$$\mathbf{f} = \{\rho u, \rho u^2 + p, \rho uv, (e + p)u\}^T \quad (27.3)$$

$$\mathbf{g} = \{\rho v, \rho uv, \rho v^2 + p, (e + p)v\}^T \quad (27.4)$$

where p is the fluid pressure, and the flux vectors describing the effects of viscosity are

$$\mathbf{R} = \{0, \tau_{xx}, \tau_{xy}, u\tau_{xx} + v\tau_{xy} - q_x\}^T \quad (27.5)$$

$$\mathbf{S} = \{0, \tau_{xy}, \tau_{yy}, u\tau_{xy} + v\tau_{yy} - q_y\}^T \quad (27.6)$$

The viscous stresses appearing in these terms are related to the derivatives of the components of the velocity vector by

$$\tau_{xx} = 2\mu \frac{\partial u}{\partial x} - \frac{2}{3}\mu \left\{ \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right\} \quad (27.7)$$

$$\tau_{xy} = \mu \left\{ \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right\} \quad (27.8)$$

$$\tau_{yy} = 2\mu \frac{\partial v}{\partial y} - \frac{2}{3}\mu \left\{ \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \right\} \quad (27.9)$$

and the x and y components of the heat flux vector are

$$q_x = -k \frac{\partial T}{\partial x} \quad (27.10)$$

$$q_y = -k \frac{\partial T}{\partial y} \quad (27.11)$$

according to Fourier's Law. In these equations, μ and k represent the coefficients of viscosity and thermal conductivity, respectively.

If the Navier–Stokes equations are nondimensionalized by normalizing lengths with respect to a representative length L , velocities by a representative velocity V_∞ , and the fluid properties (such as density and coefficient of viscosity) by their values in the free stream, an important nondimensional parameter, the *Reynolds number*,

$$\text{Re} = \frac{\rho_\infty V_\infty L}{\mu_\infty} \quad (27.12)$$

appears as a parameter in the equations. In particular, the viscous stress terms on the right-hand side of Equation 27.1 are multiplied by the inverse of the Reynolds number. Physically, the Reynolds number can be interpreted as an inverse measure of the relative importance of the contributions of the viscous stresses to the dynamics of the flow; that is when the Reynolds number is large, the viscous stresses are small almost everywhere in the flow field.

The computational resources required to solve the complete Navier–Stokes equations are enormous, particularly when the Reynolds number is large and regions of *turbulent flow* must be resolved. In 1970, Howard Emmons of Harvard University estimated the computer time required to solve a simple, turbulent pipe-flow problem, including direct computation of all turbulent eddies containing significant energy (Emmons [11]). For a computational domain consisting of approximately 12 diameters of a pipe of circular cross section, the computation of the solution at a Reynolds number based on pipe diameter of $\text{Re}_d = 10^7$ would require approximately 10^{17} s on a 1970s mainframe computer. Of course, much faster computers are now available, but even at a computational speed of 100 gigaflops—that is 10^{11} floating-point operations per second—such a calculation would require more than 3000 *years* to complete.

Because the resources required to solve the complete Navier–Stokes equations are so large, it is common to make approximations to bring the required computational resources to a more modest level for

TABLE 27.1 Hierarchy of Fluid Mechanical Approximations

problems of practical interest. Expanding slightly on a classification introduced by Chapman [9], the sequence of fluid mechanical equations can be organized into the hierarchy shown in Table 27.1.

Table 27.1 summarizes the physical assumptions and time periods of most intense development for each of the stages in the fluid mechanical hierarchy. Stage IV represents an approximation to the Navier–Stokes equations in which only the largest, presumably least isotropic, scales of turbulence are resolved; the sub-grid scales are modeled. Stage III represents an approximation in which the solution is decomposed into time- (or ensemble-) averaged and fluctuating components for each variable. For example, the velocity components and pressure can be decomposed into

$$u = U + u' \quad (27.13)$$

$$v = V + v' \quad (27.14)$$

$$p = P + p' \quad (27.15)$$

where U , V , and P are the average values of u , v , and p , respectively, taken over a time interval that is long compared to the turbulence time scales, but short compared to the time scales of any nonsteadiness of the averaged flow field. If we let $\langle u \rangle$ denote such a time average of the u component of the velocity, then, for example,

$$\langle u \rangle = U \quad (27.16)$$

When a decomposition of the form of Equations 27.13 through 27.15 is substituted into the Navier–Stokes equations and the equations are averaged as described previously, the resulting equations describe the evolution of the mean flow quantities (such as U , V , and P). These equations, called the *Reynolds-averaged Navier–Stokes (RANS) equations*, are nearly identical to the original Navier–Stokes equations written for the mean flow variables because terms that are linear in $\langle u' \rangle$, $\langle v' \rangle$, $\langle p' \rangle$, etc., are identically zero. The nonlinearity of the equations, however, introduces terms that depend upon the fluctuating components. In particular, terms proportional to $\langle \rho u' v' \rangle$, $\langle \rho u'^2 \rangle$, and $\langle \rho v'^2 \rangle$ appear in the averaged equations. Dimensionally, these terms are equivalent to stresses; in fact, these quantities are called the Reynolds stresses. Physically, the Reynolds stresses are the turbulent counterparts of the molecular viscous stresses and appear as a result of the transport of momentum by the turbulent fluctuations. The appearance of these terms in the equations describing the mean flow makes it impossible to determine even the mean flow without some knowledge of these fluctuating components.

In order to solve the RANS equations, the Reynolds stresses must be related to the mean flow at some level of approximation using a phenomenological model. The simplest procedure is to try to relate the

Reynolds stresses to the local mean flow properties. Since the turbulence that is responsible for these stresses is a function not only of the local mean flow state but also of the flow history, such an approximation cannot have broad generality, but such local, or algebraic, turbulence models based on the analogy of mixing length from the kinetic theory of gases are useful for many flows of engineering interest, especially for flows in which boundary-layer separation does not occur.

A more general procedure is to develop partial differential equations for the Reynolds stresses themselves or for quantities that can be used to determine the scales of the turbulence, such as the turbulent kinetic energy k and the dissipation rate ϵ . The latter, so-called k - ϵ model, is widely used in engineering analyses of turbulent flows. These differential equations can be derived by taking higher-order moments of the Navier–Stokes equations. For example, if the x -momentum equation is multiplied by v and then averaged, the result will be an equation for the Reynolds stress component $\langle \rho u'v' \rangle$. Again because of the nonlinearity of the equations, however, yet higher moments of the fluctuating components (e.g., terms proportional to $\langle \rho u'^2 v' \rangle$ or $\langle \rho u'v'^2 \rangle$) will appear in the equations for the Reynolds stresses. This is an example of the problem of closure of the equations for the Reynolds stresses; that is, to solve the equations for the Reynolds stresses, these third-order quantities must be known. Equations for the third-order quantities can be derived by taking yet higher-order moments of the Navier–Stokes equations, but these equations will involve fourth-order moments. Thus, at some point, the taking of moments must be terminated and models must be developed for the unknown higher-order quantities. It is hoped that more nearly universal models may be developed for these higher-order quantities, but the superiority of second-order models, in which the equations for the Reynolds stress components are solved, subject to modeling assumptions for the required third-order quantities, has yet to be established in any generality.

For many design purposes, especially in aerodynamics, it is sufficient to represent the flow as that of an inviscid, or ideal, fluid. This is appropriate for flows at high Reynolds numbers that contain only negligibly small regions of separated flow. The equations describing inviscid flows can be obtained as a simplification of the Navier–Stokes equations in which the viscous terms are neglected altogether. This results in the *Euler equations* of inviscid, compressible flow

$$\frac{\partial \mathbf{w}}{\partial t} + \frac{\partial \mathbf{f}}{\partial x} + \frac{\partial \mathbf{g}}{\partial y} = 0 \quad (27.17)$$

This approximation corresponds to stage IIb in the hierarchy described in Table 27.1.

The Euler equations comprise a hyperbolic system of partial differential equations, and their solutions contain features that are absent from the Navier–Stokes equations. In particular, while the viscous diffusion terms appearing in the Navier–Stokes equations guarantee that solutions will remain smooth, the absence of these dissipative terms from the Euler equations allows them to have solutions that are discontinuous across surfaces in the flow. Solutions to the Euler equations must be interpreted within the context of generalized (or weak) solutions, and this theory provides the mathematical framework for developing the properties of any discontinuities that may appear. In particular, jumps in dependent variables (such as density, pressure, and velocity) across such surfaces must be consistent with the original conservation laws upon which the differential equations are based. For the Euler equations, these jump conditions are called the Rankine–Hugoniot conditions.

Solutions of the Euler equations for flows containing gasdynamic discontinuities, or shock waves, can be computed using either *shock-fitting* or *shock-capturing* methods. In the former, the shock surfaces must be located, and the Rankine–Hugoniot jump conditions enforced explicitly. In shock-capturing methods, *artificial viscosity* terms are added in the numerical approximation to provide enough dissipation to allow the shocks to be captured automatically by the scheme, with no special treatment in the vicinity of the shock waves. The numerical viscosity terms usually act to smear out the discontinuity over several grid cells. Numerical viscosity also is used when solving the Navier–Stokes equations for flows containing shock waves, because usually it is impractical to resolve the shock structure defined by the physical dissipative mechanisms.

In many cases, the flow can further be approximated as steady and irrotational. In these cases, it is possible to define a velocity potential Φ such that the velocity vector \mathbf{V} is given by

$$\mathbf{V} = \nabla\Phi \quad (27.18)$$

and the fluid density is given by the isentropic relation

$$\rho = \left\{ 1 + \frac{\gamma-1}{2} \mathbf{M}_\infty^2 [1 - (u^2 + v^2)] \right\}^{\frac{1}{\gamma-1}} \quad (27.19)$$

where

$$u = \frac{\partial\Phi}{\partial x} \quad (27.20)$$

$$v = \frac{\partial\Phi}{\partial y} \quad (27.21)$$

and \mathbf{M}_∞ is a reference Mach number corresponding to the free stream state in which $\rho = 1$ and $u^2 + v^2 = 1$. The steady form of the Euler equations then reduces to the single equation

$$\frac{\partial\rho u}{\partial x} + \frac{\partial\rho v}{\partial y} = 0 \quad (27.22)$$

Equation 27.19 can be used to eliminate the density from Equation 27.22, which then can be expanded to the form

$$(a^2 - u^2) \frac{\partial^2\Phi}{\partial x^2} - 2uv \frac{\partial^2\Phi}{\partial x\partial y} + (a^2 - v^2) \frac{\partial^2\Phi}{\partial y^2} = 0 \quad (27.23)$$

where a is the local speed of sound, which is a function only of the fluid speed $V = \sqrt{u^2 + v^2}$. Thus, Equation 27.23 is a single equation that can be solved for the velocity potential Φ .

Equation 27.23 is a second-order quasi-linear partial differential equation whose type depends on the sign of the discriminant $1 - \mathbf{M}^2$, where $\mathbf{M} = V/a$ is the *local* Mach number. The equation is elliptic or hyperbolic depending upon whether the Mach number is less than, or greater than, unity, respectively. Thus, the nonlinear potential equation contains a mathematical description of the physics necessary to predict the important features of transonic flows. It is capable of changing type, and the conservation form of Equation 27.22 allows surfaces of discontinuity, or shock waves, to be computed. Solutions at this level of approximation, corresponding to stage IIa, are considerably less expensive to compute than solutions of the full Euler equations, since only one dependent variable need be computed and stored. The jump relation corresponding to weak solutions of the potential equation is different than the Rankine-Hugoniot relations, but is a good approximation to the latter when the shocks are not too strong.

Finally, if the flow can be approximated by small perturbations to some uniform reference state, Equation 27.23 can further be simplified to

$$(1 - \mathbf{M}_\infty^2) \frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} = 0 \quad (27.24)$$

where ϕ is the *perturbation* velocity potential defined according to

$$\Phi = x + \phi \quad (27.25)$$

if the uniform velocity in the reference state is assumed to be parallel to the x -axis and be normalized to have unit magnitude. Further, if the flow can be approximated as incompressible, that is, in the limit as $M_\infty \rightarrow 0$, Equation 27.23 reduces to

$$\frac{\partial^2 \Phi}{\partial x^2} + \frac{\partial^2 \Phi}{\partial y^2} = 0 \quad (27.26)$$

Since Equations 27.24 and 27.26 are linear, superposition of elementary solutions can be used to construct solutions of arbitrary complexity. Numerical methods to determine the singularity strengths for aerodynamic problems are called *Panel methods*, and constitute stage I in the hierarchy of approximations.

It is important to realize that, even though the time periods for development of some of the different models overlap, the applications of the various models may be for problems of significantly differing complexity. For example, DNS calculations were performed as early as the 1970s, but only for the simplest flows—homogeneous turbulence—at very low Reynolds numbers. Flows at higher Reynolds numbers and nonhomogeneous flows are being performed only now, while calculations for 3-D flows with modeled turbulence were performed as early as the mid-1980s.

27.2.2 Treatment of Geometry

For all numerical solutions to partial differential equations, including those of fluid mechanics, it is necessary to discretize the boundaries of the flow domain. For the panel method of stage I, this is all that is required since the problem is linear, and superposition can be used to construct solutions satisfying the boundary conditions. For nonlinear problems, it is necessary to discretize the entire flow domain. This can be done using either structured or unstructured grid systems. *Structured grids* are those in which the grid points can be ordered in a regular Cartesian structure; that is, the points can be given indices (i, j) such that the nearest neighbors of the (i, j) point are identified by the indices $(i \pm 1, j \pm 1)$. The grid cells for these meshes are thus quadrilateral in two dimensions and hexahedral in three dimensions. *Unstructured grids* have no regular ordering of points or cells, and a connectivity table must be maintained to identify which points and edges belong to which cells. Unstructured grids most often consist of triangles (in 2-D), tetrahedra (in 3-D), or combinations of these and quadrilateral and hexahedral cells, respectively. In addition, grids having purely quadrilateral cells may also be unstructured, even though they have a locally Cartesian structure—for example, when multilevel grids are used for adaptive refinement.

Implementations on structured grids are generally more efficient than those on unstructured grids since indirect addressing is required for the latter, and efficient implicit methods often can be constructed that take advantage of the regular ordering of points (or cells) in structured grids. A great deal of effort has been expended to generate both structured and unstructured grid systems, much of which is closely related to the field of computational geometry (see Chapter 32 of this volume).

27.2.2.1 Structured Grids

A variety of techniques are used to generate structured grids for use in fluid mechanical calculations. These include relatively fast algebraic methods, including those based on transfinite interpolation and conformal mapping, as well as more costly methods based on the solution of either elliptic or

hyperbolic systems of partial differential equations for the grid coordinates. These techniques are discussed in a review article by Eiseman [10].

For complex geometries, it often is not possible to generate a single grid that conforms to all the boundaries. Even if it is possible to generate such a grid, it may have undesirable properties, such as excessive skewness or a poor distribution of cells, which could lead to poor stability or accuracy in the numerical algorithm. Thus, structured grids for complex geometries are generally constructed as combinations of simpler grid blocks for various parts of the domain. These grids may be allowed to overlap, in which case they are referred to as “Chimera” grids, or be required to share common surfaces of intersection, in which case they are identified as “multi-block” grids. In the latter case, grid lines may have varying degrees of continuity across the interblock boundaries, and these variations have implications for the construction and behavior of the numerical algorithm in the vicinity of these boundaries. Grid generation techniques based on the solution of systems of partial differential equations are described by Thompson et al. [52].

Numerical methods to solve the equations of fluid mechanics on structured grid systems are implemented most efficiently by taking advantage of the ease with which the equations can be transformed to a generalized coordinate system. The expression of the system of conservation laws in the new, body-fitted coordinate system reduces the problem to one effectively of Cartesian geometry. The transformation will be described here for the Euler equations.

Consider the transformation of Equation 27.17 to a new coordinate system (ξ, η) . The local properties of the transformation at any point are contained in the Jacobian matrix of the transformation, which can be defined as

$$J = \begin{Bmatrix} x_\xi & x_\eta \\ y_\xi & y_\eta \end{Bmatrix} \quad (27.27)$$

for which the inverse is given by

$$J^{-1} = \begin{Bmatrix} \xi_x & \xi_y \\ \eta_x & \eta_y \end{Bmatrix} = \frac{1}{h} \begin{Bmatrix} y_\eta & -x_\eta \\ -y_\xi & x_\xi \end{Bmatrix} \quad (27.28)$$

where $h = x_\xi y_\eta - y_\xi x_\eta$ is the determinant of the Jacobian matrix. Subscripts in Equation 27.27 and 27.28 denote partial differentiation.

It is natural to express the fluxes in conservation laws in terms of their contravariant components. Thus, if we define

$$\{\mathbf{F}, \mathbf{G}\}^T = J^{-1} \{\mathbf{f}, \mathbf{g}\}^T \quad (27.29)$$

then the transformed Euler equations can be written in the compact form

$$\frac{\partial h\mathbf{w}}{\partial t} + \frac{\partial h\mathbf{F}}{\partial \xi} + \frac{\partial h\mathbf{G}}{\partial \eta} = 0 \quad (27.30)$$

if the transformation is independent of time (i.e., if the grid is not moving). If the grid is moving or deforming with time, the equations can be written in a similar form, but additional terms must be included that account for the fluxes induced by the motion of the mesh.

The Navier–Stokes equations can be transformed in a similar manner, although the transformation of the viscous contributions is somewhat more complicated and will not be included here. Since

the nonlinear potential equation is simply the continuity equation (the first of the equations that comprise the Euler equations), the transformed potential equation can be written as

$$\frac{\partial}{\partial \xi}(\rho h U) + \frac{\partial}{\partial \eta}(\rho h V) = 0 \quad (27.31)$$

where

$$\begin{Bmatrix} U \\ V \end{Bmatrix} = J^{-1} \begin{Bmatrix} u \\ v \end{Bmatrix} \quad (27.32)$$

are the contravariant components of the velocity vector.

27.2.2.2 Unstructured Grids

Unstructured grids generally have greater geometric flexibility than structured grids, because of the relative ease of generating triangular or tetrahedral tessellations of 2- and 3-D domains. Advancing-front methods and Delaunay triangulations are the most frequently used techniques for generating triangular/tetrahedral grids. Unstructured grids also can be more efficiently adapted locally to resolve localized features of the solution.

27.3 Best Practices

27.3.1 Panel Methods

The earliest numerical methods used widely for making fluid dynamical computations were developed to solve linear potential problems, described as stage I calculations in the previous section. Mathematically, panel methods are based upon the fact that Equation 27.26 can be recast as an integral equation giving the solution at any point (x, y) in terms of the free stream speed U (here assumed unity) and angle of attack α and line integrals of singularities distributed along the curve \mathcal{C} representing the body surface:

$$\Phi(x, y) = x \cos \alpha + y \sin \alpha + \int_{\mathcal{C}} \sigma \ln \left(\frac{r}{2\pi} \right) ds + \int_{\mathcal{C}} \delta \left(\frac{\partial}{\partial n} \right) \ln \left(\frac{r}{2\pi} \right) ds \quad (27.33)$$

In this equation, σ and δ represent the strengths of source and doublet singularities, respectively, distributed along the body contour, r is the distance from the point (x, y) to the boundary point, and n is the direction of the outward normal to the body surface. When the point (x, y) is chosen to lie on the body contour \mathcal{C} , Equation 27.33 can be interpreted as giving the solution Φ at any point on the body in terms of the singularities distributed along the surface. This effectively reduces the dimension of the problem by one (i.e., the 2-D problem considered here becomes essentially 1-D, and the analogous procedure applied to a 3-D problem results in a 2-D equation requiring the evaluation only of integrals over the body surface).

Equation 27.33 is approximated numerically by discretizing the boundary \mathcal{C} into a collection of panels (line segments in this 2-D example) on which the singularity distribution is assumed to be of some known functional form, but of an as yet unknown magnitude. For example, for a simple non-lifting body, the doublet strength δ might be assumed to be zero, while the source strength σ is assumed to be

constant on each segment. The second integral in Equation 27.33 is then zero, while the first integral can be written as a sum over all the elements of integrals that can be evaluated analytically as

$$\Phi(x, y) = x \cos \alpha + y \sin \alpha + \sum_{i=1}^N \sigma_i \int_{C_i} \ln r / 2\pi \, ds \quad (27.34)$$

where

C_i is the portion of the body surface corresponding to the i th segment

N is the number of segments, or panels, used

The source strengths σ_i must be determined by enforcing the boundary condition

$$\frac{\partial \Phi}{\partial n} = 0 \quad (27.35)$$

which specifies that the component of velocity normal to the surface be zero (i.e., that there be no flux of fluid across the surface). This is implemented by requiring that Equation 27.35 be satisfied at a selected number of control points. For the example of constant-strength source panels, if one control point is chosen on each panel, the requirement that Equation 27.35 be satisfied at each of the control points will result in N equations of the form

$$\sum_{i=1}^N A_{i,j} \sigma_i = \mathbf{U} \cdot \hat{\mathbf{n}}, \quad j = 1, 2, \dots, N \quad (27.36)$$

where

$A_{i,j}$ are the elements of the influence coefficient matrix that give the normal velocity at control point j due to sources of unit strength on panel i

\mathbf{U} is a unit vector in the direction of the free stream

Equation 27.36 constitutes a system of N linear equations that can be solved for the unknown source strengths σ_i . Once the source strengths have been determined, the velocity potential, or the velocity itself, can be computed directly at any point in the flow field using Equation 27.34. A review of the development and application of panel methods is provided by Hess [24].

A major advantage of panel methods, relative to the more advanced methods required to solve the nonlinear problems of stages II – V, is that it is necessary to describe (and to discretize into panels) only the surface of the body. While linearity is a great advantage in this regard, it is not clear that the method is computationally more efficient than the more advanced nonlinear field methods. This results from the fact that the influence coefficient matrix in the system of equations that must be solved to give the source strengths for each panel is not sparse; that is, the velocities at each control point are affected by the sources on all the panels. In contrast, the solution at each mesh point in a finite-difference formulation (or each mesh cell in a finite-volume formulation) is related to the values of the solution at only a few neighbors, resulting in a very sparse matrix of influence coefficients that can be solved very efficiently using iterative methods. Thus, the primary advantage of the panel method is the geometrical one associated with the reduction in dimension of the problem. For nonlinear problems, the use of finite-difference, finite-element, or finite-volume methods requires discretization of the entire flow field, and the associated mesh-generation task has been a major pacing item limiting the application of such methods.

27.3.2 Nonlinear Methods

For nonlinear equations, superposition of elementary solutions is no longer a valid technique for constructing solutions, and it becomes necessary to discretize the solution throughout the entire domain, not just the boundary surface. In addition, since the equations are nonlinear, some sort of iteration must be used to compute successively good approximations to the solution. This iterative process may approximate the physics of an unsteady flow process or may be chosen to provide more rapid convergence to the solution for steady-state problems. Solutions for both the nonlinear potential and Euler equations are generally determined using a finite-difference, finite-volume, or a finite-element method. In any of these techniques, a grid, or network of points and cells, is distributed throughout the flow field. In a finite-difference method, the derivatives appearing in the original differential equation are approximated by discrete differences in the values of the solution at neighboring points (and times, if the solution is unsteady), and substitution of these into the differential equation yields a system of algebraic equations relating the values of the solution at neighboring grid points. In a finite-volume method, the unknowns are taken to be representative of the values of the solution in the control volumes formed by the intersecting grid surfaces, and the equations are constructed by balancing fluxes across the bounding surfaces of each control volume with the rate of change of the solution within the control volume. In a finite-element method, the solution is represented using simple interpolating functions within each mesh cell, or element, and equations for the nodal values are obtained by integrating a variational or residual formulation of the equations over the elements. The algebraic equations relating the values of the solution in neighboring cells can be very similar (or even identical) in appearance for all three methods, and the choice of method often is primarily a matter of taste. Stable and efficient finite-difference and finite-volume methods were developed earlier than finite-element methods for compressible flow problems, but finite-element methods capable of treating very complex compressible flows are now available. A review of recent progress in the development of finite-element methods for compressible flows and remaining issues is given by Glowinski and Pironneau [14].

Since the nonlinear potential, Euler and Navier–Stokes equations all are nonlinear, the algebraic equations resulting from these discretization procedures also are nonlinear, and a scheme of successive approximation usually is required to solve them. As mentioned earlier, however, these equations tend to be highly local in nature and efficient iterative methods have been developed to solve them in many cases.

27.3.2.1 Nonlinear Potential Equation Methods

The primary advantage of solving the potential equation, rather than the Euler (or Navier–Stokes) equations, derives from the fact that the flow field can be described completely in terms of a single scalar function, the velocity potential Φ . The formulation of numerical schemes to solve Equation 27.22 is complicated by the fact that, as noted earlier, the equation changes type according to whether the local Mach number is subsonic or supersonic. Differencing schemes for the potential equation must, therefore, be type dependent—that is, they must change their form depending on whether the local Mach number is less than, or greater than, unity. These methods usually are based upon central, or symmetric, differencing formulas that are appropriate for the elliptic case (corresponding to subsonic flows), which are then modified by adding an upwind bias to maintain stability in hyperbolic regions (where the flow is locally supersonic). This directional bias can be introduced into the difference equations either by adding an artificial viscosity proportional to the third derivative of the velocity potential Φ in the streamwise direction or by replacing the density at each point in supersonic zones with its value at a point slightly upstream of the actual point. Mathematically, these two approaches can be seen to be equivalent, since the upwinding of the density evaluation also effectively introduces a correction proportional to the third derivative of the potential in the flow direction.

It is important to introduce such artificial viscosity (or compressibility) terms in such a way that their effect vanishes in the limit as the mesh is refined. In this way, the numerical approximation will

approach the differential equation in the limit of zero mesh spacing, and the method is said to be consistent with the original differential equation. In addition, for flows with shock waves, it is important that the numerical approximation be *conservative*; this guarantees that the properties of discontinuous solutions will be consistent with the jump relations of the original conservation laws. The shock jump relations corresponding to Equation 27.22, however, are different from the Rankine–Hugoniot conditions describing shocks within the framework of the Euler equations. Since entropy is everywhere conserved in the potential theory and since there is a finite entropy jump across a Rankine–Hugoniot shock, it is clear that the jump relations must be different. For weak shocks, however, the differences are small and the economies afforded by the potential formulation make computations based on this approximation attractive for many transonic problems.

Perturbation analysis can be used to demonstrate that the effect of entropy jump across the shocks is more important than the rotationality introduced by these weak shocks. Thus, it makes sense to develop techniques that account for the entropy jump, but still within the potential formulation. Such techniques have been developed (see, e.g., Hafez [20]), but have been relatively little used as developments in techniques to solve the Euler equations have mostly overtaken these approaches.

The nonlinear difference equations resulting from discrete approximations to the potential equation generally are solved using iterative, or relaxation, techniques. The equations are linearized by computing approximations to all but the highest (second) derivatives from the preceding solution in an iterative sequence, and a correction is computed at each mesh point in such a way that the equations are identically satisfied. It is useful in developing these iterative techniques to think of the iterative process as a discrete approximation to a continuous time-dependent process (Garabedian [12]). Thus, the iterative process approximates an equation of the form

$$\beta_0 \frac{\partial \Phi}{\partial t} + \beta_1 \frac{\partial^2 \Phi}{\partial \xi \partial t} + \beta_2 \frac{\partial^2 \Phi}{\partial \eta \partial t} = \frac{a^2}{\rho} \left\{ \frac{\partial}{\partial \xi} (\rho h U) + \frac{\partial}{\partial \eta} (\rho h V) \right\} \quad (27.37)$$

The parameters β_0 , β_1 , and β_2 , which are related to the mix of old and updated values of the solution used in the difference equations, can then be chosen to ensure that the time-dependent process converges to a steady state in both subsonic and supersonic regions. The formulation of transonic potential flow problems and their solution is described by Caughey [7].

Even when the values of the parameters are chosen to provide rapid convergence, many hundreds of iterations may be necessary to achieve convergence to acceptable levels, especially when the mesh is very fine. This slow convergence is a characteristic of virtually all iterative schemes and is a result of the fact that the representation of the difference equations must be highly local if the scheme is to be computationally efficient. As a result of this locality, the reduction of the low-wave-number component of the error to acceptable levels often requires many iterations. A powerful technique for circumventing this difficulty with the iterative solution of numerical approximations to partial differential equations, called the multigrid technique, has been applied with great success to problems in fluid mechanics.

The multigrid method relies for its success on the fact that, after a few cycles of any good iterative technique, the error remaining in the solution is relatively smooth and can be represented accurately on a coarser grid. Application of the same iterative technique on the coarser grid soon makes the error on this grid smooth as well, and the grid coarsening process can be repeated until the grid contains only a few cells in each coordinate direction. The corrections that have been computed on all coarser levels are then interpolated back to the finest grid, and the process is repeated. The accuracy of the converged solution on the fine grid is determined by the accuracy of the approximation on that grid, since the coarser levels are used only to effect a more rapid convergence of the iterative process.

A particularly efficient multigrid technique for steady transonic potential flow problems has been developed by Jameson [26]. It uses a generalized alternating-direction implicit (ADI) smoothing

algorithm in conjunction with a full-approximation scheme multigrid algorithm. In theory, for a wide class of problems, the work (per mesh point) required to solve the equations using a multigrid approach is independent of the number of mesh cells. In many practical calculations, 10 or fewer multigrid cycles may be required even on very fine grids.

27.3.2.2 Euler Equation Methods

As noted earlier, the Euler equations constitute a hyperbolic system of partial differential equations, and numerical methods for solving them rely heavily upon the rather well-developed mathematical theory of such systems. As for the nonlinear potential equation, discontinuous solutions corresponding to flows with shock waves play an important role. Shock-capturing methods are much more widely used than shock-fitting methods, and for these methods, it is important to use schemes that are conservative.

As mentioned earlier, it is necessary to add artificial, or numerical, dissipation to stabilize the Euler equations. This can be done by adding dissipative terms explicitly to an otherwise non-dissipative, central difference scheme or by introducing upwind approximations in the flux evaluations. Both approaches are highly developed. The most widely used central difference methods are those modeled after the approach of Jameson et al. [31]. This approach introduces an adaptive blend of second and fourth differences of the solution in each coordinate direction; a local switching function, usually based on a second difference of the pressure, is used to reduce the order of accuracy of the approximation to first order locally in the vicinity of shock waves and to turn off the fourth differences there. The second-order terms are small in smooth regions where the fourth-difference terms are sufficient to stabilize the solution and ensure convergence to the steady state. More recently, Jameson [28] has developed improved symmetric limited positive (SLIP) and upstream limited positive (USLIP) versions of these blended schemes (see also Tatsumi et al. [51]).

Much effort has been directed toward developing numerical approximations for the Euler equations that capture discontinuous solutions as sharply as possible without overshoots in the vicinity of the discontinuity. For purposes of exposition of these methods, we consider the 1-D form of the Euler equations, which can be written as

$$\frac{\partial \mathbf{w}}{\partial t} + \frac{\partial \mathbf{f}}{\partial x} = 0 \quad (27.38)$$

where

$$\begin{aligned} \mathbf{w} &= \{\rho, \rho u, e\}^T \\ \mathbf{f} &= \{\rho u, \rho u^2 + p, (e + p)u\}^T \end{aligned}$$

Not only is the exposition clearer for the 1-D form of the equations, but the implementation of these schemes for multidimensional problems also generally is done by dimensional splitting in which 1-D operators are used to treat variations in each of the mesh directions.

For smooth solutions, Equation 27.38 is equivalent to the quasi-linear form

$$\frac{\partial \mathbf{w}}{\partial t} + \mathbf{A} \frac{\partial \mathbf{w}}{\partial x} = 0 \quad (27.39)$$

where $\mathbf{A} = \{\partial \mathbf{f} / \partial \mathbf{w}\}$ is the Jacobian of the flux vector with respect to the solution vector. The eigenvalues of \mathbf{A} are given by $\lambda = u, u + a, u - a$, where $a = \sqrt{\gamma p / \rho}$ is the speed of sound. Thus, for subsonic flows, one of the eigenvalues will have a different sign than the other two. For example, if $0 < u < a$, then $u - a < 0 < u < u + a$. The fact that various eigenvalues have different signs in subsonic flows means that simple one-sided difference methods cannot be stable. One way around this difficulty is to split the flux vector into two parts, the Jacobian of each of which has eigenvalues of only one sign. Such an approach has been developed by Steger and Warming [50]. Steger and Warming used a relatively simple splitting that has discontinuous

derivatives whenever an eigenvalue changes sign; an improved splitting has been developed by van Leer [55] that has smooth derivatives at the transition points.

Each of the characteristic speeds can be identified with the propagation of a wave. If a mesh surface is considered to represent a discontinuity between two constant states, these waves constitute the solution to a Riemann (or shock tube) problem. A scheme developed by Godunov [15] assumes the solution to be piecewise constant over each mesh cell and uses the fact that the solution to the Riemann problem can be given in terms of the solution of algebraic (but nonlinear) equations to advance the solution in time. Because of the assumption of piecewise constancy of the solution, Godunov's scheme is only first-order accurate. van Leer [53,54] has shown how it is possible to extend these ideas to a second-order monotonicity-preserving scheme using the so-called monotone upwind scheme for systems of conservation laws (MUSCL) formulation. The efficiency of schemes requiring the solution of Riemann problems at each cell interface for each time step can be improved by the use of approximate solutions to the Riemann problem (Roe [42]).

More recent ideas to control oscillation of the solution in the vicinity of shock waves include the concept of total-variation diminishing (TVD) schemes, first introduced by Harten (see, e.g., Harten [21,22]) and essentially non-oscillatory (ENO) schemes introduced by Osher and his coworkers (see, e.g., Harten et al. [23] and Shu and Osher [45]).

Hyperbolic systems describe the evolution in time of physical systems undergoing unsteady processes governed by the propagation of waves. This feature frequently is used in fluid mechanics, even when the flow to be studied is steady. In this case, the unsteady equations are solved for long enough times that the steady state is reached asymptotically—often to within round-off error. To maintain the hyperbolic character of the equations and to keep the numerical method consistent with the physics it is trying to predict, it is necessary to determine the solution at a number of intermediate time levels between the initial state and the final steady state. Such a sequential process is said to be a time marching of the solution.

The simplest practical methods for solving hyperbolic systems are *explicit* in time. The size of the time step that can be used to solve hyperbolic systems using an explicit method is limited by a constraint known as the Courant–Friedrichs–Lewy (CFL) *condition*. Broadly interpreted, the CFL condition states that the time step must be smaller than the time required for the fastest signal to propagate across a single mesh cell. Thus, if the mesh is very fine, the allowable time step also must be very small, with the result that many time steps must be taken to reach an asymptotic steady state.

Multistage, or Runge–Kutta, methods have become extremely popular for use as explicit time-stepping schemes. After discretization of the spatial operators, using finite-difference, finite-volume, or finite-element approximations, the Euler equations can be written in the form

$$\frac{d\mathbf{w}_i}{dt} + Q(\mathbf{w}_i) + D(\mathbf{w}_i) = 0 \quad (27.40)$$

where

\mathbf{w}_i represents the solution at the i th mesh point, or in the i th mesh cell

Q and D are discrete operators representing the contributions of the Euler fluxes and numerical dissipation, respectively

An m -stage time integration scheme for these equations can be written in the form

$$\mathbf{w}_i^{(k)} = \mathbf{w}_i^{(0)} - \alpha_k \Delta t \left\{ Q(\mathbf{w}_i^{(k-1)}) + D(\mathbf{w}_i^{(k-1)}) \right\}, \quad k = 1, 2, \dots, m \quad (27.41)$$

with $\mathbf{w}_i^{(0)} = \mathbf{w}_i^n$, $\mathbf{w}_i^{(m)} = \mathbf{w}_i^{n+1}$ and $\alpha_m = 1$. The dissipative and dispersive properties of the scheme can be tailored by the sequence of α_i chosen; note that, for nonlinear problems, this method may be only

first-order accurate in time, but this is not necessarily a disadvantage if one is interested only in the steady-state solution. The principal advantage of this formulation, relative to versions that may have better time accuracy, is that only two levels of storage are required regardless of the number of stages used. This approach was first introduced for problems in fluid mechanics by Graves and Johnson [18] and has been further developed by Jameson et al. [31]. In particular, Jameson and his group have shown how to tailor the stage coefficients so that the method is an effective smoothing algorithm for use with multigrid (see, e.g., Jameson and Baker [29]).

Implicit techniques also are highly developed, especially when structured grids are used. Approximate factorization of the implicit operator usually is required to reduce the computational burden of solving a system of linear equations for each time step. Methods based on ADI techniques date back to the pioneering work of Briley and McDonald [6] and Beam and Warming [5]. An efficient diagonalized ADI method has been developed within the context of multigrid by Caughey [8], and a lower-upper symmetric Gauss-Seidel method has been developed by Yoon and Kwak [58]. The multigrid implementations of these methods are based on the work of Jameson [27]. Arguably the fastest convergence for transonic airfoil problems has been achieved by a multigrid implementation of the symmetric Gauss-Seidel algorithm by Jameson and Caughey [30].

An excellent summary of the development of higher-order methods for unstructured grid computations is provided by Vincent and Jameson [56].

27.3.3 Navier–Stokes Equation Methods

As described earlier, the relative importance of viscous effects is characterized by the value of the Reynolds number. If the Reynolds number is not too large, the flow remains smooth, and adjacent layers (or laminae) of fluid slide smoothly past one another. When this is the case, the solution of the Navier–Stokes equations is not too much more difficult than solution of the Euler equations. Greater resolution is required to resolve the large gradients in the boundary layers near solid boundaries, especially as the Reynolds becomes larger, so more mesh cells are required to achieve acceptable accuracy. In most of the flow field, however, the flow behaves as if it were nearly inviscid, so methods developed for the Euler equations are appropriate and effective. The equations must, of course, be modified to include the additional terms resulting from the viscous stresses, and care must be taken to ensure that any artificial dissipative effects are small relative to the physical viscous dissipation in regions where the latter is important. The solution of the Navier–Stokes equations for laminar flows, then, is somewhat more costly in terms of computer resources, but not significantly more difficult from an algorithmic point of view, than solution of the Euler equations. Unfortunately, most flows of engineering interest occur at large enough Reynolds numbers that the flow in the boundary layers near solid boundaries becomes turbulent.

27.3.3.1 Turbulence Models

Solution of the RANS equations requires modeling of the Reynolds stress terms. The simplest models, based on the original mixing-length hypothesis of Prandtl, relate the Reynolds stresses to the local properties of the mean flow. The Baldwin–Lomax model [3] is the most widely used model of this type and gives good correlation with experimental measurements for wall-bounded shear layers so long as there are no significant regions of separated flow. Attempts have also been made to include nonequilibrium effects in algebraic turbulence models, see, for example [1].

The most complete commonly used turbulence models include two additional partial differential equations that determine characteristic length and time scales for the turbulence. The most widely used of these techniques is called the k - ϵ model, since it is based on equations for the turbulence kinetic energy (usually given the symbol k) and the turbulence dissipation rate (usually given the symbol ϵ). This method has grown out of work by Launder and Spaulding [34]. Another variant, based on a formulation by Kolmogorov, calculates a turbulence frequency ω instead of the dissipation rate (and hence is

called a $k-\omega$ model). More complete models that compute all elements of the Reynolds stress tensor have also been developed. The common base for most of these models is the work of Launder, Reese and Rodi [33], with more recent contributions by Lumley [36], Speziale [49], and Reynolds [40]. These models, as well as the $k-\varepsilon$ and $k-\omega$ models, and their implementation within the context of CFD are described in the book by Wilcox [57].

More limited models, based on a single equation for a turbulence scale, also have been developed. These include the models of Baldwin and Barth [4] and the widely used model of Spalart and Allmaras [48]. These models are applicable principally to boundary layer flows of aerodynamic interest.

27.3.3.2 Large-Eddy Simulations

The difficulty of developing generally applicable phenomenological turbulence models on the one hand and the enormous computational resources required to resolve all scales in turbulent flows at large Reynolds number on the other have led to the development of LES techniques. In this approach, the largest length and time scales of the turbulent motions are resolved in the simulation, but the smaller (sub-grid) scales are modeled. This is an attractive approach because it is the largest scales that contain the preponderance of turbulent kinetic energy and that are responsible for most of the mixing. At the same time, the smaller scales are believed to be more nearly isotropic and independent of the larger scales and thus are less likely to behave in problem-specific ways—that is, it should be easier to develop universal models for these smaller scales.

A filtering technique is applied to the Navier–Stokes equations that results in equations having a form similar to the original equations, but with additional terms representing a sub-grid-scale tensor that describes the effect of the modeled terms on the larger scales. The solution of these equations is not well posed if there is no initial knowledge of the sub-grid scales; the correct statistics are predicted for the flow, but it is impossible to reproduce a specific realization of the flow without this detailed initial condition. Fortunately, for most engineering problems, it is only the statistics that are of interest.

LES techniques date back to the pioneering work of Smagorinsky [46], who developed an eddy-viscosity sub-grid model for use in meteorological problems. The model turned out to be too dissipative for large-scale meteorological problems in which large-scale, predominantly 2-D, motions are affected by 3-D turbulence. Smagorinsky’s model and subsequent developments of it find wide application in engineering problems, however. Details of the LES approach are discussed by Rogallo and Moin [43], and more recent developments and applications are described by Lesieur and Métais [35], Meneveau and Katz [37], Sagaut [44], and Garnier et al. [13].

There is a school of thought that believes that the details of the sub-grid model are not important, so long as the kinetic energy of the turbulence is dissipated at the correct rate at the sub-grid scales. Such *implicit*, or ILES, methods rely simply upon the (artificial) dissipation of the numerical scheme to provide this dissipation. A recent summary of these techniques is provided by Grinstein et al. [19].

LES continues to pose problems for wall-bounded flows, for which attached boundary layers require near-DNS resolution in the absence of adequate wall models. An effective approach for many such cases is detached-eddy simulation (DES), which combines the features of RANS turbulence models within the attached boundary layers with an LES approach within regions of massively separated flow. A recent review of this approach is given by Spalart [47].

27.3.3.3 Direct Numerical Simulations

DNS codes generally use spectral or pseudo-spectral approximations for the spatial discretization of the Navier–Stokes equations (see, e.g., Gottlieb and Orszag [17] or Hussaini and Zang [25]). The difference between spectral and pseudo-spectral methods is in the way that products are computed; the advantage of spectral methods, which are more expensive computationally, is that aliasing errors are removed exactly (Orszag [39]).

A description of the issues involved and results are given by Rogallo and Moin [43]. DNS results are particularly valuable for the insight that they provide into the fundamental nature of turbulent flows.

The computational resources required for DNS calculations grow so rapidly with increasing Reynolds number that they are unlikely to be directly useful for engineering predictions, but they will remain an invaluable tool providing insight needed to construct better turbulence models for use in LES and with the Reynolds-averaged equations.

27.3.3.4 Verification, Validation, and Uncertainty Quantification

With the ever-widening use of CFD for increasingly complex physical problems, increasing efforts are focused on determining the credibility of predictions based on CFD analyses; these efforts are similar to and, in fact, build upon efforts in related fields, especially operations research.

Because of the inherent difficulty of developing numerical methods to solve highly nonlinear systems of partial differential equations, standards have not yet been developed to certify the accuracy of flow simulations, although some progress has been made in developing a common vocabulary and guidelines for the process; see, for example, the guidelines document developed by the American Institute of Aeronautics and Astronautics (AIAA) [2].

It is generally agreed that *verification* of a code or solution generated by a code refers to the process of determining that the instantiation of a conceptual model as a computer program accurately represents the conceptual model—that is, that the algorithm used is a consistent representation of the conceptual model and that the computer program contains no coding errors. Thus, verification can be carried out without reference to the physical world or to data from experiments; it is an issue purely of the accuracy of the numerical method and its implementation within a particular computer program. Computer codes can be verified for a given range of parameters (e.g., Reynolds number and Mach number):

- By comparing computed solutions with exact solutions of the governing equations. This is possible only in those very limited cases for which exact solutions of the governing equations are known.
- By ascertaining that the convergence rates of solutions over the specified range of parameter values are consistent with those predicted by theory for the numerical methods used. Note that this technique verifies only that the solutions to *some* system of equations converge at the correct rate, but will not detect coding errors that result in an error in the system of equations actually encoded.
- Using the *method of manufactured solutions*, in which source terms are determined that allow a specified function to be a solution to the governing equations. For complex systems of equations, these source terms often are computed using numerical algebra packages to “write” the code representing the source terms, as they can be too complex to derive and code by hand.

The term *validation* refers to the adequacy of the conceptual model to represent the physical phenomena of interest. As such, it requires comparison of the results of a simulation with experimental measurements. The true complexity of validation can be understood when one realizes that the solution(s) one would usually like to verify are those for which no comparable experimental measurements exist; the role of the simulation is, in fact, to replace an (usually expensive and/or time-consuming) experiment with the results of the simulation. Thus, what one would really like to do is to *quantify the uncertainty* in the result of a simulation, where the uncertainty arises from both numerical inaccuracies in the instantiation of the model (e.g., errors associated with truncation or lack of iterative convergence) and inadequacies in the conceptual model. Some information about the uncertainty of simulation results can be provided by sensitivity studies, in which parameters upon which the simulation depends are varied in a systematic way. There are also attempts to develop models *for the inadequacy of the models themselves* within the context of Bayesian inference.

Recent books focusing on these issues in the broader context of scientific simulation include those by Roache [41] and Oberkampf and Roy [38].

27.4 Research Issues and Summary

The field of CFD continues to be a field of intense research activity. The development of accurate algorithms based on unstructured grids for problems involving complex geometries and the increasing application of CFD techniques to unsteady problems, including aeroelasticity and acoustics, are examples of areas of great current interest, as are extensions to multiphase and reacting flows. Algorithmically, the incorporation of adaptive grids that automatically increase resolution in regions where it is required to maintain accuracy and the development of inherently multidimensional high-resolution schemes continue to be areas of fertile development. Finally, the continued expansion of computational capability allows the application of DNS and LES methods to problems of higher Reynolds number and increasingly realistic flow geometries.

Key Terms

- Artificial viscosity:** Terms added to a numerical approximation that provide artificial—that is, non-physical—dissipative mechanisms to stabilize a solution or to allow shock waves to be captured automatically by the numerical scheme.
- CFL condition:** The CFL condition is a stability criterion that limits the time step of an explicit time-marching scheme for hyperbolic systems of differential equations. In the simplest 1-D case, if Δx is the physical mesh spacing and $\rho(\mathbf{A})$ is the spectral radius of the Jacobian matrix \mathbf{A} , corresponding to the fastest wave speed for the problem, then the time step for explicit schemes must satisfy the constraint $\Delta t \leq K \Delta x / \rho(\mathbf{A})$, where K is a constant. For the simplest explicit schemes, $K = 1$, which implies that the time step must be less than that required for the fastest wave to cross the cell.
- Conservative:** A numerical approximation is said to be conservative if it is based on the conservation (or divergence) form of the differential equations, and the net flux across a cell interface is the same when computed from either direction; in this way the properties of discontinuous solutions are guaranteed to be consistent with the jump relations for the original integral form of the conservation laws.
- Direct numerical simulation (DNS):** A solution of the complete Navier–Stokes equations in which all length and time scales, down to those describing the smallest eddies containing significant turbulent kinetic energy, are fully resolved.
- Euler equations:** The equations describing the inviscid flow of a compressible fluid. These equations comprise a hyperbolic system of differential equations; the Euler equations are non-dissipative, and weak solutions containing discontinuities (which can be viewed as approximations to shock waves) must be allowed for many practical problems.
- Explicit method:** A method in which the solution at each point for the new time level is given explicitly in terms of values of the solution at the previous time level, to be contrasted with an *implicit method* in which the solution at each point at the new time level also depends on the solution at one or more neighboring points at the new time level, so that an algebraic system of equations must be solved at each time step.
- Finite-difference method:** A numerical method in which the solution is computed at a finite number of points in the domain; the solution is determined from equations that relate the solution at each point to its values at selected neighboring points.
- Finite-element method:** A numerical method for solving partial differential equations in which the solution is approximated by simple functions within each of a number of small elements into which the domain has been divided.
- Finite-volume method:** A numerical method for solving partial differential equations, especially those arising from systems of conservation laws, in which the rate of change of quantities within each mesh volume is related to fluxes across the boundaries of the volume.

- Inviscid:** A model for fluid flow in which the stresses due to internal friction, or viscosity, are neglected; it is also called an ideal fluid. The equations describing the motion of an inviscid, compressible fluid are called the Euler equations.
- Large-eddy simulation (LES):** A numerical solution of the Navier–Stokes equations in which the largest, energy-carrying eddies are completely resolved, but the effects of the smaller eddies, which are more nearly isotropic, are accounted for by a sub-grid model.
- Mach number:** The ratio $M = V/a$ of the fluid velocity V to the speed of sound a . This nondimensional parameter characterizes the importance of compressibility to the dynamics of the fluid motion.
- Mesh generation:** The field directed at the generation of mesh systems suitable for the accurate representation of solutions to partial differential equations.
- Method of manufactured solutions:** A technique used in the verification of simulation programs in which source terms are determined that, when added to the right-hand side of the system of equations being solved, allow a specified function to be an exact solution.
- Panel method:** A numerical method to solve Laplace’s equation for the velocity potential of a fluid flow. The boundary of the flow domain is discretized into a set of non-overlapping facets, or panels, on each of which the strength of some elementary solution is assumed constant. Equations for the normal velocity at control points on each panel can be solved for the unknown singularity strengths to give the solution. In some disciplines, this approach is called the boundary integral element method (BIEM).
- Reynolds-averaged Navier–Stokes (RANS) equations:** Equations for the mean quantities in a turbulent flow obtained by decomposing the fields into mean and fluctuating components and averaging the Navier–Stokes equations. Solution of these equations for the mean properties of the flow requires knowledge of various correlations, the Reynolds stresses, of the fluctuating components.
- Shock capturing:** Numerical method in which shock waves are treated by smearing them out with artificial dissipative terms in a manner such that no special treatment is required in the vicinity of the shocks; to be contrasted with *shock-fitting* methods in which shock waves are treated as discontinuities with the jump conditions explicitly enforced across them.
- Shock wave:** Region in a compressible flow across which the flow properties change almost discontinuously; unless the density of the fluid is extremely small, the shock region is so thin relative to other significant dimensions in most practical problems that it is a good approximation to represent the shock as a surface of discontinuity.
- Turbulent flow:** Flow in which unsteady fluctuations play a major role in determining the effective mean stresses in the field; regions in which turbulent fluctuations are important inevitably appear in fluid flow at large Reynolds numbers.
- Upwind method:** A numerical method for CFD in which upwinding of the difference stencil is used to introduce dissipation into the approximation, thus stabilizing the scheme. This is a popular mechanism for the Euler equations, which have no natural dissipation, but is also used for Navier–Stokes algorithms, especially those designed to be used at high Reynolds number.
- Validation:** The process of determining the degree to which a model is an accurate representation of the real world from the perspective of the intended uses of the model.
- Verification:** The process of determining that an implementation of a model accurately represents the developer’s conceptual description of the model and/or that a particular solution is a sufficiently accurate solution to the model equations.
- Visualization:** The use of computer graphics to display features of solutions to CFD problems.

Further Information

Several organizations sponsor regular conferences devoted completely, or in large part, to CFD. The AIAA sponsors the AIAA Computational Fluid Dynamics Conferences in odd-numbered years, usually in July; the proceedings of this conference are published by AIAA. In addition, there typically are

many sessions on CFD and its applications at the AIAA Aerospace Sciences Meeting, held every January, and the AIAA Fluid and Plasma Dynamics Conference, which is held every summer, in conjunction with the AIAA CFD Conference in those years when the latter is held. The Fluids Engineering Conference of the American Society of Mechanical Engineers, held every summer, also contains sessions devoted to CFD. In even-numbered years, the International Conference on Computational Fluid Dynamics is held. This biennial event began in 2000 with the merger of the International Conference on Numerical Methods in Fluid Dynamics and the International Symposium on Computational Fluid Dynamics. The 2012 conference was held in Hawaii.

The *Journal of Computational Physics* contains many articles on CFD, especially covering algorithmic issues. The *AIAA Journal* also has many articles on CFD, including aerospace applications. The *International Journal for Numerical Methods in Fluids* contains articles emphasizing the finite-element method applied to problems in fluid mechanics. The journals *Computers and Fluids* and *Theoretical and Computational Fluid Dynamics* are devoted exclusively to CFD, the latter journal emphasizing the use of CFD to elucidate basic fluid mechanical phenomena. The first issue of the *CFD Review*, which attempts to review important developments in CFD, was published in 1995. The *Annual Review of Fluid Mechanics* also contains a number of review articles on topics in CFD.

The European Research Community on Flow, Turbulence, and Combustion (ERCOFTAC) has held nearly biennial meetings since 1994 on DNS and LES; proceedings of the most recent workshop are contained in the volume edited by Kuerten et al. [32].

The following textbooks provide excellent coverage of many aspects of CFD:

28.1 Introduction

Modern astronomy and *astrophysics* is a computationally driven discipline. Even during the 1980s, it was said that an astronomer would choose a computer over a telescope if given the choice of only one tool. However, just as it is impossible to separate “astronomy” from astrophysics, almost all astrophysicists would no longer be able to separate the computational components of astrophysics from the processes of data collection, data analysis, and theory. The links between astronomy and computational astrophysics are so close that a discussion of computational astrophysics is essentially a summary of the role of computation in all of astronomy. We have chosen to concentrate on a few specific areas of interest in computational astrophysics rather than attempt the monumental task of summarizing the entire discipline. We further limit the context of this chapter by discussing astronomy rather than related disciplines such as planetary science and the engineering-oriented aspects of space science.

28.2 Astronomical Databases

Physics and astronomy have been leaders among the sciences in the widespread use of and access to online access and data retrieval. This has most likely occurred because the relatively small number of astronomers is broadly distributed so that few astronomers typically reside in any one location; it also perhaps results because astronomy is less protective of data rights than other disciplines, which tend to be more driven by commercial spin-offs. Astronomers regularly enjoy online access to journal articles, astronomical catalogs/databases, and software.

28.2.1 Electronic Information Dissemination

Astronomical journals have been available electronically since 1995 [101]; now all major journals are available electronically. In recent years, several new open access journals have also appeared as alternatives to the highly visible, well-known, yet sometimes costly established journals; astrophysics has not fully moved in the direction of open access but has the possibility of doing so [86]. Meanwhile, astrophysicists tend to make heavy use of electronic preprint servers (e.g., [54]), and these have increased accessibility and citation rates (e.g., [41,65,91]).

The Astrophysical Data Service (ADS) [80] is the electronic index to all major astrophysical publications; it is accessible from a variety of mirror sites worldwide. The ADS is a data retrieval tool allowing users to index journal articles, other publications, and preprints by title, keyword, and author and even by astronomical object. The ADS is also a citation index that can be used to analyze the effectiveness of astronomical dissemination (e.g., [65]). The ADS is capable of accessing the complete text of articles and in many cases original data via electronic files. Although the integrated data management from all astrophysics missions was one of the ADS original purposes, the large amount of astronomical data available, coupled with preprocessing and data analysis tools often needed to analyze these data, has led to the parallel development of astronomical data depositories that will be described later.

Electronic dissemination plays a critical role in the collection of astronomical data. One of the newest frontiers in astronomy has been in the time domain: many variable sources (such as high-energy transients and peculiar *galaxies*) often exhibit changes on extremely short timescales. Follow-up observations require the community to rapidly disseminate source locations, brightnesses, and other pertinent information electronically (notification sometimes must go out to other observatories on timescales as short as seconds). There are a variety of electronic circulars available to the observational community: these include the GRB Coordinates Network (GCN; [12]) and circulars distributed by the International Astronomical Union (<http://www.iau.org>).

28.2.2 Data Collection

Astronomy is generally an observational rather than an experimental science (although there are laboratory experiments that emulate specific astronomical conditions). Modern astronomical observations are made using computer-controlled telescopes, balloon instruments, and/or satellites. Many of these are controlled remotely, and some are robotic.

All telescopes need electronic guidance because they are placed on moving platforms; even the Earth is a moving platform when studying the heavens. From the perspective of the terrestrial observer, the sky appears to pivot overhead about the Earth's equatorial axis; an electronic drive is needed to rotate the telescope with the sky in order to keep the telescope trained on an object. However, the great weight of large telescopes is easier to mount altazimuthally (perpendicular to the horizon) than equatorially. A processor is needed to make real-time transformations from equatorial to altazimuth coordinates so that the telescope can track objects; it is also needed to accurately and quickly point the telescope. Precession of the equinoxes must also be taken into account; the direction of the Earth's rotational axis slowly changes position relative to the sky. Computers have thus been integrated into modern telescope control systems.

Additional problems are present for telescopes flown on balloons, aircraft, and satellites. The telescopes need to either be pointed remotely or at least have the directions they were pointed while observing accessible after the fact. Flight software (which has now evolved because of increased modern processor speeds to the point where it can be compiled and uploaded) was originally written in machine code to run in real time. Stability in telescope pointing is required because astronomical sources are distant; long observing times are needed to integrate the small amount of light received from sources other than the sun, the moon, and the planets.

As an example, we mention computer guidance on the Hubble Space Telescope (HST). HST has different sensor types that provide feedback in order to maintain a high degree of telescope pointing accuracy; the Fine Guidance Sensors have been key since their installation in 1997. The three Fine Guidance Sensors provide an error signal so that the telescope has the pointing stability needed to produce high-resolution images. The first sensor monitors telescope pitch and yaw, the second monitors roll, and the third serves both as a scientific instrument and as a backup. Each sensor contains lenses, mirrors, prisms, servos, beam splitters, and photomultiplier tubes. The software coordinates the pointing of the sensors onto entries in an extremely large star catalog. The guidance sensors lock onto a star and then deviations in its motion to a 0.0028 arc second accuracy. This provides HST with the ability to point at the target to within 0.007 arc seconds of deviation over extended periods of time. This level of stability and precision is comparable to being able to hold a laser beam constant on a penny 350 miles away.

Robotic telescopes are becoming more common in astronomy [21]. Observations from robotic telescopes can be scheduled in advance (such as observations of variable stars and active galaxies), thus reducing manpower costs because users do not have to travel to an observatory or even be awake when observations are being made. Robotic telescopes also allow real-time follow-up observations to be made, including observations of supernovae, gamma-ray bursts (GRBs), minor planets, and extrasolar planet transits. They are also being used as educational tools to bring astronomy into the classroom [39]. Scheduling and control software are key to the development of a successful robotic telescope design (e.g., [78]).

Many telescopes are designed to observe in *electromagnetic spectral* regimes other than the visible. An accurate computer guidance system is needed to ensure that the telescope is correctly pointing even when a source cannot be identified optically and that the detectors are integrated with the other electronic telescope systems. Many bright sources at nonvisible wavelengths are extremely faint in the visible spectral regime. Furthermore, telescopes must be programmed to avoid pointing at bright objects that can burn out photosensitive equipment and sometimes must avoid collecting data when conditions arise that are dangerous to operation. For example, orbital satellites need to avoid operating when over the South Atlantic Ocean—in a region known as the South Atlantic Anomaly, where the Earth's magnetic field is distorted—because high-energy ions and electrons can interact with the satellite's electronic equipment. This can cause faulty instrument readings and/or introduce additional noise.

There are other examples where computation is necessary to the data collection process. In particular, we mention the developing field of *adaptive optics*. This process requires the fast, real-time inversion of large matrices [14]. *Speckle imaging techniques* (e.g., [119]) also remove atmospheric distortion by simultaneously taking short-exposure images from multiple cameras.

Detectors and electronics often need to be integrated by a single computer system. Many interesting specific data collection problems exist that require modern computer-controlled instrumentation. For example, radio telescopes with large dishes cannot move, and sources pass through the telescope's field of view as the Earth rotates. Image reconstruction is necessary from the data stream, since all sources in the dish's field of view are visible at any given time. Another interesting data collection problem occurs in infrared astronomy. The sky is itself an infrared emitter, and strong source signal to noise can only be obtained by constantly subtracting sky flux from that of the observation. For this reason, infrared telescopes are equipped with an oscillating secondary mirror that wobbles back and forth, and flux measurements alternate between object and sky. A third example concerns the difficulty in observing x-ray and gamma-ray sources. X-ray and gamma-ray sources emit few photons, and these cannot be easily focused due to their short wavelengths. Computational techniques such as Monte Carlo analysis are

needed to deconvolve photon energy, flux, and source direction from the instrumental response. Often this analysis needs to be done in real time, requiring a fast processor. The telescope guidance system must also be coordinated with onboard visual observations, since the visual sky still provides the basis for telescope pointing and satellite navigation.

28.2.3 Accessing Astronomical Databases

Database management techniques have allowed astronomers to address the increasing problem of storing and accurately cross-referencing astronomical observations. Historically, bright stars were given catalog labels based on their intensities and on the constellation in which they were found. Subsequent catalogs were sensitive to an increased number of fainter objects and thus became larger while simultaneously assigning additional catalog numbers or identifiers to the same objects. The advent of photographic and photoelectric measurement techniques and the development of larger telescopes dramatically increased catalog sizes. Additional labels were given to stars in specialty catalogs (e.g., those containing bright stars, variable stars, and binary stars). Solar system objects such as asteroids and comets are not stationary and have been placed in catalogs of their own.

28.2.4 Catalogs and Online Databases

In 1781, Charles Messier developed a catalog of fuzzy objects that were often confused with comets. Subsequent observations led to identification of these extended objects as star clusters, galaxies, and gaseous nebulae. Many of these extended astronomical sources (particularly regions of the *interstellar medium*) do not have easily identified boundaries (and the observed boundaries are often functions of the *passband* used); this inherent fuzziness presents a problem in finding unique identifiers as well as a database management problem. Furthermore, sources are often extended in the radial direction (sources are 3-D), which presents additional problems since distances are among the most difficult astrophysical quantities to measure.

As astronomy entered the realm of multi wavelength observations in the 1940s, observers realized the difficulty in directly associating objects observed in different spectral regimes. An x-ray emitter might be undetectable or appear associated with an otherwise unexciting stellar source when observed in the optical. Angular resolution is a function of wavelength, so it is not always easy to directly associate objects observed in different passbands.

Temporal variability further complicates source identification. Some objects detected during one epoch are absent in observations made during other epochs. Signal-to-noise ratios (SNRs) of detectors used in each epoch contribute to the source identification problem. Additionally, gamma-ray and x-ray sources tend to be more intrinsically variable due to the violent, nonthermal nature of their emission. Examples of sources requiring access via their temporal characteristics include supernovae, GRBs, high-energy transient sources, and some variable stars and extragalactic objects.

There are tremendous numbers of catalogs available to astronomers, and many of these are found online. Perhaps the largest single repository of online catalogs and metadata links is VizieR (<http://vizier.u-strasbg.fr/viz-bin/VizieR>) [99]. Online catalogs also exist at many other sites such as High-Energy Astrophysics Science Archive Research Center (HEASARC) (at <http://heasarc.gsfc.nasa.gov>), HST (at <http://www.stsci.edu/resources/>), and NASA/IPAC Extragalactic Database (NED) (at <http://nedwww.ipac.caltech.edu>).

Due in part to the strong public financing of astronomy in the United States and Europe, significant amounts of astronomical data are publicly available. As a result, large astronomical databases exist for specific ground-based telescopes and orbital satellites. Some of these databases are large enough to present information retrieval problems. Examples of these databases are Two Micron All Sky Survey (2MASS) [77], Digitized Palomar Observatory Sky Survey (DPOSS) [42], Sloan Digital Sky Survey (SDSS) [135], and the National Radio Astronomy Observatory (NRAO) VLA Sky

Survey (NVSS) [36]. Databases span the range of astronomical objects from stars to galaxies, from active galactic nuclei to the interstellar medium (ISM), and from GRBs to the cosmic microwave background (CMB). Databases are often specific to observations made in predefined spectral regimes rather than specific to particular types of sources; this reflects the characteristics of the instrument making the observations.

28.2.5 Virtual Observatories

Perhaps one of the greatest additions to astronomical databases in the recent years has been the introduction and development of *virtual observatories* (VOs). VOs are designed to improve accessibility, retrieval, and data analysis from international astronomical catalogs and archives. Currently, twenty international VOs are members of the International Alliance (<http://www.ivoa.net>): this includes VOs from Europe, North America, South America, Asia, and Australia. Although these cover a wide range of astronomical data, other VOs are more specific (such as the Virtual Solar Observatory [40], the Virtual Wave Observatory, [51]) and the Information and Distributed Information Service, which aims to become the European Virtual Observatory devoted to planetary sciences [32]).

The US Virtual Astronomical Observatory (VAO) was proposed in 2001 and began operations around 2005 [62]. It was established under a cooperative agreement in 2010 with support from the NSF and NASA. The VAO at last count contained over 9000 data collections, tables, and/or databases through interfaces supported at 80 different organizations [44].

28.2.6 Data File Formats

The astronomical community has evolved a standard data format for the transfer of data. The Flexible Image Transport System (FITS) has broad general acceptance within the astronomical community and can be used for transferring images, spectroscopic information, time series, etc. [63]. It consists of an ASCII text header with information describing the data structure that follows. Although originally defined for 9-track half-inch magnetic tape, FITS format has evolved to be generic to different storage media. The general FITS structure has undergone incremental improvements, with acceptance determined by vote of the International Astronomical Union.

Despite the general acceptance of FITS file format, other methods are also used for astronomical data transfer. This is not surprising given the large range of data types and uses. Some data types have been difficult to characterize in FITS formats (such as solar magnetospheric data). Satellite and balloon data formats are often specific to each instrument and/or satellite.

Due to the large need for storing astronomical images, a wide range of image compression techniques have been applied to astronomy. These include fractal, wavelets, pyramidal median, and JPEG (e.g., [84]).

28.3 Data Analysis

Mathematical and statistical analyses, and their applications to large electronic astronomical databases being archived annually, have been among the driving forces behind the use of computation in astrophysics. This has led in the past 10 years to the formal recognition of new astronomy subdisciplines: astrostatistics and astroinformatics [23].

Data analysis and theoretical software can be accessed at a variety of sites worldwide. A few of the most well-known sites are the Astrophysics Source Code Library (<http://ascl.net/>), the UK Starlink site (<http://star-www.rl.ac.uk>), and the Astronomical Software and Documentation Service at STScI (<http://asds.stsci.edu>). Data analysis tools written in RSI's proprietary interactive data language (IDL) programming language are available at the IDL Astronomy User's Library (<http://idlastro.gsfc.nasa.gov/homepage.html>). IDL has become a computing language of choice by many astronomers because of its design as an image-processing

language, because it has been written with mathematical and statistical uses in mind, because it can handle multidimensional arrays easily, and because it has many built-in data visualization tools.

28.3.1 Data Analysis Systems

In the fall of 1981, astronomers at Kitt Peak National Observatory began developing the Image Reduction and Analysis Facility (IRAF), to serve as a general-purpose, flexible, extendable data reduction package. IRAF replaced a myriad of different data analysis systems that had existed within astronomy, where separate data analysis packages were often supported at an institution (or sometimes individual groups within an institution), such that compatibility between these packages was limited or nonexistent. IRAF has grown beyond its original use primarily by ground-based optical astronomers to encompass space-based experiments as well at wavelengths ranging from x-ray to infrared.

IRAF is currently a mature system, with new releases occurring roughly annually, and is operated by about 5000 users at 1500 distinct sites. It is supported under a number of different computer architectures running Unix or Unix-like (e.g., Linux) operating systems. Oversight of IRAF development is formalized, with a Technical Working Group and various User's Committees overseeing evolution of the software. Numerous large astronomical projects have adopted IRAF as their data analysis suite of choice, typically by providing extensions to the basic system. These projects include the x-ray "Great Observatory" Chandra, the HST, PROS (ROSAT X-Ray Data Analysis System), and FTOOLS (a FITS utility package from HEASARC).

The IRAF core system provides data I/O tools, interactive graphics and image display tools, and a variety of image manipulation and statistical tools. Commonly available "packages" that are part of the standard installation include tools for basic CCD data reduction and photometry and support 1-D, 2-D, echelle, and fiber spectroscopy. Most tasks can be operated in either interactive or batch mode.

IRAF supports the FITS file format, as well as its own internal data type. In addition, extensions exist to handle other data types. Currently, those include STF format (used for HST data), QPOE format (used for event list data such as from the x-ray and EUV satellites), and PLIO for pixel lists (used to flag individual pixels in a region of interest). IRAF uses text files as database or configuration files and provides a number of conversion tools to produce images from text-based data. Binary tables can be manipulated directly using the TABLES package.

Other general-purpose data reduction packages coexist with IRAF. These include the Astronomical Image Processing System (AIPS) and its successor, AIPS++, developed at the US NRAO, and still the image analysis suite of choice for radio astronomy. Image processing has been a very important subdiscipline within computational astrophysics, and we mention a number of image reconstruction methods with special applications to astronomy: the maximum entropy method (e.g., [83]), the Pixon method [106], and massive inference [114]. XIMAGE and its relatives, XSPEC and XRONOS, serve a similar function for the x-ray astronomy community. A significant number of optical astronomers use Figaro, developed at the Anglo-Australian telescope and particularly popular throughout Australia and the United Kingdom. Recently, Figaro has been adapted to run within the IRAF system, allowing users to have the best of both worlds. While there is no formal software system operating under IDL, the profusion of programs available in that proprietary language to do astronomy makes it worthy of mention as well, while a small but growing subset of astronomers makes use of Matlab for similar purposes.

One of the most significant drivers for the development of mission-independent data analysis software within astronomy has been NASA's Applied Information Systems Research Program (AISRP). This program has encouraged the development of software to serve community-wide needs and has also fought the recurrent tendency for each project to develop its own software system, but instead to write software "packages" within the IRAF or IDL architecture. Of course, a general data analysis system is not the best solution for all specialized needs, particularly for space-based astronomy. In these cases, many missions have developed their own packages, and not all of these exist within an IRAF/AIPS/XIMAGE/IDL universe.

28.3.2 Data Mining

The topic of data mining in astronomy has become increasingly important in recent years, as databases have become large and more complex [10,75]. These large databases have arisen in both ground-based observatories and orbital ones, and they represent data collected from countries around the world. Most of these archives are available online, though the heterogenous nature of user interfaces and metadata formats—even when constrained by HTML and CGI—can make combining data from multiple sources an unnecessarily involved process. In addition, astronomical archives are growing at rates unheard of in the past: terabytes per year are now typical for most significant archives. Two recently established databases that illustrate the trend are the MACHO database (8 TB) and the SDSS (15 TB). Space-based missions are beginning to approach these data rates as well, with NASA's Kepler mission generating and downlinking approximately 2.5 TB annually [79]. Even these rates will seem small when the Large-Scale Synoptic Telescope (LSST) comes online, as LSST will generate a data rate of roughly 0.5 GB per second [8].

The simplest kinds of questions one might ask of these kinds of data sets involve resource discovery, for example, “find all the sources within a given circle on the sky,” or “list all the observations of a given object at x-ray wavelengths.” Facilities such as SIMBAD [129], VisieR [99], NED [87], and Astrobrowse [64] permit these kinds of queries, though they are still far from comprehensive in their selection of catalogs and/or data sets to be queried. One problem arises from the nature of the FITS format, which is poorly defined as far as metadata are concerned—XML may provide a solution here, but astronomers have yet to agree on a consistent common set of metadata tags and attributes.

Difficulties due to heterogeneous formats and user interfaces are being addressed by VO projects, such as the US VAO [109]. The most basic intent of all of these projects, which are coordinated with one another at some level, is to deliver a form of integrated access to the vast and disparate collection of existing astronomical data. In addition, all are in the process of providing data visualization and mining tools.

In its most encompassing form, astronomical data mining involves combining data from disparate data sets involving multiple sensors, multiple spectral regimes, and multiple spatial and spectral resolutions. Sources within the data are frequently time variable. In addition, the data are contaminated with ill-defined noise and systematic effects caused by varying data sampling rates and gaps and instrumental characteristics. Finally, astronomers typically wish to compare observations with the results of simulations, which may be performed with mesh scales dissimilar to that of the observations and which suffer from systematic effects of their own. It has been observed [103] that data mining in astronomy presently (and in the near future) focuses on the following functional areas:

1. Cross-correlation to find association rules
2. Finding outliers from distributions
3. Sequence analysis
4. Similarity searches
5. Clustering and classification

In spite of the difficulties previously outlined, the nature of astronomical data—it is generally freely available and in computer-accessible form—has led to numerous early applications of data mining techniques in the field. As far back as 1981, Faint Object Classification and Analysis System (FOCAS) [73] was developed for the detection and classification of images on astronomical plates for the automatic assembly of catalogs of faint objects. Neural nets and decision trees have also been applied for the purposes of discriminating between galaxies and stars in image data [100,134] and for morphological classification of galaxies [117].

There has been an increasing need for astronomers to use data mining techniques in recent years, as large astronomical data sets now contain data collected in a variety of detector formats, observed by a range of telescopes and space instruments, and spanning a large range of spectral characteristics. As a

result, data mining has progressed from individual tools and techniques developed for specific purposes to toolkits containing a wide range of data mining tools in the tradition of WEKA [61]. Toolkits contain standard data mining tools spanning supervised methods (e.g., artificial neural networks, decision trees, support vector machines, and k nearest neighbor analyses) and unsupervised methods (e.g., kernel density estimation, k-means clustering, mixture models, expectation maximization, Kohonen self-organizing maps, and independent component analysis), as well as other algorithms (including genetic algorithms [GAs], the information bottleneck method, association rule mining, and graphical models) (e.g., [10,27,43,88]).

The greatest successes of data mining are likely to arise from its application to large but coherent data sets. In this case, the data have a common format and noise characteristics, and data mining applications can be planned from the beginning. Recent projects satisfying these conditions have included the SDSS [135] and the 2MASS (e.g., [98]). SDSS uses a dedicated 2.5 m telescope to gather images of approximately 25% of the sky (some 10^8 objects), together with spectra of approximately 10^5 objects of cosmological significance. Pipelines were developed to convert the raw images into astrometric, spectroscopic, and photometric data, which were stored in a common science database that is indexed in a hierarchical manner. The science database is accessible via a specialized query engine. The SDSS required Microsoft to put new features into their SQL server; in particular they added a tree structure into it to allow rapid processing of queries containing massive amounts of data for discrete as well as nebulous sources. Future astronomical observatories will continue this trend; the ground-based 8.4 m LSST, the Chinese Large Sky Area Multi-Object Fiber Spectroscopic Telescope (LAMOST) (with its $6.67 \text{ m} \times 6.05 \text{ m}$ mirror), and the orbital James Webb Space Telescope are some examples of this trend.

The key problem in astronomical data mining will most likely continue to revolve around interpretation of discovered classes. Astronomy is ruled by instrumental and sampling biases; these systematic effects can cause data to cluster in ways that mimic true source populations statistically. Since data mining tools are capable of finding classes that are only weakly defined statistically, these tools enhance the user's ability to find "false" classes. Subtle systematic biases are present (but minimized) even in controlled cases when data are collected from only one instrument. The astronomical community must be careful to test the hypothesis that class structures are not produced by instrumental and/or sampling biases before accepting the validity of newly discovered classes.

28.3.3 Multiwavelength Studies

Multiwavelength studies have become of ever-increasing importance in astronomy, as new spectral regimes (x-ray, extreme UV, gamma ray) have opened to practitioners, and astronomers have become aware that most problems cannot be adequately addressed by studies within any one spectral band. Such studies are now recognized as essential to the understanding of objects ranging from the sun and stars through x-ray bursters and classical novae to the ISM and active galactic nuclei. The computational requirements peculiar to multiwavelength astrophysics essentially fall into one of two categories, where the distinction is in the time rather than spectral domain.

In the first case, we have situations where the timescales associated with the phenomena under study are long compared with typical observational timescales. One such case is studies of the ISM, which is important in astrophysics because galactic gas and dust clouds are the source of new generations of stars. The ISM becomes more enriched as generations of stars die and return heavy elements to it. In the study of the ISM, one can identify three characteristic temperature scales, $<100 \text{ K}$, $\approx 10^4 \text{ K}$, and $\approx 10^7 \text{ K}$ —these temperatures necessitate observations at radio/infrared, optical/UV, and x-ray wavelengths, respectively (e.g., [136]). In each case, the strength of its emission or absorption depends on the local density, composition, metallicity, temperature, and distribution of ambient photons. Since this causes the ISM (and to a lesser extent the intergalactic medium) to interfere with observations of other galactic and extragalactic sources, stellar, galactic, and extragalactic astronomers are interested in knowing the radiative properties of the ISM, which is by definition nebulous and 3-D, as well as knowing where

this material is located. An example of code used to locate the ISM in the visual spectral regime can be found at <http://ascl.net/extinct.html> [59]. Since the characteristic evolutionary timescale of the ISM is long by human standards, simultaneous (and even contemporaneous) multiwavelength observations are unnecessary. In this milieu, catalogs and databases come into their own, and archival multiwavelength research is possible, focusing on spatial rather than temporal correlations. An idea of the numerous databases and collections of online data available on the ISM can be found at http://adc.gsfc.nasa.gov/adc/quick_ref/ref_ism.html.

A different situation pertains with variable sources such as gamma-ray bursters, extremely short-duration and high-energy events occurring at cosmological distances. The source of the bursts is as yet unknown, and they may be created by mergers of a pair of neutron stars or black holes or by a hypernova, a type of exceptionally violent exploding star. GRBs have been detected at gamma-ray, x-ray, and optical wavelengths, and further study of these objects clearly calls for multiwavelength studies (e.g., [57]). However, unlike the case obtaining for the ISM, GRBs have timescales ranging from milliseconds up to perhaps $\approx 10^3$ s, and thus, coordinated and simultaneous (or near-simultaneous) multiwavelength observations are essential. In this case, the computational demand is more on rapid deployment of various computer-controlled telescopes (both on the ground and in space) than on correlation analyses of existing databases. Thus, systems such as GCN and Virtual Observatory Events (VOEvents) have been developed [12] to distribute locations of GRBs to observers in real time or near real time and to distribute reports of the resulting follow-up observations.

28.3.4 Specific Examples

28.3.4.1 Cosmic Microwave Background Data Analysis

One of the main goals of CMB data analysis is to derive the power spectrum of the temperature fluctuations that correlates directly to fluctuations in the density of matter in the early universe. The precise spectrum of matter perturbations depends acutely on cosmological parameters, and hence, CMB data are an excellent diagnostic for determining the parameters of cosmological models. However, the task of constructing the power spectrum is daunting since the raw CMB signal has instrument noise, as well as noise from the ISM and other astrophysical objects, imposed upon it. To further complicate matters, all of these sources of noise are often correlated.

Analysis proceeds by first creating a physical map from the time series of instrument pointings. A pixel map is first constructed by dividing up the area of sky surveyed. For the COBE experiment [115], only a few thousand pixels were necessary, while for the PLANCK Surveyor satellite (<http://planck.esa.int>), tens of millions of pixels are required. The main step in creating the map is then the separation of noise, which can be done under the assumption that the time series of noise signals is drawn from a Gaussian distribution. Linear algebra methods are used to calculate the pixel–pixel noise correlation, which is then used to calculate the map. However, brute force methods on large maps are intractable, and exploiting efficient methods for sparse matrices is the only way to do the calculation. Even so, regardless of the method adopted, the calculation is still sufficiently large that massively parallel computing is necessary.

Having constructed the map, the next step is to calculate the power spectrum. This is a significantly more difficult process than map creation, since each pixel contains information about the signal on all scales within the map. During the early development of the field maximum likelihood, approaches were used that relied upon iterative convergence methods, such as Newton–Raphson schemes. However, for very large maps, the correlation matrices and numerical derivatives that must be calculated make this method too costly. Reducing the resolution of the data is possible, but that limits the resolution of the entire map. More recently Monte Carlo frequentist approaches to calculating the power spectrum have become popular. These methods essentially calculate the harmonics of the power spectrum convolved with all the noise, filters, and mixing (called the pseudo power spectrum) and then attempt to recover the original power spectrum through an inversion of a relationship between the true and pseudo

power spectra. Monte Carlo sampling is used in this last step [68]. While such approaches make the calculations more tractable, they require an extremely detailed knowledge of the noise statistical properties that is a considerable challenge in itself. Nonetheless, it seems probably that the Monte Carlo approaches will remain the preferred method for very large data sets for the foreseeable future.

28.3.4.2 Gamma-Ray Burst Data Analysis

GRBs are short bursts of primarily gamma radiation having flux and spectra that evolve on short timescales. Evidence suggests that GRBs result from relativistic shock waves that collide with each other and with the ambient ISM. The source of the shocks is currently presumed to originate from two types of sources: *hypernovae* (supernovae in which a significant portion of the collapsing stellar core's energy is focused into shocked bipolar accelerated particle beams) or colliding binary neutron stars. GRBs exhibit a wide variety of complex behaviors and yet there is evidence of multiple GRB classes. Class identification is as important in astrophysics as it is in other sciences; the properties of distinct GRB classes can lead to a better general understanding of GRB physics as well as to a better understanding of the different sources and/or environments producing the classes. However, class identification is not helpful if the mechanisms responsible for producing the classes cannot be determined.

Data mining techniques have proven useful in the study of GRB classes. Data mining techniques are needed to identify clusters in the GRB attribute space because individual GRB behaviors overlap. Some overlap results from the large intrinsic range of GRB behaviors, some is due to distinctly different properties of GRB classes, and some is due to observational and instrumental bias. Bias can cause phantom classes to appear by creating clustering where no distinct source populations exist.

GRB data mining has been used primarily with the large GRB database collected by the Burst And Transient Source Experiment (BATSE on NASA's Compton Gamma-Ray Observatory) and Swift because the instrumental characteristics of these experiments are well-documented properties [52,102]. Data mining tools identify three distinct GRB classes rather than two known historically (e.g., [71,94]). Interpretation of the data mining data suggests that the third GRB class does not represent a separate source population; it is instead produced by observational biases resulting primarily from low signal-to-noise observations and from the instrumental trigger characteristics [58]. This successful result indicates that scientific data mining can be used not just to determine that classes exist but also to determine *why* they exist. As a further clue behind why these class differences exist, recent observations indicate that the *pulses* making up GRBs have similar, correlated properties regardless of the class to which a GRB belongs [60]. Data mining classification of the pulses, however, does not yield a clear delineation between pulses belonging to different classes [3]; this suggests that it is the distribution of pulses that indicates the class to which a GRB belongs, rather than the pulse properties.

28.3.4.3 Time Series Analysis

Astronomers make use of time series analysis techniques for a variety of purposes, including studies of variable stars and cataclysmic variables [104,133], pulsating or oscillating stars [7,72], asteroid rotation rates [128], active galactic nuclei [47], sunspot number [118], and extrasolar planets [24]. Typically, astronomical time series suffer from relatively low SNRs, uneven sampling, and numerous gaps, at times leading to severe aliasing at the 1 day^{-1} frequency and difficulties in estimating a traditional autocorrelation function. In addition, some applications (Active Galactic Nuclei [AGN] studies and planetary detection) are dominated by nonsinusoidal signals or pulses.

Historically, the primary tools used to support these efforts have been discrete Fourier transforms and periodograms [111]. Both of these estimators of the autocorrelation function can be defined in such a way as to satisfactorily represent unevenly sampled data, and small gaps in the time series can be handled using clever binning or interpolation techniques, but these necessarily distort the data and lead to the loss of information. In some cases, aliasing can be minimized or eliminated by experimental design (e.g., GONG), but more often astronomers are confronted with this fundamental problem and this has

driven numerous recent efforts in the area. Recent developments in this area focus on the application of nonlinear, nonstationary techniques and Bayesian methods. The wavelet transformation shows great promise [130], as unlike the DFT it can be used to construct power spectrum estimators that are nearly independent of the signal shape and amplitude in the presence of noise. Such estimators are likely to find increasing use in the planetary detection and AGN modeling communities. Perhaps an even more useful application of wavelets is to the denoising of power spectra, a technique pioneered by the solar physics community. Bayesian methods are also increasing in popularity, as they are well-suited to finding change points in long series of time-tagged data such as is typically obtained from high-energy astrophysics experiments [49,112].

A rapidly growing difficulty is the size of power spectra produced by astronomical experiments. Helioseismological observations can easily give rise to time series with in excess of 10^7 points, and asteroseismological observations are rapidly approaching this level [113]. Achieving the maximum time resolution inherent in data such as time-tagged x-ray photon lists can require estimators with in excess of 10^9 points [108]. Furthermore, upcoming space-based experiments, such as European Space Agency's (ESA) PLATO mission [34], will give rise to data sets that are so large as to mandate the use of automated techniques.

28.4 Theoretical Modeling

Prior to the advent of computers, theoretical modeling consisted largely of solving idealized systems of equations for a given problem. Very often, to make problems tractable, simplifying assumptions like spherical symmetry and linearization of the problem would be necessary. Rapid numerical solutions of equations avoid the need for simplifying assumptions, but at a cost: one can no longer achieve an elegant formula for the solution to the problem, and insight often derived from solving the equations by hand is lost.

28.4.1 Role of Simulation

Although computation is commonplace in theoretical modeling, perhaps the most heavily computationally biased aspect is *simulation*. Simulation can be viewed as an extension of finding numerical solutions to a given equation set; however, the set of equations is often enormous in size (such as that produced by the gravitational interaction problem between a large number of bodies). Simulation also often involves visualizing the “data set” to help understand the phenomenon being studied, and the systems under investigation are almost always cast as an initial value problem.

The roots of simulation in astrophysics can be traced back to at least the 1940s. Driven by a desire to understand the clustering of galaxies, Holmberg built an analog computer consisting of light sources and photocells to simulate the mutual interaction of two galaxies via gravity. Today, almost all simulation is conducted on digital computers. Development of fast efficient algorithms for solving complex equation sets can often lead to programs containing tens of thousands of lines of code. Although it has been the tradition for individual researchers to develop codes in isolation, the last few years have seen the appearance of collaborations of researchers who work together on large coding projects. This trend is likely to continue, and it is probable that in the near future researchers will converge to using a handful of readily available simulation packages (e.g., NEMO, <http://bima.astro.umd.edu/nemo/>).

28.4.2 Gravitational n -Body Problem

Although Newton's law of universal gravitation has been supplanted by *General Relativity*, Newton's law remains highly accurate for a very large number of astrophysical problems. However, solving the interaction problem for any number of bodies (“ n ” bodies) is difficult because at first appearances the number of operations scales as n^2 . However, provided small errors in the force calculation are acceptable

(RMS errors typically less than 0.5%), then approximate solutions can be found using order $n \log n$ operations. Roughly speaking, the algorithms used by researchers fall into two categories: treecodes [11] and grid (FFT) methods [70]. Treecodes are usually about an order of magnitude slower than grid codes for homogeneous distributions of particles, but are potentially much faster for very inhomogeneous distributions. To date, the largest gravitational simulations conducted contain over 300 billion particles and have been used to coarsely simulate volumes representing as much as 30% of the entire visible universe at high resolution (<http://www.hits.org/english/research/tap/projects.php>).

28.4.3 Hydrodynamics

Hydrodynamic modeling, or equivalently computational fluid dynamics, plays an extremely important role in astrophysics. Although most astrophysical *plasmas* are not fluids in the everyday sense, the physical description of them is the same. Modern hydrodynamic methods fall into two main groups: Eulerian (fixed) descriptions and Lagrangian (moving) descriptions. Eulerian descriptions can be broadly decomposed into finite difference and finite element methods. In astrophysics, the finite difference method is by far the most common approach. Lagrangian descriptions can be decomposed into “moving mesh” methods where the grid deforms with the flow in the fluid, and particle methods of which smoothed particle hydrodynamics (SPH) is a popular example [53].

Because shocks play an important role in the evolution of stars and the ISM, a significant amount of research has focused on “shock-capturing methods”. Most early approaches to shock capturing, and indeed a number of methods still in use today, provide stability by using an artificial viscosity to smooth out flow discontinuities (shocks). Although these methods work well, they often introduce additional, unwanted, dissipation into the simulation. Perhaps the best alternative approach is “Godunov’s method” [55], which is a simple example of a first-order method where the Riemann shock tube problem is solved at the interface of each grid cell. More modern algorithms have extended this idea to higher-order integration schemes, such as the piecewise-parabolic method [35].

28.4.4 Magnetohydrodynamics and Radiative Transfer

Magnetic fluid dynamic modeling, or MHD, is the source of a large amount of research in computational astrophysics [116]. The system of equations for MHD is that of hydrodynamics plus the addition of coupling terms corresponding to magnetic and electric forces and Maxwell’s equations that constrain and evolve the magnetic and electric fields. Because of severe complexities arising from the divergenceless nature of the magnetic field, most MHD methods are finite difference, and although particle methods have been used, quite often they produce significant integration errors.

Modern methods, as in hydrodynamics, often cast the problem in terms of a system of conservation laws. It is usual to look at variation along a given axis direction and to recast the problem in terms of “characteristic variables” that are constructed from eigenvalues and the primitive variables, such as density, pressure, and flow speed. Such recasting aids development of the numerical method since time stepping can be viewed as propagating the system an infinitesimal amount along a characteristic. This formulation often allows development of stable integration schemes that produce accurate numerical solutions even when large time steps are used.

Radiative Transfer (RT), the study of how radiation interacts with gaseous plasmas, is an extremely difficult problem. It bears parallels to gravity in that all points within a system can usually affect all others, but is further complicated by the possibility of objects along any given direction producing nonisotropic attenuation. The radiation intensity is a function of position, two angles for direction of propagation, and frequency, a total of six independent variables. There are many different approaches to solving RT, ranging from explicit ray tracing to Monte Carlo methods as well as characteristic methods [105]. Much of the modern research effort is focused on deriving useful approximation methods that ease the computational effort required.

28.4.5 Planetary and Solar System Dynamics

Recent advances in telescope instrumentation have lead to a cascade of discoveries of extrasolar planets, and at the time of writing, over 700 extrasolar planets are known, and over 2000 candidates awaiting confirmation. Consequently, there is now a large amount of interest in studying planet and solar system formation. Solarsystem formation occurs during star formation, and the inherent differences in the planets are due to a differentiation process that enables different elements to condense out of the solar nebula at different radii.

Planets form by a hierarchical merging processes within the disk of the solar nebula. Dust grains form the first level of the hierarchy and planets the last, while objects of all mass scales and sizes exist in between. It should be noted that representing this variation of masses and sizes within a simulation is impossible since resolution is always limited by the available computing power and memory. Theoretical models of the agglomeration process must include hydrodynamics and gravity, although currently there is debate about the role of hydrodynamics in gas giant planet formation. At present, theory can be roughly divided into two approaches: the first being the study of stability properties of the solar nebula disk from an analytic perspective and the second being simulation of the process from a first principle perspective. Simulations with a million mass elements, designed to follow the agglomeration process in the inner part of the solar system, were conducted in 1998 [110].

The realization that our solar system contains many small asteroids and meteorites capable of causing severe damage to the Earth has renewed interest in solar system dynamics. Calculating accurate orbits for these systems is hard since very often they may have chaotic orbits. Chaotic systems place great demands on numerical integrations because truncation errors can rapidly pollute the integration. Thus, the integration schemes used need to be highly accurate (often quadruple precision is used), and much effort has been devoted into “long term” integrators (such as “symplectic integrators”, see [33]) that preserve numerical stability over long periods of simulation time. The chaos observed in long-term simulations of the solar system inspired a new theory [95] that demonstrates the solar system is chaotic (Uranus could possibly be ejected) but the timescale for this is extremely long (10^{17} years).

28.4.6 Exoplanets

Searches for exoplanets have come of age in astronomy, with 553 confirmed exoplanets as of this writing (the most current count is available at <http://www.planetary.org/exoplanets/list.php>). Searches generally proceed using Doppler spectroscopy to search for radial velocity variations or high-precision photometry to search for exoplanet transits. NASA’s Kepler mission and ESA’s Convection Rotation and Planetary Transits (COROT) telescope both adopt the latter approach. Kepler observes some 156,000 stars with 30-min cadence (and a smaller number with 1-min cadence), and data processing and conditioning is hence demanding [74]. In addition to large-scale traditional photometry, the transit search involves application of a wavelet-based, adaptive matched filter to identify transit-like features with durations in the range of 1–16 h. Light curves with transit-like features whose combined (folded) transit detection statistic exceeds 7.1σ for some trial period and epoch are designated as threshold crossing events (TCEs) and subjected to further scrutiny.

One outstanding issue with such programs involves the validation of planet candidates that have been detected photometrically. Space-based missions such as COROT and Kepler, as well as their ground-based counterparts, including OGLE [123], HATNet [9], and TrES [5], typically give rise to a large number of false positives for each true detection (see, e.g., [13]). The most common form of false positive involves an unresolved eclipsing binary star in the same field of view as the planet candidate; dilution of the binary eclipse can mimic a planetary transit. Generally, differentiating between the two cases involves high-SNR, high-resolution, time-resolved spectroscopy, which is both time- and resource-prohibitive, particularly for the smaller planets that are of the most interest.

Instead, a technique nicknamed BLENDER has been developed that makes use of the photometric light curves themselves [120,121]. BLENDER compares the transit photometry of the planet candidate

against a suite of synthetic light curves of eclipsing binaries, attenuated by the light of the planet candidate star. Models account for depth, duration, ingress, and egress time of the candidate, as well as accounting for stellar astrophysical effects including limb darkening, gravity brightening, mutual reflection, oblateness, and differential extinction. The code can also account for more complex systems, including hierarchical triples with multiple planets. The numerous free parameters are varied to map a multidimensional χ^2 surface, with the goal of determining the probability that the observed transit might possess a non-planetary cause.

28.4.7 Stellar Astrophysics

Among the first astrophysical problems to be addressed using modern computational methods were models of stellar interiors [38,66] and atmospheres [81]. One simplifying assumption needed for early stellar codes was that of local thermodynamic equilibrium, which meant that stellar structural variations were not expected to occur on short timescales. Such assumptions are no longer necessary: stellar interior and atmosphere codes have become increasingly complex as computers and computational techniques have evolved. Theoreticians have been able to study rapid evolutionary phases and complex atmospheric processes in stars. Some of the difficult problems currently being addressed include evolution of rotating stars [93], radial and nonradial stellar pulsations [29,37], stellar magnetospheres [124], evolution of stars in binary systems [15], and supernovae [132].

28.4.8 Star Formation and the Interstellar Medium

One of the greatest challenges in astrophysics is understanding the star formation process. Star formation is an enormously difficult problem since it encompasses gravity, hydrodynamics, RT, and magnetic fields. Further, the difference in density between the initial gas cloud from which the star forms and the final star itself is 21 orders of magnitude or, equivalently, a change in physical scale of 7 orders of magnitude.

One of the most significant questions in this field is: Why do most stars form in binary systems? To address this question, numerical simulations have been run that follow the fragmentation of a large cloud of gas. The methods used have been primarily Lagrangian ones (such as SPH) although adaptive mesh refinement (AMR) techniques [17] are becoming more popular. The reason for the growth of interest in AMR is that recent results have demonstrated a severe error in a large body of numerical simulations of the cloud fragmentation process: they lacked resolution to adequately follow the balance between gravitational forces and local pressure forces [122]. Simulations currently suggest that turbulent fragmentation plays a critical role in determining the formation of multiple star systems and that a filamentary structure is the main mechanism for transferring mass to the protostellar disk [76]. A not dissimilar process seems to govern formation of the first stars in the universe [1].

Studying the ISM presents different challenges. Traditionally the ISM is understood as having a series of distinct phases that determine local star formation [89], with regulation of the phases provided by heating and cooling mechanisms. Stellar winds and supernovae are the primary heating mechanism, while radiative cooling is the dominant cooling mechanism for the hot gas phases. The supernovae and winds also constantly stir the ISM, which, in combination with rapid radiative cooling, serves to make it a highly turbulent medium. Turbulent media are difficult to understand because motions on very large scales can quickly couple to motions on much smaller scales, and thus accurate modeling requires resolution of large and small scales [85]. Because of this range of scales, achieving sufficient resolution to be able to accurately model turbulence is difficult, and a number of researchers rely on 2-D models to provide sufficient dynamic range. Recent 3-D simulations have shown that self-gravity alone, without the stirring provided from supernova explosions, is sufficient to produce the spectrum of perturbations expected from analytical descriptions of turbulence [25].

28.4.9 Cosmology

The study of the Big Bang and quantum gravity epoch is still largely conducted analytically, although some aspects of this research lend themselves to computer algebra. Following these earliest moments, the universe undergoes a series of phase transitions (or “symmetry breaking”) as the forces of nature separate out of the “unified field” [127]. Computation has been used to examine the nature of the phase transitions that occur as each of the forces separates. For example, the electroweak phase transition has been extensively examined using lattice calculations to explore whether the phase transition is first or second order (e.g., [82]). Current constraints on the measurement of the mass of Higgs boson from the Large Hadron Collider in combination with the lattice models strongly suggest that the phase transition must be second order. Numerical simulations of the early universe have also investigated how nonuniform symmetry breaking can lead to the formation of defects [2].

Computation is used extensively in the study of *Big Bang Nucleosynthesis* (BBN) and the relic CMB. However, at present, CMB data analysis probably represents the biggest challenge computationally. Theoretical modeling of BBN dates back to the 1940s [6], and a very detailed numerical approach to solving the coupled set of equations describing the reaction network was developed comparatively early [125]. Currently there are a number of BBN codes available, and considerable effort has been put into reconciling results from different codes. CMB modeling is comparatively straightforward since the equations describing the evolution of a thermal spectrum of radiation in an expanding universe are not overly complex. However, because the CMB spectrum we measure has foreground effects superimposed upon it (such as clusters of galaxies), a large amount of effort is expended simulating the effect of foreground pollution [22]. Indeed in the past few years, CMB experiments have provided new ways of detecting previously unobserved objects like galaxy clusters (e.g., [107]).

The theoretical modeling of large-scale structure in the universe has relied heavily on computation. Because on large scales “dark matter” dominates dynamics, only gravity need be included, and a Newtonian approximation can be used without significant error. Particle-based algorithms are used to evolve an initially smooth distribution of particles into a clustered state representative of the universe at its current epoch. The first simulations with moderate resolution (3×10^5 mass elements) of the distribution of galaxies were conducted in the early 1980s [45]. Simulations have played a leading role in establishing the accuracy of the *Cold Dark Matter* (CDM) model of structure formation [20]. In this cosmological model, structures are formed via a hierarchical merging process. Simulation has also shown that dark matter tends to form cuspy halos that have a universal core profile [96], while the large-scale distribution of matter is dominated by filamentary structures.

28.4.10 Galaxy Clusters, Galaxy Formation, and Galactic Dynamics

Modeling of clusters of galaxies and galaxy formation relies upon the same codes as the study of large-scale structure, with the addition of hydrodynamics to model the gas that condenses to form stars and nebulae within galaxies. Typically the hydrodynamic methods used are either Eulerian grid-based algorithms or Lagrangian particle-based methods [50] although, as in star formation, AMR methods are being adopted. Modeling of galaxy clusters is comparatively straightforward since the intracluster gas tends toward hydrostatic equilibrium. However, simulations have shown that the gas in galaxy clusters shows evidence of an epoch of preheating [46].

Galaxy formation is an exceptional difficult problem to study numerically because the evolution of the gas is strongly affected by supernova explosions and heating from supermassive black holes in active galactic nuclei, both of which processes occur initially on scales smaller than the best simulations can currently simulate (e.g., [16]). The physics is also technically challenging since galaxy formation occurs in the very nonlinear regime of gravitational collapse while simultaneously being a radiation hydrodynamics problem (although an optically thin approximation for the gas works moderately well, at least in the late time universe). Only within the last 2 years has a sufficient

understanding evolved to enable simulations of galaxy formation to produce moderate facsimiles of the galaxies we observe [56]. In the near future, increases in resolution should provide a significant step forward in the accuracy of star formation modeling as the sites of star formation, namely, giant molecular clouds, should be resolved.

The first large-scale numerical studies of galactic dynamics were conducted in the 1960s [69]. At least initially, and to a large extent today, most n-body simulations are used to confirm analytic solutions derived from idealized models of galactic disks [19]. Typically these simulations begin with a model of a given galaxy, which usually consists of a disk of stars and an extended dark halo, which is then perturbed in some fashion to mimic the phenomenon under study. Recently it has been highlighted that accurate modeling of galactic dynamics in CDM universes is exceptionally hard due to coupling between the substructure in the larger galactic halo and the galactic disk [126]. Traditionally, researchers believed that approximately 1 million particles was sufficient to model galaxies reasonably; however, these new results have pushed that estimate at least an order of magnitude higher. Although researchers in this field use codes similar to those in large-scale structure, specialist codes, which are designed to reduce numerical noise, have been developed (i.e., the self consistent field code of [67]).

28.4.11 Numerical Relativity

General relativity calculations are extremely computationally demanding as not only is the theory exceptionally nonlinear, but also there are a number of elliptic constraint equations that must be satisfied at each iteration. Further, the rapid change of scales that can accompany collapse problems often requires adaptive methods to resolve. There are also other subtleties related to the boundary conditions around black holes that present severe intellectual challenges. Currently the strongest science driver behind these calculations is the need to calculate the gravitational wave signal of cataclysmic events (such as binary black hole coalescence) that may be detectable with the LIGO gravitational wave detector (<http://www.ligo.caltech.edu>). Because of the large amount of computation involved in computing space-time geometry and the comparatively low amount of communication between processors, numerical relativity is an ideal candidate for grid-based computation. The Cactus framework has been developed to aid such calculations (<http://www.cactuscode.org>).

Relativity calculations are most often grid based (although spectral methods are used occasionally). Before determining the evolution equations for the space-time, a gauge must first be decided upon, and the most common gauge is the so-called “3 + 1 formalism” where the space-time is sliced into a one-parameter family of space-like slices. Other formulations exist, such as the characteristic formalism, and in general, the gauge is chosen to suit the problem being studied. Initial conditions for the space-time are provided, and then the simulation is integrated forward, with suitable boundary conditions being applied. Building upon this body of research, the first calculation of the gravitational waveform from binary black hole coalescence was performed in 2001 [4].

28.4.12 Compact Objects

The study of compact objects such as white dwarf and neutron stars presents a formidable theoretical challenge. These systems exhibit extreme density, in turn requiring detailed nuclear physics as well as relativistic descriptions. Compact objects are widely believed to be the source of energy behind GRBs, with energetic scenarios, such as sudden mergers, driving a highly relativistic “fireball” shock wave that produces an extreme amount of γ -ray radiation during collisions with other shock waves or the ISM [90].

Neutron star collisions have been simulated for similar reasons to black holes: the calculation of their gravitational wave spectrum [31]. Neutron stars are also the beginning point of core collapse (type II) supernovae, and the simulation of the ignition process has attracted much attention. Fully general relativistic models are now beginning to appear [28]. Of particular interest is how the neutrinos drive a wind shortly after collapse begins [30].

Type I supernovae occur when white dwarfs accrete sufficient mass to exceed the Chandrasekhar limit and subsequently undergo collapse. The physics is challenging because the process occurs far from equilibrium and entails RT as well as hydrodynamic instabilities. As in studies of type II supernovae, to date most calculations use a 2-D approximation [97] and Eulerian approaches; however, some explorations have used SPH in 3-dimensions [26]. The push toward full high-resolution 3-D calculations is gathering momentum (e.g., /citeHillebrandt2010). Such simulations are necessary to fully understand instabilities and include more accurate physics. However, the computational challenge is significant and ultimately progress awaits the development of 100 teraflop computers.

28.4.13 Parallel Computation in Astrophysics

Parallel computing in astrophysics is often used to examine problems that simply cannot be addressed on a desktop computer, regardless of how long one could wait. The primary driver in this case is the large amounts of memory available in parallel computers as compared to serial ones: the largest parallel computations just don't fit into a desktop. The secondary use of parallel computation is to speed up data analysis that involves performing the same analysis on many subsets of data. In this case, parallel computers significantly help in lowering the data reduction time. Along similar lines, the significant computational requirements of many astrophysics calculations can utilize special-purpose computational hardware. The rise of general-purpose computing on graphics processors (GPGPU) is attracting much interest within the astrophysics community (e.g., [48]). A number of simulation and analysis codes have already been ported to this specialist hardware.

Around 10% of the total cycles at supercomputing centers are typically devoted to astrophysics. This share is lower than in previous decades as there has been significant growth in parallel computation in other fields, in many cases benefitting directly from new codes and approaches developed within astrophysics. Astrophysicists have a history of developing unique and ingenious parallel algorithms to solve the problems they face. Indeed, a number of research problems in astrophysics, such as binary black hole coalescence and the formation of galaxies, have long been considered computational "grand challenges." These problems have computing demands that are similar to the nuclear ignition codes in the Advanced Simulation and Computing Program, which is an integral element of the US Government Stockpile Stewardship Program.

Parallel codes for distributed memory platforms are most often developed using the Message Passing Interface (MPI). Higher-performance Application Programming Interfaces (APIs), such as the remote direct memory access provided by MPI-2, are yet to receive significant attention primarily because vendors have failed to provide full support for this emerging standard. All of these APIs can lead to a significant increase in the size of a parallel program compared to the serial one. It is not uncommon for parallel codes to be over twice the length of serial ones. Codes written using these APIs have the potential to scale to many thousands of processors.

Shared memory parallel codes are most often developed using the standardized OpenMP API. This API is particular simple to use since it enables simple parallelization of codes by using "pragmas" that are inserted into the code before iterative loops. The iterations within the loop, provided that they meet certain data independence requirements, can then be distributed to different CPUs, thereby speeding up execution speeds. The OpenMP API often does not lead to significantly longer parallel programs, but is limited in terms of scalability by the requirement of running on shared memory computers that typically have a maximum of around 32 processors.

Over the past few years, it has become increasingly apparent that although often the physics being simulated by two codes is quite different, the underlying data structures being used, such as grids or trees, are quite similar. This has led to the development of skeleton packages in which a researcher needs only to add the numerical implementation of their equations and the communication between processors is handled by the package. Cactus and Paramesh are an example of this type of framework. However, most researchers seem reluctant to rely on these packages and instead develop an optimized communication layers themselves.

The Asteroseismic Modeling Portal (AMP) provides a web-based interface to the MPIKAIA asteroseismology pipeline [92,131], allowing astronomers to run and view simulations that derive the properties of sunlike stars from observations of their pulsation frequencies. AMP represents a simplified orchestration of TeraGrid computational resources; the web-based interface was developed as a traditional stand-alone database-backed web application using the Python-based Django web development framework, leveraging the Django frameworks capabilities while cleanly separating the user interface development from the grid interface development.

The motivation for the interface structure arises from the fact that running a single MPIKAIA simulation requires propagating several independent batches of MPI jobs and can consume 512 processors for over a week of wall-clock time. A complete optimization run to determine the best-fit model for a single Kepler target star consists of four GAs runs executed in parallel, with each GA run modeling a population of 126 stars, using 128 processors, for 200 iterations. Using the science gateway approach allows researchers to run the model without using local resources, disseminates model results to the community, and introduces a uniform analysis structure.

Cloud computing is particularly attractive for a number of problems in analyzing astrophysical data, such as image processing [18]. But it is unclear what role cloud environments will play in the development of theoretical modeling. Large parallel computations remain nontrivial to implement and web-based interfaces to large codes run at supercomputing centers are, at least at present, not widely used.

28.5 Research Issues and Summary

In this section, we first highlight a number of key areas in computational astrophysics that will receive increasing attention in the future. No significance should be attached to the ordering of the items:

1. Data analysis and visualization in the age of VOs: The complexity and large size of VO databases will increase the need for powerful data analysis, visualization, and data mining toolkits for the effective and rapid scientific exploration of the resulting massive data sets. VOs are enabled by technology but driven by science, so data mining tools need to recognize the need to incorporate measurement uncertainty, incomplete sampling, and measurement bias. Visualization tools need to have flexible scaling parameters and resolution, as well as the ability to visualize multidimensional data. Many pattern recognition algorithms currently define classes without regard to data quality; poorly measured data can smear out true clusters that would be easily visible if the data were limited to that of high quality. In some cases, poor-quality measurements can cause data to artificially cluster (e.g., when an upper flux limit is used in lieu of a measurement). Since the scientific method is statistical in nature, computational tools for science are needed that better reflect statistical uncertainties.
2. Planet formation: Current observations are already challenging theoretical models for planet formation and dynamical evolution. Future models need to include radiation, chemistry, hydrodynamics, and dust to better understand both formation and migration processes.
3. Star formation: Following the full collapse of a gas cloud through to nuclear ignition remains an enormously challenging theoretical proposition. A large number of outstanding questions relating to the role of turbulence and magnetic fields remain, and a better understanding of the formation of high-mass stars has a number of implications for other areas of astrophysics, most notably galaxy formation.
4. Galaxy formation: Progress is limited by both a lack of numerical resolution and an incomplete understanding of the physics of the process. It is currently unclear how to model the extremely important effect of heating from supernovae and active galactic nuclei on protogalactic collapse. New discoveries will depend heavily on the growth of understanding of the star formation and black hole growth processes.

5. CMB data analysis: While new approximation algorithms have been developed to reduce the enormity of the analysis calculations for high-resolution data sets, their accuracy is questioned. Brute force and larger computers are not the answer, as their computational requirements exceed the capacity of even the soon to be built exaflop class supercomputers.
6. Black hole coalescence: Despite a vast growth in technical capabilities over the past decade, calculations still have significant room for adding additional physics (incorporating drag from gas disks remains a notable challenge). In addition to the value of calculating gravitational wave forms for future detectors, these calculations have significant implications for galaxy formation scenarios.
7. Supernovae ignition and modeling: Advances in computational power have shown notable differences in the 2-D versus 3-D results, highlighting that hydrodynamic instabilities need much further study. A coherent theory will require developing a clear understanding of the ignition process through to the observational signals (especially transients).
8. Autonomous spacecraft/instrumentation operation: Autonomous spacecraft are being designed to carry out day-to-day operations independent of ground control. Some of these operations include navigation and the scheduling and execution of observations and experiments. Support technologies for autonomous spacecraft include robotics, artificial intelligence, and control theory. This approach will reduce mission operation costs while simultaneously allow orbital satellites to work dynamically rather than passively.

Astrophysics is gradually and irreversibly becoming a computational science. Astronomical data are being stored in and retrieved from progressively large databases; data and metadata are being used by larger audiences. The analyses of these data are aided by pattern recognition algorithms and improved data visualization tools. Theoretical modeling has developed beyond the point where elegant calculations using relatively simple assumptions suffice; detailed models with many physical parameters are often required to adequately explain the detailed observations made by the newest orbital and ground-based telescopes spanning the electromagnetic spectrum. Parallel computation is often used in carrying out time-consuming calculations. High-precision is needed to accurately calculate model parameters, and computationally-intensive statistical tools are required to evaluate theoretical model efficacies. Astrophysics is thus evolving, and the new generation of astrophysicist is increasingly well-versed in the use of computational tools. This can only help us to better understand the structure, evolution, and nature of the universe.

Glossary

- Adaptive optics:** An active form of observing light (rather than a passive one) in which lasers are fired at the sky from the telescope site, and the reflected laser light is used to differentially correct observed starlight for atmospheric refraction and convection.
- Astrophysics:** The study of the physical properties, structure, kinematics, dynamics, and evolution of celestial objects.
- Big Bang nucleosynthesis:** The epoch of the early universe when the nuclei of atoms were formed. Theories of this epoch reproduce observations of elemental abundances exceptionally well, strongly supporting the hot Big Bang theory.
- Cold dark matter:** Hypothesized subatomic particles that contribute roughly 30% of the mass in the universe. Although in the early universe these particles interacted vigorously, their influence is now seen only via gravitation. Theories that include the effects of these particles match observations exceptionally accurately.
- Cosmic microwave background:** Relic electromagnetic radiation left over from 300,000 years after the Big Bang. The distribution of radiation is very close to being homogeneous and isotropic, but carries small perturbations on it that correspond to perturbations of the matter density in the early universe.

- Cosmology:** The branch of astrophysics dealing with the structure and evolution of the universe on the largest scales.
- Electromagnetic spectrum:** Classification of light by wavelength (which is inversely related to energy). Ranging from light with the shortest wavelength (and largest energy) to that with the longest wavelength (and smallest energy), the electromagnetic spectrum includes gamma-ray, x-ray, ultraviolet, visible, infrared, and radio.
- Galaxy:** A large, gravitationally-bound ensemble of stars, gas, and dust. Galaxies are traditionally classified as spiral, elliptical, irregular, or peculiar based on their morphological structure. Our *Milky Way* galaxy is a large spiral galaxy containing more than a hundred billion stars.
- General relativity:** Einstein's theory of gravitation that casts gravity not as a force, but rather a consequence of warping in the local space-time continuum. The theory relies strongly upon geometrical concepts of distance and curvature.
- Interstellar Medium (ISM):** The material between the stars. It is composed primarily of hydrogen and helium gas, with 1%–2% heavy elements chemically mixed to form larger molecules ("dust"). Dense, cool molecular clouds are the seeds of star formation.
- Passband:** An electromagnetic regime defined by the spectral response of a particular filter and/or instrument.
- Plasma:** An ionized gas. A plasma behaves differently than a normal gas (which can often be modeled as a fluid) because a treatment of electromagnetic theory is needed to address the electrical charges found within it.
- Supernova:** A massive stellar explosion during which a star can briefly brighten to almost one billion times its original luminosity. Such events can be seen at enormous distances, although maximal luminosity usually lasts only for tens of days.
- Virtual observatory:** Publicly accessible metadatabase of archived ground-based, balloon, and satellite astronomical observations. The database will also be associated with a variety of search engines and data mining tools.

29.1 Introduction

Computational chemistry is now firmly established as an integral part of chemistry at all levels. It has made its way into introductory level textbooks, and it has become a standard tool in many research applications. However, it is still a work in progress. The use of computational programs cannot be expected to provide a perfect solution, but it almost always affords chemists better insights into chemical processes and theoretical issues than would otherwise be available.

In this chapter, we present perspectives from generalists who use computational methods to solve or understand complex problems, and we provide perspectives from specialists who have made careers out of improving or creating new computational methods for their own uses and use by others. This is reflective of the state of the art in the use of computational chemistry. It has progressed from being an area of use only dared by those most intimately aware of the underlying programming and mathematical theory to those who recognize the value and limits of the methods provided in readily available resources.

29.2 Computational Resources

Computational chemistry requires computational resources that are varied and in proportion to the specific problem at hand. The speed, power, and location of the resources needed to conduct computational investigations can also depend on the purpose of the computation, be it education or research. Software licensing issues also impact hardware decisions; hence, decisions require consideration of many factors. Complicating this is the reality that advances in computational chemistry and the state of computational resources are not static; there is a constant need for new upgrades to software and hardware—not just to avoid obsolescence but to ensure the reliability of the computing platform. In most cases, trade-offs must be made to balance time, cost, and accessibility, so there are no absolutes except for “there are no absolutes.”

29.2.1 Software Impact on Hardware Decisions

This discussion could just as easily be titled, “Hardware Impact on Software Decisions,” but more frequently than not the software decisions are made sooner, based on the desired chemistry application. Since they have been described elsewhere in some detail, for purposes of illustrating the process of choosing hardware based on a prior software decision, consider the trade-offs between Gaussian, MOPAC, and GAMESS, assuming the user is looking for the highest efficiency generated by their computation and communication technology budget. (It should be noted that software providers may argue with the gross generalizations made here, but the characterizations of performance are based on real tests on real hardware in a variety of settings and are therefore considered firm opinion of the authors.)

Given the kinds of problems that one would address with Gaussian, experience shows that this package requires substantial CPU (computing) and RAM (cache and memory) resources, but minimal I/O. In single processor mode then, hardware needed to support a Gaussian installation would be the fastest machine with the most memory that one can afford per processor, without regard for memory or network speed. Choices would range from a stand-alone personal computer or workstation to a loosely coupled cluster of many nodes and cores, each with sufficient memory to support an instance of Gaussian running independently. The licensing details of proprietary software per core or per cpu then will limit the number of copies of Gaussian that can be run simultaneously, but each run of the code will finish in optimal time.

For a single chemist running multiple jobs, or multiple students running a single job, having sufficiently rapid response will require enough computing to handle the “throughput” of many jobs rather than needing to apply multiple processors to accelerate the completion of any given large computation. The total computing infrastructure needed to support a Gaussian installation, therefore, depends on the number of jobs to be run and the average runtime of each job. On a single laptop/desktop/workstation computer, having the faster processor and most memory may keep a small research effort fully productive. For a class of users, a multiprocessor server with substantial core memory to enable multiple jobs to run at the same time would suffice. Faster turnaround times are achieved by getting more processors, assuming the cost of acquiring additional licenses for the software is within the budget. While Gaussian has some parallel capability, it is rather modest at the time this chapter is written, and few users report substantial benefit for single runs on multicore/many-core computer architectures.

Any given run of MOPAC has lower memory requirements along with a light I/O load when compared to Gaussian, but it still requires substantial computing resources. MOPAC, therefore, is best implemented on single machines, or very loosely coupled clusters of single machines. Again, throughput—running as many jobs as possible in the least amount of time rather than getting any single job to run faster—is achieved by having more processors available to distribute the workload of the multiple jobs. As with Gaussian, a well-provisioned individual computer could be fine for a small effort. Large numbers of runs by a single user or a class of students would require many more cores, so a multicore server or massive cluster with sufficient memory per core would be called for.

While the cost may be attractive for GAMESS, among the three exemplars, it has the greatest need for fast communication between the processor and disk memory, since it needs really fast disk access for scratch space. The computing requirements are still substantial, but each run requires less memory than other software packages. If run on a server with slow disks, even for smaller jobs, actual time to completion for multiple jobs running at the same time can be compromised.

29.2.2 Locality and Control

Besides the actual hardware decisions to support a satisfactory experience, there are other issues that impact getting real work done in real time, and whether the chemist must also augment deep knowledge of DFT and molecular orbital theory with substantial system programming, hardware optimization, HVAC, electrical loads, and grant writing.

For a modest research effort, “having your own” computing resource that is managed by the chemist could be sufficient. The user has universal access to the use of the computer as much or little as needed at any hour of the day. There are many chemists who resign themselves to having to run their own cluster. However, for them, the frustration of becoming more of a computing administrator than a chemist must be outweighed by maintaining control over their own computing resources. For a shared resource at the department, lab, or campus level, one has to trade away full-control accessibility for the lower workload and stress of maintaining the computing resources as an operational tool, including acquiring space in a building, system maintenance, storage backups, power, and cooling requirements. Many chemists engaged in education and research adopt a hybrid approach, having one computing infrastructure for their research and another for the class computing laboratories and exercises. Again, this usually requires one or more trade-offs starting with choice of software, size of the problems to be addressed, and expected time to completion.

A growing need is for more and more long-term storage of the results of one’s computations. The National Science Foundation (NSF) is now mandating, for instance, a data management plan for all of its grants that requires grantees to assure long-term access to the results of funded research. In similar fashion to the raw computing needs, the need for storage and backup and online repositories is large and growing and has the same local versus control trade-off. The costs of providing this storage, with rare exception, have not been adequately addressed by most individuals, departments, or organizations.

A growing solution to the problem of acquiring substantially more computing resources to implement and support a computational chemistry effort has been to access resources on a network. This solution can range from free resources funded by the NSF for research and class accounts for education (<http://www.gridchem.org>, <http://www.xceded.org>) to cloud resources from commercial providers (e.g., <http://www.amazon.com/ec2/>). While ceding most control to someone else to provide the resource, these remote resources give substantial flexibility to grow or contract computing resources. In the case of NSF resources, many of the software licensing issues have been addressed, but commercial providers have more layers of licensing to go through, depending on the choice of software.

29.3 Computation in Chemical Education

Computational chemistry has transitioned from the developmental stages to become an essential tool used to understand the structure, reactivity, and spectroscopic details of the new compounds. It is fitting that chemistry education should mirror this (Gilbert, 2002). In the chemistry classroom, computation ranges from various forms of modeling (molecular and mathematical modeling, solving complex simulation problems, and molecular visualization/animation) to text and classroom supplements (homework and testing, computational tools, demonstrations and simulations, and interactive figures). Computation appears in all aspects of teaching laboratories: prelaboratory assignments (discussion of theoretical concepts and the proper use of equipment), simulated experiments and instrument use, and the use of computational tools for data analysis. The use of computers and electronic media for

data storage/sharing in the academic laboratory as a replacement for the traditional written laboratory notebook is not yet commonplace, but it seems inevitable (especially given the NSF mandate for data management plans and the impending demand to train health-care professionals for mandated use of electronic medical records).

The use of computation helps students understand chemistry, keeps them more engaged, and takes advantage of their accumulated interest and familiarity with technology.

The quality and quantity of computational work by the student continues to increase as the available technology has become more robust. Today, students are using supercomputers, workstation clusters, desktop and laptop computers, classroom “clickers,” “smart” phones, and tablet PCs. Common computational tools are readily available with access to classroom software often controlled through a “learning management system” (LMS), a local installation, or a third-party website. The software may be provided by the publisher of a specific textbook or from a more generic commercially available package. Inexpensive software is available in “special issue software collections” from the Journal of Chemical Education’s JCE software. Some web-based software is available for use at no charge. Appropriate sites can most readily be found through a hosted collection such as the Computational Science Education Reference Desk (CSERD) or the Chemistry Education Digital Library (ChemEd DL) pathways to the National Science Digital Library (NSDL) (Sendlinger, 2008).

Computational chemistry education involves both pedagogical (chemical education) and disciplinary (computational chemistry) focus. In chemical education, developments include new approaches to the use of existing software, models, apps, visualizations, and other tools to enhance the educational environment. These materials, usually prepared by others, often include visualizations of phenomena occurring at the atomic or molecular level that cannot be easily relayed by other means (Gordon, 1995). In the arena of computational chemistry, the aim is to enable students to learn the process of using software to build models. Workshops and websites are available for this purpose (Sendlinger, 2011). The computational tools used usually include spreadsheets, mathematics software, and molecular modeling programs. The details of model building might require coding cells in a spreadsheet, writing a subroutine or complete program in a programming language, or learning to use advanced graphical user interface (GUI)-enabled molecular modeling software. Students building models also should learn about verification, validation, and accreditation (VVA) of their work. The verification process involves checking that the model is correct, runs properly, uses the correct algorithm, etc. Validation is the process of comparing calculated and experimental data. Accreditation insures that the model achieves the educational purpose and is appropriate for the intended audience.

29.3.1 Computational Chemical Education

A vast number of websites have been created to assist the chemistry educator. To help the educator find quality websites, the NSDL bills itself as the “nation’s online portal for education and research on learning in Science, Technology, Engineering, and Mathematics (STEM)” (Zielinski, 2009). A wide variety of Pathway Partners of the NSDL focuses on providing content to specific types of user communities. A key resource for computational chemistry materials is the CSERD (Sendlinger, 2009). The goals of CSERD include assisting students in learning about computational science and helping teachers incorporate effective material into the classroom. CSERD account holders can suggest additions to the computational resources collected and can also sign up to become reviewers. Many of the resources include these reviews, based on the VVA process. The collection can be browsed by several means, and the search functionality offers a quick and convenient method for finding appropriate computational resources.

One example is the molecular model for an ideal gas. The corresponding CSERD site provides a description of the applet along with detailed reviews. In a classroom or laboratory setting, the instructor (with an LCD projector) or individuals/groups of students with computers can be assigned to collect

volume (V) data while varying the pressure (P), number of particles (N), particle velocity (v), or the temperature (T). Appropriate graphs of the data reveal $V \propto 1/P$ under conditions of fixed N and v , $V \propto N$ under conditions of fixed P and v , and $V \propto v^2$ (or $V \propto T$) under conditions of fixed P and N . Thus, Boyle's, Avogadro's, and Charles's law can all be deduced. Combining these relationships with the postulates of an ideal gas, a derivation of $PV \propto nT$ can be completed. Instead of being told, the mathematical relationship in each law, the students have had the opportunity of discovering these laws for themselves. Recent work provides evidence for increased student conceptual understanding through the use of this type of inquiry-based approach (Bridle, 2012).

The American Chemical Society (ACS) provides the ChemEd DL as a Pathway Partner of the NSDL (Moore, 2009). This pathway includes resources from the JCE Digital Library, the ACS Education Division, and the ChemCollective project. High school lesson plans that include online resources, a Moodle-based course management system where personalized resources can be added, a question database for tests and homework, and a wide variety of visualization resources are available.

29.3.2 Computational Chemistry in Education: Molecular Modeling

Using available software, students build their own molecular models in order to better understand chemistry in both classroom work and research projects. Students can investigate energy differences of various molecular conformations, calculate and visualize dipole moments, look at molecular orbital energy levels and shapes, visualize electron distributions and electrostatic potentials to investigate reactivity, calculate vibrational and UV-Vis transition frequencies, identify transition structures and reaction pathways, determine NMR chemical shifts and coupling constants, etc. Educational uses of molecular modeling allow the student to visualize key chemical concepts that are difficult to share in another manner. Molecular modeling has become another tool to assist chemists in doing what they do, just as various forms of spectroscopy became important tools in the mid-twentieth century. Compared to spectroscopic techniques (Alexander, 1999), computation is a recent newcomer to the mix (McDougal, 2012). Technological advances such as WebMO software that uses the web browser as a computational interface have made research-grade computational tools readily available.

An example of the educational use of molecular modeling appropriate for general chemistry includes investigating different bond types. Geometry optimization followed by calculation of the electron density for H_2 (covalent bonding), HF (polar covalent bonding), and LiH (ionic bonding) provides the results summarized in Figure 29.1.

After learning about covalent, polar covalent, and ionic bonding, students can easily perform the calculations and visualize results such as those in Figure 29.1 to cement this knowledge and deepen their understanding. Visual learners also greatly benefit from this approach.

Another example of molecular modeling suitable for use in an organic chemistry class would be to calculate potential energy conformational profiles as in an examination of the rotational barrier for the C2-C3 bond in *n*-butane. The calculated results at the density functional theory (DFT) B3LYP/6-31G(d) level are shown in Figure 29.2 (experimental results in parentheses, units of kcal/mol).

FIGURE 29.1 Electron density calculated using semiempirical PM3 and visualized at an isovalue of $0.01 e^{-}/\text{\AA}^3$.

FIGURE 29.2 Energy versus dihedral angle for rotation about the C2–C3 bond in butane, obtained using B3LYP/6-31G(d).

FIGURE 29.3 Tautomeric isomers from research project.

Students at the undergraduate level can also become involved in research projects that utilize computation. For example, an undergraduate research student attempted the synthesis of I but considered that tautomer II might also be produced during the synthesis (Knight, 2007). A clear distinction between these tautomers (see Figure 29.3) is difficult to determine from elemental analysis, nuclear magnetic resonance (NMR) spectroscopy, and infrared (IR) spectroscopy.

A molecular model of each tautomer was constructed and the energy was minimized using B3LYP/6-31G(d). The energy minimization was followed by a vibrational calculation at the same level to assure that a minimum energy structure had been attained. The results showed that I was more stable than II—approximately 0.9 kcal/mol lower in energy than II. Theoretical calculations of NMR and IR spectra for I at the same level were useful in interpreting the experimental spectra.

Suitable single crystals of the compound were obtained and an x-ray diffraction dataset was collected. That structure analysis, available free of charge from the Cambridge Crystallographic Data Centre, indicated that I was the preferred structure. In this case, an assumption was made that results of molecular modeling for a single gaseous molecule and x-ray diffraction for a solid crystal will agree with each other. This is not always true. However, molecular modeling can be used as one of the tools just as NMR, IR, etc., to help determine the outcome of a chemical synthesis.

29.3.3 Computational Chemistry in Education: Mathematical Modeling

Pedagogical applications of mathematical modeling in chemistry include statistical analysis of data, database searching, and reaction mechanisms in chemical kinetics. The software programs associated with these topics range from highly specialized programs to simple spreadsheets. Student involvement with this software can be a straightforward use of preexisting applications to record data and print results, or it can involve having students create an application from “scratch.”

A mechanism, sometimes referred to as a chemical reaction sequence (CRS), consists of a theoretical series of elementary steps that describes the interactions of the various species involved in the chemical reaction. Based on the law of mass action, differential rate equations can be written for each species involved in the CRS. To decide whether or not a proposed CRS is an acceptable description of the chemical reaction, either the set of differential rate equations needs to be converted into concentration–time information that can be compared directly with experimental data or the experimental dataset needs to be converted into rate information using a mathematic method or a graphical technique (e.g., a Lineweaver–Burk plot).

There are two major approaches used to convert the differential rate equations from a CRS into the time dependence of concentration. The first approach is to either derive the integrated form of the differential form or locate the solution in a suitable reference (Andraos, 1999, 2008). Robust mathematics programs such as Mathcad, Mathematica, MATLAB®, and Sage have various differential equation solvers that might be successful. Some of these solvers are capable of working with systems of stiff differential systems. The second approach is to solve the differential equations using numerical integration. Numerical integration can be performed using any of these four mathematics programs or for simple systems, using a spreadsheet.

There is another group of programs (e.g., Vensim PLE, Berkeley Madonna, and STELLA) known as system dynamics software that is capable of performing numerical integrations. These programs range from being a free download to being rather expensive. Some of these programs are able to handle sets of stiff differential equations. The numerical integration methods generally range from Euler’s method to the Runge–Kutta 4 method and results are available in graphical and tabular formats. The modeling of the differential equations usually uses rectangles (known as box variables, stocks, or reservoirs) to represent quantities of substances, circles (known as variables or constants) to represent time independent quantities, arrows (known as connectors) to represent mathematical connections of various quantities, and a pipe/valve symbol (known as a rate or flow) to represent the flow of substances into or out of box variables. Most mathematical programs, spreadsheets, and system dynamics programs permit adding scroll bars (or sliders) to control the values of the rate constants k_{ij} so that the values can be changed conveniently for instructional purposes or for matching experimental data to the theoretical results.

The system dynamics software can be used to describe complex kinetics systems such as competing reactions, higher-order reactions, Michaelis–Menten systems, and cyclic reaction systems such as the Belousov–Zhabotinskii reaction. In addition, numerical integration calculations can be used to generate acid–base titration curves, perform general and limiting reagent system stoichiometric calculations, and predict various thermodynamic properties ($U-U^0$, C_v , S , A) using the Debye theory for crystals containing monatomic species. There are many more computational tools available to the researcher in chemical kinetics. Often, these are based on Monte Carlo methods involving probabilities of energy, position, etc. Available as a free download, Chemical Kinetics Simulator is a software package that is based on a stochastic algorithm and is capable of handling stiff systems. This program can model complex reactions such as explosions, systems in which volume changes occur during the reaction, and very small systems.

As one example, consider the use of system dynamics software to model a two-step consecutive, reversible unimolecular reaction. Such a reaction is described as compound A being converted into compound B, then compound B being converted into compound C. This two-step mechanism would be described by the rate equation shown in Figure 29.4, where the equations for the time dependencies of A, B, and C are as described.

$$\frac{d[A]}{dt} = -k_{AB}[A] + k_{BA}[B]$$

$$\frac{d[B]}{dt} = k_{AB}[A] - k_{BA}[B] - k_{BC}[B] + k_{CB}[C]$$

$$\frac{d[C]}{dt} = k_{BC}[B] - k_{CB}[C]$$

FIGURE 29.4 Mathematical relationships for modeling a simple CRS system. The use of [] indicates the concentration of a value: [A] = concentration of A.

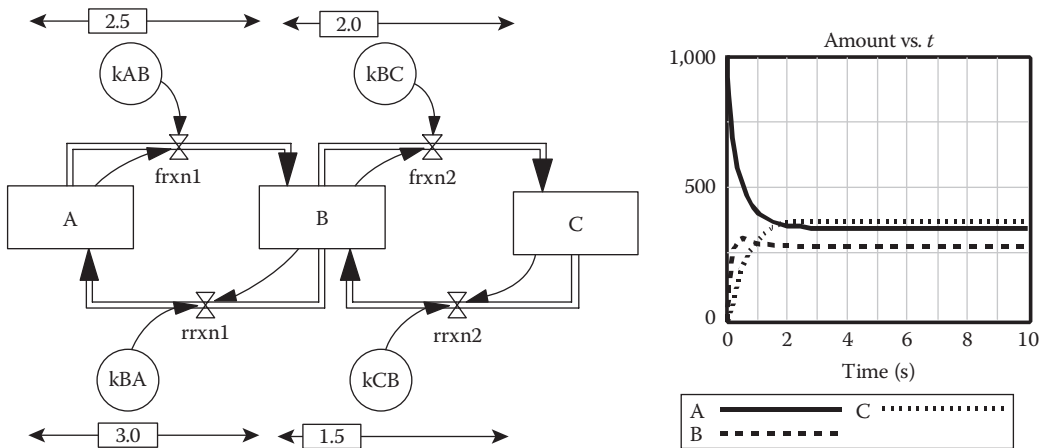

FIGURE 29.5 A system dynamics model to study chemical kinetics.

Although available in the literature, the integrated concentration–time equations are rather complicated. However, the system dynamics model is straightforward, as seen in Figure 29.5. This system dynamics model can be used to describe less complicated systems by setting the values of the respective rate constants equal to zero. For example, setting $k_{BC} = k_{CB} = k_{BA} = 0$ gives the model for a unimolecular forward reaction A to B. Setting $k_{CB} = k_{BA} = 0$ gives the model for a consecutive, nonreversible unimolecular system A to B and B to C. Or setting $k_{BC} = k_{CB} = 0$ gives a reversible CSR system A to B and B to A for which equilibrium studies are possible.

Note that the integrated concentration–time equations become more complicated as the number of steps in the consecutive reaction system increases. Analytical expressions for the integrated rate laws are available for n consecutive steps, but the equations cited in the literature are difficult to use and often contain typographical errors. It is easy to add additional sets of reservoirs, constants, and flows to the system dynamics model to describe the exact system under consideration.

29.4 Chemical Principles of Absorption Spectroscopy

The use of ultraviolet–visible (UV–Vis) spectroscopy is one of the oldest forms of characterization of compounds. In the visible range (400–800 nm), the absorption of light gives rise to complimentary colors characteristic of dyes and pigments. The absorption of both visible and ultraviolet light (200–400 nm) provides a means of nondestructive characterization that requires only a very small quantity of a compound to yield both quantitative and qualitative information. Two of the major disadvantages of characterization by UV–Vis spectroscopy are the low resolution of the observed spectrum and the relatively poor fit

between experimental observation and theoretical prediction. These limitations are especially evident when compared to the advances made over the past 50 years in matching experimental spectra and theoretical simulations for other common spectroscopic techniques such as IR, Raman, and nuclear magnetic resonance.

The chemical basis of the UV-Vis characterization begins with the chromophore. Organic chromophores possess conjugated pi systems that can readily absorb UV-Vis energy light. Inorganic chromophores may also possess d/f-type electrons that can accomplish the same result. In either case, the general process of the UV-Vis experiment is that the incident light results in promotion of an electron in the chromophore from a position of low energy known as the ground-state electronic configuration into a higher-energy electronic configuration, the excited state. The relaxation of the excited state to the lower-energy ground state is sometimes associated with the emission of UV energy that gives rise to two other spectrophotometric characterizations (fluorescence and phosphorescence). The characteristics of those relaxation processes are associated with many fundamental studies of biological systems.

A particular chromophore is associated with an ability to absorb light of a particular wavelength. But structural alterations to the chromophore can cause relatively large alterations to those initial excitation wavelength expectations. For example, this might be brought about by extending the length of the pi system in an organic system or changes of the conformation of the chromophore.

The chemical problem of understanding the UV-Vis process is further compounded by the fact that the absorption of light is most often measured for compounds in solution. This leads to slight variations in absorption wavelengths due to the interactions of solvent molecules with the solute molecules that are absorbing the light. It also results in the presence of multiple conformational structures of the same compound in solution at the same time, where each conformer can have a different absorption. And a final consideration is that compounds do not absorb light with equal efficiency. Experimentally, the efficiency with which a compound absorbs UV-Vis light is a quantifiable measure called molar absorptivity.

The absorption of light in organic compounds involves molecular orbitals, where electrons from highest energy-filled molecular orbitals (HOMO) or orbitals with energies just below that of the HOMO (designated as HOMO-1 or HOMO-2, etc.) are promoted to the lowest energy-unoccupied molecular orbital (LUMO) or orbitals just above the energy of the LUMO (designated as LUMO+1, LUMO+2, etc.). For organic compounds, this generally involves molecular orbitals associated with pi bonds and lone pairs.

29.4.1 Computational Approaches to Predicting UV-Vis Spectra

Initial approaches to the prediction and correlation of observed UV-Vis spectra to chemical structures were developed in the 1950s and are based entirely on experimental correlations. Once a common feature of intermediate level spectroscopic analysis course texts (Shriner, 1998; Silverstein, 1991), the results of chemists like Woodward, Hoffman, and Smith established nominal excitation values for various structural organic chromophores (e.g., dienes, enones, and benzenoid aromatic compounds) and a set of rules for increases or decreases from those values based on well-defined placements of specific auxochromes, the extension of the conjugated systems, and corrections for use of different solvents. These correlation rule predictions are still the best predictor for simple organic compounds of an absolute value for the key characteristic feature of the UV-Vis spectrum of a compound, the lambda max. However, the use of these rules cannot be extended to new systems.

One of the two most widely used computational methods to predict UV-Vis spectra was developed initially by Zerner and is called the ZINDO method (Ridley, 1973). The ZINDO method is a semiempirical approach based on application of molecular orbital theory. The primary strengths of the ZINDO method for absorption spectroscopy are its speed and reliability. With greater speed comes the ability to predict values for large molecules in reasonable time periods (minutes to hours using common desktop single-core machines). The primary computational limitation of the ZINDO method is that

it is applicable only to molecules composed of atoms for which spectroscopic INDO/S parameters are provided (H, Li, B, C, N, O, F, P, S, Cl, Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, and Zn). A recent improvement of the ZINDO/S method, ZINDO-MN (Zerner, 2011) provides enhancements for solvent molecule interactions, partial charges, and inclusion of better parameters for oxygen.

The other commonly used computational method for predicting UV-Vis spectra is the time-dependent DFT, called TD-DFT (Lewars, 2011; Marques, 2003). TD-DFT is often considered to be an *ab initio* method, but that it is not a true *ab initio* method is important in the context of spectroscopic predictions. TD-DFT does make certain assumptions in order to make the computation effort manageable. Key among these assumptions is distinguishing between valence electrons that are involved in bonding and the core electrons that are not involved in bonding. As the principal quantum number of an atom increases, the ratio of valence to core electrons exhibits a significant decline. Since it is generally agreed that the UV-Vis excitation involves the valence electrons, this is not considered to be a significant issue. In most respects however, TD-DFT is considered to be an *ab initio* method. Since TD-DFT is not limited to specific atoms, it is not limited by molecular composition. Its primary limitation is that it is a more expensive computation (requiring hours to days with a desktop computer).

29.4.2 Computational Chemistry Impact on Use of UV-Vis

Despite the elegance and sophistication of the semiempirical and *ab initio* computational methods, the older empirical rules are superior for accurately predicting the lambda max with simple systems, as, for example, with acetophenones (Doig, 2008). The ZINDO and TD-DFT methods are both generally reliable in correctly predicting relative lambda max absorbances of a related series—although the base prediction of wavelength is expected to be shorter than the experimental value in most cases because of a systematic overestimation for the difference in energy between the HOMO and LUMO orbitals. However, there are cases where these methods result in predictions of longer wavelength, illustrating the need to calibrate the results to known values for any computational methods.

Both computational methods continue to be used effectively to predict UV-Vis spectral data in a variety of interesting applications ranging from characterizations of potential new dyes (Fleming, 2011) to art history (Fantacci, 2010) to the design of tunable initiators for radical polymerization processes (Jankowiak, 2009). There are numerous studies where either method has been shown to be effective; one such example dealt with substituted coumarins, compounds used as laser dyes (Xu, 2009). One issue in considering the choice of ZINDO or TD-DFT is intramolecular charge transfer (ICT). The successful study of oxazine dyes using TD-DFT is particularly illustrative of the difficulty in dealing with ICT and the need to carefully consider the possibility of failure of the TD-DFT method in such cases (Fleming, 2011). Other systems with large ICT characteristics are dealt with adequately with ZINDO, as in the case of 5-(3-indolyl)oxazoles (Grotkopp, 2011) where the structure shown in Figure 29.6 had a calculated absorbance predicted at 344 nm and an observed absorbance at 306 nm. The HOMO coefficients were most centered the oxazole extending into the indole ring, and the LUMO coefficients were most centered on the aromatic ring attached to the indole at the 2 position extending into the indole ring,

FIGURE 29.6 Substituted 5-(3-indolyl)oxazole.

indicative of ITC. Numerous studies that provide direct comparisons of TD-DFT and ZINDO methods generally have led to the following conclusions. ZINDO is preferred when speed is important, the major expected transitions include n to p^* or p to p^* transitions, and ITC is a dominant factor. TD-DFT is preferred when economy is not essential, if ITC is not problematic and a close fit to experimental data is desired, or if atom parameterization is not available in ZINDO.

UV-Vis is most useful in structural characterization of species that are found in solution but not easily isolated or stable out of solution. Figure 29.7 illustrates structures associated with two recent examples of this application. The first example is a use of ZINDO to differentiate intermolecular charge transfer alignment of electron donor in a species like pyridine with an electron acceptor like chloranil (Pandey, 2011). In this example, two prominent coordination geometries are proposed, a T-shaped structure where the primary electron donation from pyridine is derived from the lone pair (n type) electrons on nitrogen and the other geometry largely results in electron donation from the aromatic ring electrons (p type). As part of the solution to this differentiation, the authors compared observed and computationally predicted transitions related to excitation of n and p electrons from pyridine to the LUMO π^* orbitals of chloranil (Pandey, 2011). These results (observed transitions 374 nm for π to π^* and 466 nm for n to π^* , T-shaped predicted absorptions 310 and 448 nm, cofacial predictions 380 and 435 nm) pointed, unexpectedly, toward the cofacial geometry. The computational work used self-consistent reaction field (SCRF) to model the influence of solvent on the absorption predictions.

In another application for proof of structure, the ZINDO-MN program available in Gaussian was used in order to identify a transient chromophore generated in the oxidation of *para*-aminophenol (Lerner, 2011). This required predicted absorptions of four proposed structural candidates for comparison to the observed solution chromophore, Chromogen 550. The UV-Vis predictions (550 and 366 nm) were a far better fit for both the longer and shorter wavelengths absorptions (experimentally observed values were 550 and 380 nm; the next closest computational fits were for a different proposed structure, 436 and 343 nm). The problem was compounded by the fact that there are actually two different structures present in solution, both of which have absorbance at 380 nm. The less stable chromophore, Chromogen 550, had absorptions at 550 and 380 nm.

The final research application involves the use of computational ZINDO UV-Vis spectral predictions as a key element in the *de novo* synthesis of new materials designed for use as photovoltaics

FIGURE 29.7 UV-Vis aids in structural characterizations of chromophores made in solution.

used in solar energy production (Boyle, 2011). These authors performed a computational investigation of 132 monomers that could be cross-coupled to produce over 90,000 oligomeric copolymers with potential application as photovoltaic materials. The compounds were refined geometrically using a fast empirical MMFF94 optimization, then by a PM6 semiempirical method. The authors noted that a more robust geometry optimization might have yielded better UV-Vis predictions because the semiempirical methods generally yield geometries that are underrepresentative of the extent of pi conjugation (the geometries are not as planar as seems evident based on experimental data). However, a subset of 60 oligomers were used to calibrate the UV-Vis spectral predictions to known experimental absorptions ($\sim +40$ to -4 nm variance, with only two predictions of lower energy than the experimental values) indicating that the computational predictions could be used as a starting point to guide selecting the best candidates for synthetic consideration. As interest in materials science grows, the demands for improved computational methods to accurately predict molecular properties such as optical absorption will increase.

29.5 Computational Medicinal Chemistry

The development of new, safe, and effective drugs is one of the most interesting and challenging areas of research today. Scientists involved in drug discovery are at the interface of chemistry and the biomedical sciences. Medicinal chemistry is therefore inherently an interdisciplinary field. Medicinal chemistry includes many of the traditional branches of chemistry (organic, inorganic, physical, analytical, and biochemistry) coupled with pharmacology, physiology, anatomy, statistics, biophysics, and computer sciences. Historically, in collaboration with pharmacologists, medicinal chemists were primarily synthetic organic chemists who prepared novel molecules with desired biological activities. Today, medicinal chemistry may be more broadly defined to include virtually any chemically oriented endeavor related to drug discovery. Pharmaceutical companies, however, still may divide scientists into organizational sections emphasizing their specialties.

29.5.1 Critical Issues in Medicinal Chemistry

The challenges that stand between the preparation of an investigational new drug (IND) to a new drug approval (NDA) application and final approval by the Food and Drug Administration (FDA) are daunting. Traditionally, thousands of compounds are prepared and screened for biological activity against some specific disease target(s). Structural modifications are made, and the compounds are then subjected to a new round of biological tests. The most active, least toxic, and pharmacokinetically viable compounds move into animal model studies and ultimately into human clinical trials. Approximately 14 years pass from laboratory inception to market availability. Moving a chemical entity from the laboratory to human clinical trials is no guarantee that the drug candidate will be approved. Many drug candidates fail in clinical trials, most typically due to poor pharmacokinetic profiles. Other factors that impact the rate of attrition may include safety concerns, toxicity, poor patient compliance, and corporate decisions (Hale, 2005).

The costs of successfully bringing a drug from the laboratory to the market are simply staggering. In the United States, for example, approximately \$800 million was spent in 2001, and this price escalated in 3 years by more than \$100 million (Kola, 2004). Prior to the 1970s, the pharmaceutical industry was built on a model where random screening was essentially the only method available. Medicinal chemists would modify functional groups and/or the molecular skeleton of lead compounds through a systematic trial-and-error approach, and the compounds would be tested in animal model studies by pharmacologists until clear correlations between structure and biological function were established. The process is iterative and time-consuming. For example, the sulfa drugs originally developed in the 1930s in Germany and later in France established the optimal molecular geometry (Hager, 2006): a sulfonamide group that was bound to an aromatic ring with a *para*-amino group (Brunton, 2010). Figure 29.8 shows

FIGURE 29.8 Sulfanilamide, an antimetabolite and the first of the sulfa drugs, is shown in a side-by-side comparison with *p*-aminobenzoic acid.

the structure of sulfanilamide and *p*-aminobenzoic acid (PABA). Sulfanilamide resembles PABA and prevents this metabolite from being used in the synthesis of folic acid. Microorganisms generate their own folic acids, whereas humans get folic acid through the consumption of foods.

29.5.2 Drug Design in Medicinal Chemistry

From the perspective of the practicing medicinal chemist, the combination of the 3D arrangement of functional groups of a molecular structure that is required to produce the desired biological response is known as the pharmacophore. The concept was developed by Paul Ehrlich who many considered to be the father of medicinal chemistry. The knowledge gained about the correlation of biological activity with molecular structure was important. As the biochemical basis of drug action became better understood over time, a more “rational” approach to drug discovery was undertaken.

The objective of rational drug design was to develop a drug by understanding the mechanism of action. A classic example is the discovery and development of captopril (Capoten[®]), the first FDA-approved angiotensin-converting enzyme (ACE) inhibitor (Cushman, 1977; Ondetti, 1977, 1982). Captopril along with the many fast follow-up drugs revolutionized hypertension therapy. ACE, a Zn(II)-containing enzyme, is responsible for the peptide bond cleavage of two terminal amino acids of the decapeptide angiotensin I to yield the octapeptide angiotensin II. Angiotensin II is a potent vasoconstrictor. In the 1970s, it was hypothesized that inhibition of angiotensin II would be an effective treatment for hypertension and cardiovascular diseases. The story of the development of captopril is an exciting precomputer exercise in rational drug design (Silverman, 2004). At the Royal College of Surgeons, Vane, Ferreira, and Bakhle discovered that the venom of the Brazilian pit viper (*Bothrops jararaca*) was a potent vasodilator (Bakhle, 1968, 1969; Ferreira, 1971). At the University of North Carolina at Chapel Hill, research by Byers and Wolfenden demonstrated that (*R*)-2-benzylsuccinic acid was an inhibitor of carboxypeptidase A (Byers, 1972, 1973). Ondetti, Cushman, and coworkers at Squibb (now Bristol-Myers Squibb, BMS) skillfully merged the knowledge of small peptides ACE inhibitors with small molecule inhibitors of carboxypeptidase A to generate captopril (Figure 29.9).

FIGURE 29.9 Captopril (Capoten[®]), introduced in 1978, was the first FDA-approved angiotensin-converting enzyme (ACE) inhibitor. The drug works by inhibiting ACE, which is the enzyme responsible for the conversion of angiotensin I to angiotensin II. The latter is a potent vasoconstrictor, and its use ushered in a new age in hypertension therapy.

29.5.3 Computational Chemistry in Drug Design

Any methodology that would allow pharmaceutical companies to bring a drug to the market more rapidly has huge financial rewards as well as the obvious benefits of a potential new therapeutic treatment for patients. Since the first commercial computers became available in the 1950s, there has been an explosion of computer-based applications in chemistry. Most of the fundamental concepts of quantum mechanics (QM) and molecular mechanics (MM) were developed or outlined in the 1920s and 1940s, respectively. The methodology of treating a system of particles classically with mathematical physics was worked out in the days of Sir Isaac Newton, and this serves as the foundation of modern molecular dynamics (MD) simulations.

The ability to solve complex equations through computations truly has ushered in a new age in science, and the impact in drug discovery has been no less dramatic (Bowen, 2004). The field of computer-assisted drug design (CADD) emerged in the 1970s with the introduction of quantitative structure–activity relationships (QSAR) by Corwin Hansch (Hansch, 1995). Currently, the *in silico*-based methods available to medicinal chemists are far-reaching, but drug discovery is ultimately an experimental science involving *in vitro* biological assays, *in vivo* animal testing, human clinical trials, and long-term postapproval studies. Computer-based methods are clearly reducing experimental efforts, but not replacing them. It is better to view CADD as an exciting and robust set of tools to help medicinal chemists understand drug–receptor interactions at the molecular level and make predictions about biological activity.

29.5.4 Pharmacophore Development and QSAR

The ability to understand interactions at the molecular level with computer-based methodologies is the basis of CADD. There is a full range of potential strategies that may be useful when approaching a drug design problem. The specific methods that may be used range from traditional computational chemistry (e.g., MM, QM, and MD simulations, which are described elsewhere in this chapter) to information-based methods (e.g., QSAR, 3D-QSAR, and database searching that are described herein). In many cases, the methodologies that are used to tackle a problem are a function of the scientists who have been hired, their backgrounds, resources, and available data. The corporate cultural environment of each pharmaceutical company also plays a role. For example, Merck seems to have a greater overall focus on structure-based drug discovery approaches compared to Pfizer, where the focus has been on the development of leads generated from high throughput screening with subsequent synthetic modifications.

Biological activity induced by a drug is a direct result of its molecular structure and ability to interact with the target macromolecule. In addition to the size and shape of the drug, the combination of organic chemistry functional groups and their 3D orientation when interacting with a macromolecular target is responsible for the biological activity of the vast majority of drugs. This simple yet powerful idea of the pharmacophore was first proposed by Paul Ehrlich as the molecular framework that carries (phoros), the essential features responsible for a drug's (pharmacon) biological activity (Ehrlich, 1909). Contrast this original definition to a more modern one as presented by Peter Gund who suggested that the pharmacophore is a set of structural features in a molecule that is recognized at a receptor site and is responsible for that molecule's biological activity (Gund, 1977). The definition of pharmacophore has been generalized in recent years to avoid the use of specific functional groups and highlighting regions of electron density, H-bond donors, H-bond acceptors, etc.

The development of a hypothesis of drug action as a function of molecular structure is the basis of structure–activity relationships (SAR), where structural modifications are made systematically to existing lead compounds to generate new compounds. The new compounds are then tested in animals for biological activity. The process, as indicated earlier, was the foundation of drug discovery, and it was only restricted to the imagination of medicinal chemists and the scientific limitations of the specific times. Knowledge of SAR is critical, but the data are qualitative or semiquantitative at best. It was in the 1960s that Corwin Hansch developed a simple yet powerful mathematical method that correlates

biological activity with mathematical equations (Hansch, 1969). His work quantified SAR and is known as QSAR. The QSAR approach introduced the age of CADD in the 1970s.

The basic idea behind QSAR is the recognition that molecular structure determines the physical properties of a compound. Since the biological activity of a compound is a consequence of its molecular structure, it should also be related to the physical properties. For the correlation and prediction of biological activities, some physical properties are more important than others. For example, the narcotic action of a set of compounds on tadpoles was correlated to the oil–water partition coefficients, P , by Meyer and Overton over a century ago. There is a thermodynamic tendency of a compound to distribute itself between the two phases of a water–hydrocarbon mixture. The partition coefficient, P , (where $P = [\text{drug}]_{\text{organic}}/[\text{drug}]_{\text{aqueous}}$) is the ratio of the drug concentration in an organic phase compared to an aqueous phase. For ionizable compounds, the situation is more complicated and a function of the pH of the medium.

The partition coefficient is an equilibrium constant and therefore related to the differences in the Gibbs energy at standard state conditions for the phase distribution. The relationship between K and P is given by the famous equation, $\Delta G^\circ = -2.303RT \log K$, where K is P . The more positive the value of the partition coefficient, the greater is the tendency for a drug to move from the water phase to the hydrocarbon phase. Typically, $\log P$ is used rather than P because of the direct relationship to the Gibbs energy. Octanol has been the organic solvent of choice for many years. Instead of using $\log P$ values, a substituent hydrophobicity constant π is often used. It is defined as the difference between the $\log P$ values of the parent compound and a derivative of the parent structure, where a functional group has replaced a hydrogen atom ($\pi_x = \log P_x - \log P_H$). Positive values of π mean that the derivative is more hydrophobic than hydrogen, while negative values of π mean that the derivative is less hydrophobic than hydrogen. In this formulation, it is straightforward to use the π values in an additive scheme along with the original $\log P$ value of the parent compound to estimate the $\log P$ of a new compound.

Hansch recognized this term as a physical observable that could be related to the hydrophobic nature of a drug's ability to cross cell membranes and/or interact with hydrophobic regions within the receptor. Other important factors are sterics and electrostatics. The original Hansch approach relied on the data generated by physical organic chemists who examined steric effects (Taft E_s parameters) or electrostatic effects (Hammett σ parameters). The Hansch equation describes the biological activity as a function of sterics, electrostatics, and hydrophobicity (biological activity = f [sterics, electrostatics, hydrophobicity]). This methodology relies on the use of statistical correlation methods (regression analyses) to develop valid and predictive equations.

The QSAR method has been widely used since the 1970s. Consider the example of hydrochlorothiazide. Hydrochlorothiazide is a specific example of a thiazide diuretic. The drug is administered orally and used extensively in the treatment of high blood pressure, edema, and congestive heart failure. The drug inhibits reabsorption of NaCl in the distal convoluted tubules of the kidney through inhibition of the Na⁺/Cl⁻ cotransporter. The net effect is diuresis, increased excretion of urine. Note the 1,3 relationship between the two sulfonamide groups ($-\text{SO}_2\text{NH}_2$) on the aromatic ring and shown in Figure 29.10. One of the sulfonamide groups is part of another ring system. The requirement of the locations and types of functional groups necessary for diuresis in this class of diuretics was determined by observation and SAR.

FIGURE 29.10 Hydrochlorothiazide blocks the reabsorption of NaCl, which leads to diuresis. The drug is used primarily in the treatment of hypertension and other disease states affecting the cardiovascular system. In many cases, hydrochlorothiazide is used in combination with other drugs (e.g., Avalide® is a combination of hydrochlorothiazide and irbesartan, an angiotensin II receptor antagonist, which is used for hypertension management).

Like all methods, the Hansch approach has advantages and disadvantages. Overall, traditional QSAR studies are usually (not always) straightforward and predictive. The computing time is minimal. However, the method does require a minimum number of compounds to be prepared and some trial and error in determining the best descriptors. Over the years, scientists have extended the descriptors to include other representative experimental data and/or calculated values (equilibrium A values, dipole moments, charge densities, molecular orbitals, etc.).

Orita et al. published a study that illustrates the QSAR method reasonably well (Orita, 1983) as a working example. They examined thirteen analogs with group variations in the 6- and 7-positions of the core structure. The diuretic activity (A) could be predicted with a formal charge (FC7) calculated for the 7-position, as well as a van der Waals (VW) steric parameter and a hydrophobic parameter (π) at the 6-position. This results in an equation [$\ln A = (0.2695 \times 10^{-3}) \pi + (7.62535)VW + (15.7681)FC7 + 0.98502$] generated through a nonlinear regression analysis ($n = 13$, $r = 0.98$). The relationship shows a positive correlation with the diuretic activity and the VW, π , and FC7 descriptors.

The Hansch formulation traditionally has correlated biological activities with the physical properties of the compounds being studied. Some physical properties can be calculated readily. For example, strategies have been developed to generate log *P* values *in silico*—based on the additive scheme of π values and are incorporated into software such as ClogP (Daylight Chemical Information Systems, Inc.; <http://www.daylight.com>). Perhaps the major complication is that π values are not only additive, but they are also constitutive. This means they are a function of their molecular environment. Such computational approaches are quite sophisticated when taking into account the branching, molecular connectivity, and other structural characteristics that contribute to the overall value of log *P*. This additive scheme is similar to how net dipole moments and thermodynamic properties are generated in MM. Notwithstanding, the QSAR correlation was primarily between experimental biological data and physical properties. More recent methodologies, often referred to as 3D-QSAR, have attempted to make correlations directly with the molecular structure and not the physical properties *per se*.

The comparative molecular field analysis (CoMFA) ushered in a new age for QSAR (Cramer, 1988). CoMFA is available in the program SYBYL (Tripos® a Centara™ Company; <http://www.tripos.com>). The basic idea is to calculate steric and electrostatic interactions at various positions in space for a set of molecular structures with a probe atom the size of a sp^3 carbon and a positive point charge. The steric and electrostatic interactions are determined by Lennard–Jones and Coulomb’s law equations, which are shown in Figure 29.11. Both of these types of equations are found in many MM force fields. The optimal alignment of the structures is critical for CoMFA. The calculated steric and electrostatic information are placed in a table, and a partial least squares (PLS) statistical analysis is carried out to prepare a mathematical model. From the mathematical model, color-coded steric and electrostatic fields are displayed to inform medicinal chemists of the regions in space where molecules may be altered to enhance activity.

3D-QSAR validation is necessary. Unlike the r^2 regression factor that is a positive value ranging from 0.0 to 1.0, where the latter represents a model in perfect agreement with the experimental data, the cross-validated R^2 used in 3D-QSAR is something different. It has been argued that instead of using a cross-validated R^2 , it may be better to refer to this result as q^2 to avoid confusion with r^2 because the regression variance may be negative. Therefore, cross-validated numbers range from –1.0 to 1.0. Essentially negative values indicate that random numbers provide a better fit to the experimental data than does the 3D-QSAR model.

Since CoMFA was introduced other methodologies have been developed. An improved method, known as comparative molecular similarity indices analysis (CoMSIA), is now widely used (Klebe, 1994). In this approach, property fields based on similarity indices of drug molecules with a common alignment and fields are calculated. Like CoMFA, a mathematical model is generated and evaluated by a PLS analysis.

Molecular skeleton analysis (MoSA) is a 3D-QSAR program that was developed and presented but never released (Liang, 1996, 2004). Similar to other methodologies, a set of molecular structures are aligned. Physicochemical properties (e.g., partial charge, atomic volume, and H-bonding potential) are assigned to each atom of the set of molecular structures. A 3D grid box is constructed for each property included. Gaussian functions are used in the calculations of molecular property distributions for all the atoms on

FIGURE 29.11 CoMFA creates a 3D grid around molecular structures and uses a probe atom to determine the steric and electrostatic fields at the grid points. The steric energy is based on a simple Lennard–Jones potential and the electrostatic calculations are based on Coulomb’s law. Both equations are presented. (Adapted with permission from Cramer III, R. D., Patterson, D. E., Bunce, J. D. Comparative Molecular Field Analysis (CoMFA). 1. Effect of Shape on Binding of Steroids to Carrier Proteins. *J. Am. Chem. Soc.* 1988, 110, 5959–5967. Copyright 1988 American Chemical Society.)

the grid points. The accumulated property distributions at grid points serve as descriptors. PLS is used to generate the final QSAR model. MoSA has the advantage that it does not use a probe atom, it is force field independent, and multiple conformations with a flexible weighting scheme can be used in the analysis.

29.5.5 Gibbs Free Energy Calculations in Medicinal Chemistry

The free energy perturbation (FEP) method is a computational stratagem used to calculate $\Delta\Delta G$ energy differences (Jorgensen, 1989; McCammon, 1987). Consider a lead compound (A) that binds with a receptor (R) to generate a molecular complex (A–R) in Figure 29.12. The Gibbs energy for this reaction is ΔG_1 , whereas a similar reaction with a modified lead compound (B) would yield a different molecular

FIGURE 29.12 The thermodynamic cycle depicts the possible formation of the drug–receptor complexes A–R and B–R when drug candidate A reacts with receptor R ($\text{A} + \text{R} \rightarrow \text{A-R}$, ΔG_1) and drug candidate B reacts with receptor R ($\text{B} + \text{R} \rightarrow \text{B-R}$, ΔG_2). Both reaction ΔG values can be measured experimentally. The conversion of $\text{A} \rightarrow \text{B}$ and $\text{A-R} \rightarrow \text{B-R}$ are nonphysical processes, and the associated ΔG_3 and ΔG_4 values may be determined computationally. This process is known as the FEP method, and it is computationally demanding.

complex (B-R) with a different Gibbs energy ΔG_2 . Both ΔG_1 and ΔG_2 may be obtained experimentally, but the determination of the data can be challenging. From a drug discovery perspective, the goal is to know the differences in the Gibbs energy for the two reactions. The vertical conversions of $A \rightarrow B$ and $A-R \rightarrow B-R$ are *in silico* processes. These transformations and the associated ΔG_3 and ΔG_4 are fictitious. Taking advantage of a thermodynamic cycle, $\Delta\Delta G$ can be calculated by recognizing that $\Delta G_3 + \Delta G_2 = \Delta G_1 + \Delta G_4$ and rearranging to yield $\Delta\Delta G = \Delta G_2 - \Delta G_1 = \Delta G_4 - \Delta G_3$. Thus, the desired $\Delta\Delta G$ may be obtained by computational chemistry methods rather than by experiments.

29.5.6 Computational Structure-Based Drug Design

The use of macromolecular structures, most typically protein structures, is the starting point in a drug discovery project. This approach is known as structure-based drug design (SBDD). SBDD has been an extremely productive field. There are now many examples of FDA-approved medicines that are based on CADD methods. A few examples are discussed.

The 3D protein structures used in SBDD are based on (1) x-ray crystallography, (2) NMR spectroscopy, and (3) homology modeling. X-ray and NMR are experimental techniques, whereas homology modeling relies on computational methods and the similarity between various folding patterns in proteins. The explosion of protein x-ray data (RCSB Protein Data Bank: <http://www.pdb.org>) is due in part to progress in the field but more importantly to the ready availability of proteins through the advances in molecular biology. Ironically, molecular biology can trace its roots to the correct prediction of the DNA double helix structure by Watson and Crick who used precomputer molecular modeling methods. The development and use of macromolecular structures derived from *in silico* methods (e.g., homology modeling) is important.

Dorzolamide (Trusopt[®]) is used in the treatment of open-angle glaucoma and hypertension of the eye. The drug, shown in Figure 29.13, reduces intraocular pressures by inhibiting carbonic anhydrase and is administered as an eyedrop. After a decade in development, dorzolamide holds the distinction of being the first FDA-approved drug (1995) that was designed with structure-based methods to reach the market (Greer, 1994). Among the computational chemistry methods used, *ab initio* calculations played a role in the prediction of substitution patterns.

All diseases are cruel, but Alzheimer's disease (AD) seems to strike a particular fear, especially among seniors. There is no cure at this time. It was shown that patients with AD have decreased levels of acetylcholine in their brains. A combination of QSAR, molecular shape analysis, molecular modeling, docking, and related CADD methods resulted in donepezil (Aricept[®]) being introduced into the market (Kawakami, 1996). This drug, shown in Figures 29.14 and 29.15, is a reversible inhibitor of acetylcholinesterase (AChE).

Another noteworthy example where SBDD played a significant role was in the development of human immunodeficiency virus type 1 (HIV-1) protease inhibitors. The US FDA has approved several HIV protease inhibitors since 1995. They include (in chronological order) saquinavir (Invirase[®], Roche, 1995; Fortovase[®], Roche, 1997), indinavir (Crixivan[®], Merck, 1996), zidovudine (Retrovir[®], Abbott, 1996), nelfinavir (Viracept[®], Pfizer, 1997), amprenavir (Agenerase[®], GlaxoSmithKline, 1999), lopinavir (Kaletra[®], Abbott, 2000), atazanavir (Reyataz[®], BMS, 2003), tipranavir (Aptivus[®], Boehringer Ingelheim, 2005), and darunavir (Prezista[®], Tibotec, 2006).

FIGURE 29.13 Dorzolamide (Trusopt[®]) was approved for use in the United States in 1995. The drug is an eyedrop that is used to treat glaucoma. It has the distinction of being the first FDA-approved drug that was designed with structure-based methods to reach the market. Inhibition of carbonic anhydrase is the mechanism of action for this drug.

FIGURE 29.14 Donepezil (Aricept®), a reversible inhibitor of AChE, was developed by Eisai and marketed by Pfizer. QSAR, molecular modeling, and SBDD methods were used in its development.

FIGURE 29.15 The energy minimized structure of Donepezil (Aricept®) is shown with a molecular surface displayed.

HIV protease, a member of the aspartyl protease family, is a symmetrical dimer with 99 amino acids in each monomer and has been a target for successful drug discovery (Huff, 1991). The protease is expressed as part of the reproductive cycle of the virus. It is one of several viral enzymes that are initially expressed as a large polyprotein encoded by the HIV-1 pol gene, one of the three major genes of the retroviral genome. The retroviral genome also encodes various small auxiliary proteins. It is known that during the maturation of nascent viral particles, via hydrolysis reactions catalyzed by the catalytic aspartate residues, the protease enzyme cleaves the viral polyproteins at specific sites to generate the structural proteins and enzymes essential for viral replication. A water molecule presumably assists in the peptide bond hydrolysis. X-ray crystal structures show that the NH groups of the protein are bound to the water molecule as well as to the carbonyl groups of the inhibitor. Figures 29.16 and 29.17 illustrate computational modeling of saquinavir.

FIGURE 29.16 Saquinavir (Invirase®; Fortovase®) was the first FDA-approved HIV inhibitor developed. It was developed by Roche and, like all drugs in this class, was developed with structure-based CADD methods. Saquinavir, in the center, is shown bound to HIV-1, rendered as a ribbon.

FIGURE 29.17 This image is a close-up view of saquinavir bound to HIV-1. The bridging water molecule between the ligand and the receptor can be seen readily. Note the hydrogen bonding interactions, which are depicted by the football-shaped objects. The greater the hydrogen bonding interactions, the larger the objects. This image of the drug–receptor complex was prepared in Benchware 3D Explorer (Tripos® a Centara™ Company). (Courtesy of Dr. Tom Jones.)

29.5.7 Informatics in Medicinal Chemistry

CADD methods are employed by medicinal and/or computational chemists to enhance understanding of the factors that contribute to the stabilization of the drug–receptor complex. The potency, solubility, and permeability are the physical variables that may be modified to enhance the activity of drug candidates. Maximizing the thermodynamic interactions between a drug and its receptor is not, however, the only aspect involved in successful drug design. The absorption, distribution, metabolism, and excretion properties of a drug are vitally important. It may be more beneficial to sacrifice some favorable thermodynamic interaction energies in a drug–receptor complex in order to minimize some undesired biotransformations or to maximize solubility and permeability. In this vein, Lipinski has championed the idea of predictive ADME. The potential that a drug candidate will have poor absorption or permeation may be expected when at least one of the following four properties is present: (1) more than 5 hydrogen bond donors, (2) more than 10 hydrogen bond acceptors, (3) more than a 500 molecular weight, and (4) more than a 5 computed logP (Lipinski, 1997). There have been other equivalent ways to include these factors in the analysis of small molecule preclinical candidates (e.g., the number of nitrogen centers, the number of oxygen centers).

In many cases, ADME and toxicity are easier to predict than biological activity. Lipinski's rules may work well because absorption is in part a function of solubility. There are relatively few physicochemical principles underlying solubility. Today, many pharmaceutical companies have invested significant resources into screening virtual libraries and using a scoring function to rank the compounds prior to their synthesis.

Database searching is also a popular and successful endeavor (Martin, 1992). For example, Zhong et al. created a pharmacophore model based on five potent MMP-9 inhibitors (Zhong, 2011). A database search of thousands of structures resulted in nine hits from commercial or in-house sources of compounds. The compounds identified in the database search were then subjected to an SVR proliferation assay. Several of the compounds were promising inhibitors. There are many similar examples for successful database mining techniques.

29.5.8 Future Trends in Drug Discovery

Large pharmaceutical companies are undergoing dramatic changes in their approach to research, which includes mergers, downsizing, outsourcing, and even reexamining their research commitments

to future drug discovery projects. The use of computational chemistry and computer-based methodologies will be a part of most future drug discovery projects because of the reasonable success that has been demonstrated. Unfortunately, the success rate has been much less than desired, which may in part be due to overexpectations and the inherent difficulty of designing compounds that do not have some hidden flaw that is eventually discovered in human clinical trials. There have been a number of speculations for the problems facing drug approval, and it is beyond the scope of this book chapter to review them. Drug discovery, however, is too important to disappear altogether. Most probably there will be a new emphasis on drug discovery in academic centers and small biopharmaceutical companies. The use of computational chemistry and CADD methods in the right hands can be very effective tools for medicinal chemists.

29.6 Computational Inorganic Chemistry

The improvements in methods and computational power have not yet equaled the challenges presented by large atoms and molecules (Gladysz, 2011). The computational chemistry tools were originally developed for small systems with limited atomic diversity. One of the key decisions in determining how to model an inorganic compound is the trade-off between accuracy and the computational expense. Despite this limitation, computational chemistry has been applied effectively in many areas of inorganic chemistry, including the study of structure and bonding in complex systems; solvation effects on reactive species; chemical catalysis, especially the nature of transient species and energy changes; electrochemical as related to electron transport and storage of organometallic complexes; and the properties of new materials.

29.6.1 Computational Methods for Inorganic Chemistry

Empirical methods, like MM2, do not contain most of the atoms and geometries needed to predict reasonable inorganic structures. Semiempirical methods suffer from the same limitation. Complete *ab initio* calculations using either Hartree-Fock or Møller-Plesset treatments are generally too time-consuming to run for inorganic compounds. Even generally accepted modifications to the complete wave functions like the Born-Oppenheimer approximation for fixed nuclear geometries cannot simplify the calculations enough for these molecules that often contain hundreds to thousands of electrons (Stradi, 2011). It is often necessary to model a portion of the molecule containing just the active metal or other heavy atom center with theories taking into account unpaired delocalized electrons using post self-consistent field models to get an accurate single-point energy calculation after completing a series of modeling trials that use more approximations to gain a good geometric representation. The optimized fragment geometry can then be incorporated into the full structure. Another significant area of research within *ab initio* modeling studies is using plane wave basis sets for the valence electrons with a correction for the effective core potential (ecp) to study conduction in metals instead of Slater- or Gaussian-type orbitals to better match the long-range nature of electron transfer in these materials (Lopez, 2011).

The major computational tools used in all branches of inorganic chemistry utilize DFT models with basis set polarization corrections to take into account d and f orbital contributions and diffuse functions for electronic excited-state calculations. The most frequently used basis sets also take into account the ecp approximations, where the electron interactions for the inner shell electrons are frozen and coupled with the cationic atomic nuclei as a rigid, nonpolarizable core. Even evaluations of ligands like bipyridine, which is among the most studied bidentate organic ligands used in organometallic chemistry, can yield interesting results by utilizing broken symmetry DFT functionals ranging from the oft-referenced B3LYP through more complicated hybrid systems that take into account additional correlation and electron exchange terms in the integrals (Scarborough, 2011). The best fit to the experimental spectral data for the titanium(III) cyclopentadienyl bipyridine diradical complex was seen using B3LYP compared to three other more complex hybrid functionals. Furthermore, for systems that contain a wide range of

atom types, a different basis sets need to be used for different atoms within one computational study. Highly complex basis sets that take into account d and f orbitals using polarization and diffusion at long distance from the core are used for the metal atoms, and simpler Pople basis sets are used for the main group atoms and hydrogen.

29.6.2 Main Group Computational Chemistry

A recent study is representative of this type of work (Wittmaack, 2011). A series of derivatives of halogenated structures (X_nA) for the group 4A elements carbon through lead was evaluated to see how the charge transfer from the halides to the group 4A elements was impacted by the number of halides attached to the molecule and by the atomic number of the group 4A central atom. Since these are small, discrete molecules, it was possible to use full *ab initio* Møller–Plesset (MP2) and coupled cluster calculations to incorporate electron correlation effects. For the smaller atoms, full MP2 evaluations were completed; for the largest atoms like lead (Pb) and tin (Sn), approximations to incorporate electron core potential effects were included. Additional calculations using natural bond order rather than molecular orbital calculations were then carried out on the optimized geometries to determine point charges for all of the atoms. These studies have shown that after a certain level of substitution, the charge on the central atom does not change much regardless of the addition of more halides to the structure. This approach of multiple steps in model refinement is again typical of most modeling studies for inorganic compounds.

29.6.3 Computations with Metal-Containing Compounds

New density functionals have been developed that incorporate relativistic effects, *ecp*'s, and electronic correlation effects. For heavier atoms, the near-relativistic speeds of inner shell electrons results in higher effective electron masses that can skew results tremendously. In addition to the hybrid functional B3LYP, many researchers in organometallic chemistry are using the Perdew, Burke, and Ernzerhof (PBE) or the Heyd–Scuseria–Ernzerhof (HSE) generalized gradient approximation hybrid functionals when studying metal atoms as they give good geometrical matches to published crystal structures and available vibrational spectroscopy (Stradi, 2011). Metal phthalocyanine systems have been modeled to determine the source of bands in the emission spectra of these compounds. The major goal of the study was to evaluate the energy minima and vibrational spectra of the materials adsorbed as a thin film on a solid surface to compare the results to the available gas-phase data. The best agreement from the model data in this case came with the HSE hybrid functionals compared to all of the other systems tested.

Sometimes, modeling is a useful method for evaluating chemicals that are difficult to isolate and work with because of stability problems and air sensitivity. While neutral, +2, and +4 oxidation states of palladium have been extensively studied, there are few reports on +3 oxidation state (Pd(III)) complexes. A recent synthetic study on the isolation and x-ray analysis of these compounds used DFT to explain the distorted octahedral geometry for these complexes, and the DFT-derived singly occupied molecular orbital descriptions for these species gave a very accurate prediction for EPR signals that matched the experimental data for these paramagnetic species, showing how complex computational studies are now used by synthetic chemists in conjunction with spectral analysis (Khusnutdinova, 2010).

Molecular modeling using high-level DFT studies have been used in the past few years to study whether assumptions made concerning the non-innocence (lack of involvement in the oxidative process) of homoleptic dithiolene ligands in metal complexes from x-ray, spectral, and simple MO calculations were correct. The models showed that on changing the redox state of the overall organometallic complex the oxidation state changed not just on the metal but on the ligand as well, hence the “non-innocence” sobriquet given this class of ligands. Using modern computational techniques, electron density distributions that matched the spectral data and supported this theory were completed, confirming this long-debated point (Eisenberg, 2011). A recent review highlights many of the uses that have been made of these computational studies in evaluating bonding in very complex compounds (Lin, 2010).

Many inorganic reactions can only be studied effectively by taking into account interactions between the reaction center and its surroundings. A recent study highlights the difficulty in modeling the formation of large clusters that contain highly charged metals, where ion–dipole effects present from solvation change the calculated energy levels of the molecule (López, 2011). The possibility of modeling all of the solvent–solute interactions is very challenging from a computational standpoint, so solvent effects are taken into account using a conductor-like screening model (COSMO) that approximates the electrostatic interactions between the model complex and the solvent by treating the solvent as a set continuum governed by the solvent dielectric constant to give a much more realistic representation of the zero point energies and corresponding vibrational frequencies in highly polarized molecules. These COSMO studies are generally in good agreement with more rigorous molecular dynamic studies using Car–Parrinello simulations where all solvent molecules are treated explicitly and motion of the solvent molecules is allowed during the computational cycle.

29.6.4 Computational Issues Related to Catalysis

Understanding the mechanisms, intermediate structures, and reaction kinetics of catalytic cycles is central to process improvement. Often, these properties can be evaluated by use of molecular models as well as using mathematical models to model rates. In the case of the Suzuki–Miyaura coupling reaction, a system whose discovery was chosen as part of the Nobel Prize in chemistry in 2010, the mechanism is not well understood. The Suzuki–Miyaura coupling reaction uses a palladium catalyst to form new carbon–carbon bonds. The active species in the oxidative addition, transmetalation, and reductive elimination steps in the catalytic cycles are not clearly understood, and experimental characterization does not clarify the structure of these species, so a number of computational studies have been undertaken recently (Jover, 2010). All of the key reaction intermediates were evaluated using very standard DFT functionals and basis sets except for the transition metal palladium and bromine, where basis sets taking into account the ecp as well as triple-zeta orbital descriptions are needed to describe the more complex bonding. The study results were in good agreement with spectral data obtained during actual catalyst trials, and based on variations in the models, the reasons large electron-donating phosphine ligands improve catalytic efficiency was explained, even though the actual energies were not in total agreement with the actual data as fairly simple calculations were attempted. The use of DFT-based molecular modeling is now so pervasive in organometallic catalysis that even groups whose primary goal is the synthetic utility of a catalyst will run DFT studies to confirm proposed reaction cycles.

One of the key parameters in evaluating any catalyst system is the turnover frequency, which measures the number of molecular transformations over a period of time catalyzed by a single active catalytic site; thus, it is a measure of catalytic efficiency. A recent study develops a new computational model for all of the steps in a catalytic cycle using the energetic span model (Kozuch, 2011). The goal of the study was to link experimentally derived rate constants (kinetics) with energy level descriptions of the transition states (thermodynamics) calculated using modeling by linking the results using the transition state theory developed by Eyring. A computational model developed from this connection between kinetics and thermodynamics was successfully employed with a series of nickel center–catalyzed cross-coupling reactions of anhydrides with organozinc compounds. The resulting transition state measure of turnover frequency was able to accurately predict the experimentally observed turnover frequencies, and the technique is being expanded to other catalyst systems.

29.6.5 Electrochemistry

There has been a tremendous upsurge in interest in electrochemical systems involving inorganic chemistry over the last 5 years, and very often computational methods using DFT analysis are being utilized to evaluate the reduction and oxidation potentials in these systems (Geiger, 2011). Now that

there is a wide availability of tools to study these systems, many groups are modeling the changes in the valence-state electrons of the metals using DFT models coupled with basis sets optimized for use with ecp approximations (Roy, 2009). One of the results of these studies on well-understood systems like the one electron oxidation of the iron ferrocene complex is the determination that the choice of the basis sets has less of an impact on the energy and geometry calculations than does the choice of the DFT functionals. Using a wide range of DFT models including generalized gradient approximations and hybridized approximations had a major impact on the overall calculated oxidation potential. By varying the basis set on the iron core atom from all electron triple-zeta models to basis sets with ecp approximations, or with ecp approximations with relativistic effects taken into account, the overall calculated oxidation potentials changed dramatically. Only the basis set taking into account the ecp with relativistic effects incorporated into the approximation matched the experimental data. In the same study, changing the solvent used from acetonitrile to acetone or DMSO resulted in having to change the DFT used from a hybridized DFT to an unhybridized version of the same DFT. Just using one model without evaluating other possibilities can lead to very uncertain results.

29.6.6 Clusters and Nanomaterials

The area of chemistry that results in the most public interest, outside of medicinal chemistry, is the study of nanomaterials. Many metal-containing species are being studied in regard to these nanomaterials; two of the areas of greatest interest involve graphene nanomaterials and metal-organic frameworks (MOFs). These systems are so large and entail so many atoms and electrons that fully modeling them is impossible, but it is also increasingly evident that the chemistry of these complexes changes as the size of the clusters grow from localized single metal centers to clusters with thousands to millions of metal centers. The interaction of the first-row transition metal centers with the six-member carbon rings found in graphene nanotubes has now been modeled using computational methods (Valencia, 2010). To be of practical interest, these studies need to take into account enough atoms to allow for measurement of electron transfer across the entire model surface to emulate the band structure for electrical conduction, as well as model the Brillouin zone of the nanomaterial, as that is the representative lattice cell of interest for the determination of the macro properties. The necessity of modeling enough atoms and electrons to take into account these lattice properties is computationally expensive. Since the electrical conduction of these materials is a very important property, the modeling is often done using plane wave basis sets instead of Gaussian-type orbitals.

The study of MOFs is another area of nanomaterials where modeling is being used to predict relevant properties. MOFs are extended 3D cage-like crystal lattices containing multidentate organic ligands that are coordinatively bound to metal centers. These MOFs are being evaluated as catalyst supports, gas storage matrixes, and drug delivery vehicles among many end uses. Since DFT can be used to measure bond strength, it is possible to relate calculated energy profiles and geometries from modeling studies in the MOF to overall mechanical properties such as shear modulus, by determining the individual bond stiffness over the entire unit cell of the lattice in all planes of the cell (Tan, 2011). Actual experimental measurement of these MOF materials is primarily limited to the technique of nanoindentation, since large individual crystals have not yet been created. Nanoindentation only measures penetration distance and applied force, which is of limited utility when comparing to applied shear forces, since many of these compounds exhibit differing levels of dimensional stability. Overall, the comparison to the calculated shear forces is interesting as the shear forces and the force of indentation have a strong linear correlation.

29.6.7 Future Issues for Computational Inorganic Chemistry

Dealing with the lanthanides and actinides, with *f* orbital electrons, might be the ultimate challenge since the energy levels are nearly degenerate many different electronic orientations are possible. Coordination numbers of as great as 12 are possible and a wide range of oxidation states from 1 to 7 can be seen in some complexes. A recent survey on the use of computational studies in the evaluation of actinide containing

molecules summarized these challenges (Schreckenbech, 2010). For bioinorganic structures, the problems are additionally compounded (Ghosh, 2011). Researchers often use combined QM/MM; however, this can lead to large discrepancies in the calculated results. The choice of exchange correlation functionals has a huge impact on the final agreement between computational and experimental results, and occasionally, no DFT models come close to the experimentally determined spectra (Gutten, 2011). Uncertainty in valence electron location between the metal center and the ligand shell makes it difficult to explain electron transfer mechanisms. One group overcomes this problem with DFT methods; some groups are completing complex high-level *ab initio* studies on iron(III) porphyrin studies using post-SCF methods including the complete active space self-consistent field model (CASSCF). By using more rigorous computational models, they are able to predict the spectral properties and give insight into the actual mechanism of electron transfer.

New functional descriptions for DFT to improve the incorporation of long-range electron interactions need to be created. In the absence of a reliable single method, computational chemists must try several different modeling protocols and chose the one that best matches the experimental data. The field of computational inorganic chemistry is just starting to deal with all the complexity inherent in large molecules containing elements with many electrons in a series of atomic orbitals that extend across all available orbitals.

29.7 Summary

There is obviously still room for improvements in computational chemistry. But the role of computation in chemistry is now essential to most areas of chemical inquiry. Perhaps this is most evident in a quick glance at some recent special issues of leading review journals and communications from journal editors. In the opening to the 2006 special issue in *Accounts of Chemical Research*, the editors wrote: "At the outset of the twenty-first century, theoretical and computational chemistry has arrived at a position of central importance not only for theorists but also in the laboratories of most experimentalists and in many disciplines" (Carter, 2006). The December 2011 issue of *Chemical Physics and Physical Chemistry*, dedicated to computational chemistry, includes the following editorial comment: "... the development of new methods and density functionals continues to be a vibrant field of research in a sustained effort to develop reliable approaches for almost any problem in chemistry" (Batista, 2011). Another 2011 editorial attests to the widespread acceptance of computational chemistry: "Approximately one-third of current submissions to the *Journal of Medicinal Chemistry* report computational work of varying weight and complexity." The editors go on to describe a new set of standards for computational chemistry in that journal (Stahl, 2011). The January 2012 issue of *Chemical Reviews* is dedicated to quantum chemistry. In the opening introduction to that section is the following statement: "... quantum chemistry has yielded a very important product: software packages, some of them representing commercial enterprise and others given away freely ... In either case, these programs are being used by an ever growing base of users" (Pyyjkko, 2012). It seems clear that computational chemistry is here to stay and that we can look forward to advances and improvements that will increase the foothold of computation in the myriad disciplines of chemistry.

Key Terms

Acetophenones: A class of organic compounds that have a methyl carbonyl ($\text{CH}_3\text{-CO-}$) attached to a benzenoid aromatic ring.

Auxochromes: A term derived from the Greek aux, meaning to grow, and the Greek chroma, meaning color. An auxochrome is any group added to a chromophore that causes a change in the interaction of the group with UV-Vis light.

Belousov-Zhabotinskii: The specific reaction is the oscillating reaction involving BrO_3^- , HBrO_2 , H^+ to give BrO_2 , H_2O , and BrO_2 , Ce^{3+} , H^+ to give HBrO_2 , Ce^{4+} , H_2O . Reactions that oscillate are sometimes referred to as Belousov-Zhabotinskii-type reactions. They are representative of reactions that are not in chemical equilibrium but instead are treated as dynamic systems.

- Benzenoid aromatic:** A compound that has a six-membered ring with alternating single and double bonds is a benzenoid aromatic compound (e.g., benzene, molecular formula C_6H_6).
- Bipyridine:** A common organic ligand composed of two pyridine rings, where each ring contains one nitrogen and five carbons in a six-member aromatic structure.
- Brillouin zone:** The unit cell in a crystal lattice that fully describes the electron distribution and electronic band structure.
- Broken symmetry approximations:** Single determinant wave functions that are not pure spin states and therefore are not expected to represent the true wave functions of the system. Unsymmetrical determinants are used to represent uneven distribution of electrons in a molecule.
- Catalysis:** Using a reagent in a chemical reaction that significantly increases the rate at which the reaction proceeds, without using up any of the reagent.
- Chromophore:** Derived from the Greek *chroma*, for color, and *phoros*, for bearing, the chromophore is the core structural feature of a compound that gives rise to its ability to absorb UV-Vis light.
- Conjugated:** If atomic orbitals that make up pi bonds can overlap in a side-to-side manner with pi bonds or atomic orbitals on contiguous positions, then the electrons in all of the overlapping orbitals are treated as a single integrated system that is said to be conjugated.
- d/f-type electrons:** Atoms with a principal quantum number of 3 or higher can have d-type electrons. For each d-type principal quantum number, there are five atomic orbitals with an allowed capacity of 10 d-type electrons. Atoms with a principal quantum number of 4 or higher can also have f-type electrons. For each f-type principal quantum number, there are seven atomic orbitals with an allowed capacity of 14 f-type electrons.
- De novo:** From Latin *dē*, from, and *novō*, new, *de novo* refers to a process of discovery that makes minimal preliminary assumptions, thus representing a new approach.
- Dentate, mono, bi, multi:** Binding of atoms to the central atom in a coordination complex is referred to as denticity, where every point of contact is a bond to the central atom.
- Dienes:** Dienes are compounds that contain two pi bonds between two different sets of carbon atoms. In UV-Vis, the term diene almost always refers to conjugated dienes.
- Dyes:** Dyes are compounds that both absorb visible light causing the appearance coloration and have intermolecular attractions to compounds/materials to which they are applied, such as textiles.
- Electrochemistry:** Chemistry occurring at the interface of an electrical conductor, where the flow of electrons either to or from the interface impacts the chemical reaction that occurs.
- Enones:** Enones refer to a conjugated system composed of a C=C pi bond and a C=O pi bond, as found in the compound methyl vinyl ketone: $CH_2=CH-CO-CH_3$.
- Ferrocene:** An organometallic species containing an iron atom bound to two five-member aromatic rings so that the rings are centered perpendicularly above and below the iron atom.
- Fluorescence:** The emission of light energy of a lower-energy and longer wavelength than the concurrently applied light energy, or other forms of energy, used to generate the excited state, is known as fluorescence.
- Functional:** A mathematical operation that converts a vector into a scalar field; an example would be the scalar field of temperature gradients around a solid body. A functional is a function that is a function of another function.
- Graphene:** A form of pure carbon that exists as an extended sheet of six member rings in a very stable form. Sheets of graphene combine to form the mineral graphite.
- Halides:** Elements in group 17, formerly 7A, on the periodic table that are characterized by high electron affinity (e.g., F, Cl)
- Homoleptic:** Any organometallic complex in which all of the attached ligands are identical.
- INDO/S:** It is the acronym for intermediate neglect of differential overlap/screened approximation. The ZINDO method is the Zerner modification of the INDO/S method.

In silico: A process or test or evaluation performed on a computer is termed *in silico*, in deference to the use of silicon chips.

In vitro: A process or test or evaluation performed in glassware is termed *in vitro*.

In vivo: A process or test or evaluation performed in living systems is termed *in vivo*.

Intramolecular charge transfer: The shifting of electron density from an electron-donor region or substance to an electron-accepting region or substance creates a weak attractive force between the two regions. When this occurs between two molecules, it is called a charge transfer complex, when it occurs within one molecule, it is called ICT.

Lambda max: A peak in a UV-Vis spectrum is broad, on the order of 10–100 nm wide, and the identity of the peak is based on the point of highest absorptivity of light in that range, called the lambda (λ) maximum (max), given the notation λ_{max} .

Law of mass action: The law of mass action states that the rate of a chemical reaction at each instant is proportional to the concentrations of the reactants, with each concentration raised to a power equal to the number of molecules of each species participating in the process. If the reaction involves more than one step, the rate of formation or removal of a given substance will contain terms for each step in which the substance is involved. Once overall equilibrium is reached, the law predicts the usual expression for the equilibrium constant K in which the numerator is the product of the concentrations (partial pressures, etc.) of the products raised to the respective stoichiometric coefficient in the overall chemical equation divided by the product of the concentrations of the reactants raised to the respective stoichiometric coefficient.

Ligand: A molecule or ion that donates electrons to the central atom, usually a metal, in an organometallic coordination compound.

Michaelis-Menten: This is the relationship used to describe rates of enzyme-substrate process in biochemical reactions, where the rate of conversion, V , equals the maximum rate of conversion, V_{max} , times the concentration of the substrate, $[S]$, that quantity divided by the sum of the rate constant, K_m , and the concentration of the substrate: $V = (V_{\text{max}}[S])/(K_m + [S])$.

Molar absorptivity: Molar absorptivity, also known as extinction coefficient in older literature, describes the quantification of light apportion as a function of the amount of the chromophore molecule present in solution. Beer's law ($A = \epsilon cb$) is used to define the relationship, where A = measured absorbance intensity, ϵ is the molar absorptivity, c is the concentration of the molecule, and b is the path length of the sample cell.

Molecular orbitals: As atoms are combined to make molecules, the atomic orbitals and associated electrons from the atoms are combined to produce new orbitals, called molecular orbitals, into which the molecules electrons are placed.

Oxidation potential: A measure in electron volts of the energy required to remove an electron from a compound.

Pharmacokinetic: The description for the rates of the fundamental processes that a drug undergoes in the body is called pharmacokinetics. Those processes include absorption, bioavailability, distribution, metabolism, and excretion.

Phosphine: An organophosphorus compound with an easily donated electron pair on a phosphorus atom that can act as a ligand.

Phosphorescence: The delayed emission of light energy of a lower-energy and longer wavelength than the concurrently applied light energy, or other forms of energy, used to generate the excited state, is known as phosphorescence.

Photovoltaics: The process of capturing sunlight and using that energy to generate electrical energy is known as photovoltaics.

Phthalocyanine: A cyclic organic species with 4 nitrogens on the inside of the cyclic ring that readily binds metals. Structurally related to the porphyrin ring seen in many biological enzymes like hemoglobin.

Pi bond/electrons: If two atomic orbitals on adjacent atom are coplanar so that they can overlap in a side-to-side manner and they share a pair of electrons, the result is covalent bond known as a pi bond, and the electrons in the pi bond are called pi electrons. The pi covalent bond electrons are less tightly held by the two atoms than the initial sigma bond that if formed between the two atoms.

Principal quantum number: The principal quantum number, n , describes the average size of an atomic orbital, where a larger number represents a larger orbital that is located on the average a greater distance away from the nucleus of an atom. In general, as electrons get farther away from a nucleus, they become more susceptible to excitation by UV-Vis light.

Sigma bond/electrons: If two overlapping atomic orbitals on adjacent atom are aligned along the same line, they can overlap in an end-to-end manner and share a pair of electrons to form a strong covalent bond known as a sigma bond. The electrons in the sigma bond are called sigma electrons.

Solvation: The interaction of solvent molecules with a solute, or dissolved species, which leads to an overall stabilization of the solute.

Tautomers: Two compounds are tautomers of each other if they are structural isomers that can be converted one into the other in a rapid equilibrium controlled process. The process generally involves a structural change in connectivity of a hydrogen atom and a pi bond within the molecule.

TD-DFT: The acronym for time-dependent density functional theory. The TD-DFT adds in a time delay to allow for calculation of molecular orbitals and associated properties after a system has been perturbed, such occurs in the excitation.

Valence: The number of electrons in the outer shell of an atom that determines how many bonds an atom can form. The valency of an atom is the number of bonds that atom generally makes.

Zeta: The zeta value is used to describe how diffuse or large an orbital can be. A double-zeta orbital is composed of two separate type orbitals, for instance, an s- and a p-type orbital. Triple zeta is composed of three types of orbitals.

ZINDO: This is the acronym for the computational model developed by Dr. Zerner, of the University of Florida, based on modification of the INDO/S routine.

30.1 Introduction

The subdisciplines within computational biology, especially those of bioinformatics, are relatively new, the word “bioinformatics” not being coined until the early to mid-1970s by Hesper and Hogeweg, 2011. With roots in computer science, information theory, biochemistry, and biology, it was and is a natural nexus of the four disciplines. However, before it could really take off, two essential factors had to become a reality, that of readily and freely available sequence and 3D structural databases and the development of powerful and relatively inexpensive computing power. Both of these are now very much a reality, having followed and/or exceeded the 18 month doubling exponential growth rate of Moore’s law (e.g., Moore, 1965; Wetterstrand, 2012; and see GenBank growth statistics at <ftp://ftp.ncbi.nih.gov/genbank/gbrel.txt>) since their development. Within this entire field, one of the most important developments has been the ability for researchers to gain biological understanding of molecules and organismal systems based solely on sequence data.

So, given the nucleotide or amino acid sequence of a biological molecule, what can be known about that molecule? Searching for small relevant patterns in sequences that may reflect some function allows for the inference of biologically relevant information. These can be cataloged motifs ascribed to catalytic activities; restriction enzyme or protease cut sites; regional physical attributes, such as secondary structure predictions, hydrophobicities; or even a sequence’s overall content and composition, as is used in some of the gene finding techniques. However, what about comparisons with other sequences? Can one molecule tell another’s story? Yes, naturally it can; inference through homology is a fundamental principle to all the biological sciences. A tremendous amount of knowledge can be gained by comparing one sequence against others. When a sequence is found to fall into a preexisting

biological gene family, function, enzymatic mechanism, evolution, and possibly even structure can all be inferred based on homology with its neighbors.

However, in order to learn anything by comparing sequences, one needs to know how to compare them. Constrained sequence portions, common patterns between them, could be used as “anchors” to create sequence alignments allowing comparison, but this brings up the alignment problem and “similarity.” It is easy to see that sequences are aligned when they have identical symbols at identical positions, but what happens when symbols are not identical and sequences are not the same length? How can anybody know when the most similar portions of sequences are aligned, when is an alignment optimal, and does optimal mean anything as far as biology is concerned?

30.2 Databases

Sequence-based methods more often than not compare similar sequences one way or another. Acquiring the similar sequences usually requires sequence databases. These began with Dayhoff et al.'s hardbound *Atlas of Protein Sequence and Structure* in the mid-1960s (1965–1979). Databases have long since outgrown a hardbound atlas. They have become huge and have evolved considerably. In the United States, the National Center for Biotechnology Information (NCBI) (<http://www.ncbi.nlm.nih.gov/>), a division of the National Library of Medicine (NLM), at the National Institute of Health (NIH), supports and distributes the GenBank nucleic acid sequence database, which began in 1982 (Bilofsky et al., 1986), and the GenPept coding sequence (CDS) translations database, as well as a host of specialized sequence databases (in particular see the non-redundant RefSeq genomic, complementary DNA (cDNA), and protein databases). The National Biomedical Research Foundation (NBRF) (<http://www-nbrf.georgetown.edu/>), an affiliate of Georgetown University Medical Center, maintains the protein identification resource (PIR) (George et al., 1986) database of polypeptide sequences. In Europe, the European Molecular Biology Laboratory (EMBL) (<http://www.embl.de/>) and the European Bioinformatics Institute (EBI) (<http://www.ebi.ac.uk/>) maintain the EMBL nucleotide sequence database, which began in 1980 (Hamm and Cameron, 1986), and the excellently annotated Swiss-Prot (Bairoch, 1991) protein sequence database (also supported by the Swiss Institute of Bioinformatics [SIB] <http://www.isb-sib.ch/>), as well as the minimally annotated translations from EMBL (TrEMBL)—those EMBL translations not yet in Swiss-Prot—protein sequence databases, in Heidelberg, Germany; Cambridge, United Kingdom; and Geneva, Switzerland. EBI, SIB, and PIR coordinate to maintain the Universal Protein Resource (UniProt) (<http://www.uniprot.org/>), which is a single, nearly non-redundant, comprehensive, fully classified, richly and accurately annotated protein sequence knowledge base, with extensive cross-references and querying interfaces, all freely accessible to the scientific community. Additional, less well-known, sequence databases include sites with the military, with private industry, and in Japan (the DNA Data Bank of Japan, DDBJ, <http://www.ddbj.nig.ac.jp/>). In most cases data are openly exchanged between the databases so that many sites “mirror” one another. This is particularly true with GenBank, EMBL, and DDBJ, organized under the auspices of the International Nucleotide Sequence Databases Collaboration (INSDC). There is never a need to look in more than one of these databases; they all contain the same organized, reliable, comprehensive, and openly available libraries of genetic sequence data.

Additionally, a myriad of specialized sequence databases exist. These include sequence pattern databases such as restriction enzyme (e.g., <http://rebase.neb.com/rebase/rebase.html>) and protease (e.g., <http://merops.sanger.ac.uk/>) cleavage sites, promoter sequences and their binding regions (e.g., <http://www.gene-regulation.com/pub/databases.html> and <http://epd.vital-it.ch/>), protein motifs (e.g., <http://prosite.expasy.org/>) and profiles (e.g., <http://pfam.janelia.org/>), and organism or system-specific databases such as the sequence portions of *A. C. elegans* database (ACeDb) (<http://www.acedb.org/>), FlyBase (the *Drosophila* database, <http://flybase.org/>), the *Saccharomyces* Genome Database (SGD) (<http://www.yeastgenome.org/>), and the Ribosomal Database Project (RDP) (<http://rdp.cme.msu.edu/>). Many sites present their data in the context of a genome map browser, for example, the University of California, Santa Cruz, bioinformatics group's genome browser (<http://genome.ucsc.edu/>),

and the Ensembl project (<http://www.ensembl.org/>), jointly hosted by the Wellcome Trust Sanger Institute and EBI. Genome map browsers attempt to tie together as many data types as possible using a physical map of a particular genome as a framework. They are a particularly effective way to explore bioinformatics and a great starting point for many analyses. This is but the “tip of the iceberg” when it comes to specialized sequence databases—visit the major sites and explore.

Two other types of databases are commonly accessed in bioinformatics: reference and 3D structure. Reference databases run the gamut from Online Mendelian Inheritance in Man (OMIM) (Pearson et al., 1994), which catalogs human genes and phenotypes, particularly those associated with human disease states, to PubMed (<http://www.ncbi.nlm.nih.gov/pubmed>), which provides free public access to more than 22 million citations from MedLine (the NLM’s citation and author abstract bibliographic database of over 5500 biomedical research and review journals), other life science journals, and online books. In nearly all cases, complete abstracts are supplied, and in many cases, links are provided to full-length text content. Other databases that could be put in this class include things like proprietary medical records databases and population studies databases. Finally, the Research Collaboratory for Structural Bioinformatics (RCSB) (<http://home.rcsb.org/>), a consortium of three institutions: the State University of New Jersey, Rutgers; the San Diego Supercomputer Center at the University of California, San Diego; and the University of Wisconsin–Madison, supports the 3D structure Protein Data Bank (PDB) (Bernstein et al., 1977). RCSB PDB is now a member of a World Wide PDB organization (<http://www.wwpdb.org/>, Berman et al., 2003), along with centers in Japan and Europe, whose mission “is to maintain a single Protein Data Bank Archive of macromolecular structural data that is freely and publicly available to the global community.” The NIH maintains “Molecules To Go” (<http://helixweb.nih.gov/cgi-bin/pdb>) as a very easy-to-use interface to PDB. Other 3D structure databases include the Nucleic Acid Databank (NDB) at Rutgers (<http://ndbserver.rutgers.edu/>) and the proprietary Cambridge small molecule crystallographic structural database (CSD) (<http://www.ccdc.cam.ac.uk/products/csd/>).

30.3 Primary Algorithms: Just the Basics

Even with the ready availability of sequence databases, the methods of computational biology can be daunting. The bases of the necessary algorithms were already developed within and before the time period when bioinformatics began. Many are discussed elsewhere in this computing handbook series. In particular, various pattern recognition algorithms have been adopted for use in bioinformatics. Computer science concepts used in bioinformatics include dynamic programming, hash tables, edit distances, hierarchical clustering, suffix-trees, hidden Markov models (HMMs), statistical methods of maximum likelihood and Bayesian inference, neural networks, and genetic algorithms. This chapter will concentrate on only those fundamental concepts upon which the entire discipline has grown, that of pair-wise and multiple-sequence alignment, database searching, and their applicability.

Many other realms of computational biology not reviewed in this chapter overlap with the basic concepts of bioinformatics discussed. These include 3D data analysis such as x-ray crystallography, nuclear magnetic spectroscopy, and high-resolution microscopy; “next-generation” DNA sequence assembly; protein and RNA microchip analysis; all the “omics”—genomics, transcriptomics, and proteomics; and, importantly, molecular phylogenetics, population biology, and biogeography. Some of these topics will be discussed elsewhere in this series; all have foundations laid in the fundamental bioinformatics principles discussed here.

30.3.1 Pair-Wise Methods

This category includes all of the programs that perform full length and best segment pair-wise sequence alignment and the numerous database similarity searching algorithms that incorporate alignment. A fundamental aspect of most of these types of programs is a variation of a standard computer science dynamic programming algorithm. The biggest problem is that a “brute force” approach just won’t work. Even without considering the introduction of gaps, the computation required to compare all possible

alignments between two sequences requires time proportional to the product of the lengths of the two sequences. Therefore, if the two sequences are approximately the same length (N), this is a N^2 problem. To include gaps, one would have to repeat the calculation $2N$ times to examine the possibility of gaps at each possible position within the sequences, now a N^{4N} problem. Waterman (1989) pointed out that using this naïve approach to align two sequences, each 300 symbols long, would require 10^{88} comparisons, more than the number of elementary particles estimated to exist in the universe and clearly impossible to solve! Part of the solution to this problem is the dynamic programming algorithm, as applied to sequence alignment.

However, first, a very simple method that provides a “gestalt” of all the various ways that two sequences can be compared will be described. This is the dot matrix or “dot plot” technique of sequence analysis, and it can often show things not seen by any other technique, as well as provide a great introduction to all of the pair-wise comparison techniques.

30.3.1.1 Dot Matrix (Plot) Methods

Dot matrix analysis is performed by plotting one sequence on a vertical axis against another on a horizontal axis, upon a grid, using a very simple approach: wherever the two match according to some specified scoring and filtering criteria, a dot is generated in the intersecting cell. So, why use dot matrix analysis? Dot matrices can point out areas of similarity between two sequences that all other methods might miss. This is because most other methods align either the overall length of two sequences or just the “best” parts of each to achieve optimal alignments. Dot matrix methods enable the user to visualize the entirety of both sequences all at the same time; all alignments can be seen, the “less than best” comparisons as well as the main one. Regions of interest can then be “zoomed in” on using more detailed procedures, if desired. The human eye and brain are still better than a computer at discerning complex visual patterns, especially when more than one pattern is being considered. This is what makes the technique such a powerful analytic tool with sequences, from short fragments through complete genes or even chromosomes, all the way to entire genomes (see, e.g., MUMmer, Delcher et al., 1999).

Even comparing a sequence to itself can be informative. A main identity diagonal is obvious; however, other features such as palindromes can also be seen. Perfect palindromes directly cross the main diagonal, and if comparing double-stranded DNA or RNA to itself, these inverted repeat regions could be indicative of potential cruciform pseudoknots at that point. Inverted repeats that are not palindromes show up as perpendicular lines to the diagonals but lie off the main diagonal. Direct internal repeats, duplicated sequence regions, will show up as parallel diagonals off of the main diagonal. Rows or columns of diagonals in any dot plot, whether the sequences are the same or different, clearly point out multiple duplications. Comparing different sequences to one another allows for the immediate recognition of insertions and deletions between the two. It is impossible to tell whether an evolutionary event that caused this sort of discrepancy between two sequences was an insertion or a deletion, and hence this phenomenon is called an “indel.” Jumps or shifts in the register of the main diagonal on a dot plot clearly points out the existence of an indel. Diagonals displaced off the center of the plot can also show the occurrence of “transposition.” In fact, dot matrix analysis is one of the few ways transpositions can be recognized in sequences.

However, the use and interpretation of dot plots is entirely up to the user—one must know how to successfully filter out extraneous background noise with appropriate parameters and what the plots mean—to identify areas between sequences that may have significant matches that no other method would ever notice. Much of sequence analysis is all about balancing signal to noise, and this is particularly important with dot plots. Often a filtered windowing approach is used—a dot will only be placed on the plot if some “stringency” is met. Within some defined window size, and when some defined criteria is met, then and only then will a dot be placed at the middle of that window. The window is then shifted over one position and the entire process is repeated. This process allows extraneous, random noise, due merely to the composition of the sequences, to be eliminated, while allowing any significant

similarity to come through. As a general guide to stringency levels, pick whatever window size is most appropriate for the analysis at hand, that is, about the size of the feature trying to be recognized, if known, and then choose a stringency within that window that produces the cleanest plot, without filtering out too much of the signal.

Dot plots can be particularly helpful in the analysis of small nucleic acid sequences, such as transfer RNAs (tRNAs). Consider the set of examples in Figure 30.1 using the phenylalanine tRNA molecule from yeast, GenBank:K01553, compared against itself. The sequence and structure are both known for this molecule, and the illustration shows how simple dot matrix procedures can quickly lead to functional and structural insights, even without complex folding algorithms, such as Zuker's (1989). Figure 30.1 illustrates many of the previous concepts and how dot plots work using this yeast tRNA molecule as an example.

30.3.1.2 Dynamic Programming

Dynamic programming is a widely applied computer science technique, often used in many disciplines whenever optimal substructure solutions can provide an optimal overall solution. The technique applied to sequence alignment will be illustrated using an overly simplified visualization method. Instead of calculating the "score matrix" on the fly, as is often taught as one proceeds through the graph, a "match matrix" will be completely filled in first, and then points will be added to those positions that produce favorable alignments next. Therefore, the solution will occur in two stages. The first begins very much like the dot matrix methods previously shown; the second is totally different. Furthermore, the process will be illustrated working through the cells, in spite of the fact that many authors prefer to work through the edges; they provide equivalent solutions. Points will be added based on a "looking-back-over-your-left-shoulder" algorithm rule where the only allowable trace-back is diagonally behind and above any particular cell. Matching sequence characters will be worth one point; nonmatching characters will be worth zero points. Subtracting one point for initially creating a gap, and subtracting another point per gap for extending a gap, will penalize the scoring scheme, unless the gaps are at the beginning or end of the sequence. In other words, end gaps will not be penalized; therefore, both sequences do not have to begin or end at the same point in the alignment. This zero penalty end-weighting scheme is the default for most alignment programs but can often be changed with program options, if desired. The gap penalty function described here, and illustrated in Table 30.1, is called an "affine," function, the standard " $y = mx + b$ " equation for a line that does not cross the X,Y origin, where "b," the Y intercept, describes how much initial penalty is imposed for creating each new gap (Gotoh, 1982): total penalty = ([length of gap] \times [gap extension penalty]) + gap opening penalty. The affine function is the usual gap penalty scheme in most pair-wise alignment programs; however, the gap "creation" or "opening" penalties and gap "extension" penalties used in the example are not typical of most programs. Furthermore, the one/zero match/mismatch scoring scheme is also not typical. These scores are used here for the sake of simplicity. Available program default values are usually quite appropriate and attempt to balance biological feasibility and sensitivity.

The example in Table 30.1 uses two random sequences that happen to fit the TATA promoter region consensus of eukaryotes and of bacteria. The most conserved bases within the consensus are capitalized by convention. The eukaryote promoter sequence is along the X-axis, and the bacterial sequence is along the Y-axis in the example. There may be more than one best path through the matrix. This time, with the relatively simple scoring function used, starting at the top and working down, and then tracing back, only one optimal alignment, with a final score of five, was discovered. This score is the highest, bottom-right value in the trace-back path graph, the sum of five matches minus no interior gaps. Notice that this would not be the optimal alignment, and the matrices would be all wrong, if end gap penalties had been imposed. Also notice that its 62.5% identity score could be improved by sliding the first "c" on the lower sequence to the left but that the gap cost scheme used prevented that from happening. The alignment score, based on the scoring scheme used, is the only number optimized by the algorithm, not any type of a similarity or identity percentage!

FIGURE 30.1 A dot plot analysis of the yeast phenylalanine tRNA. (a) Here the yeast tRNA is compared to itself with a window size of 7 and a stringency value of 5. Several direct repeats are obvious as off-diagonal alignment segments. (b) The yeast tRNA sequence compared to its reverse complement is shown next, using the same 5 out of 7 stringency setting. Now the potential for inverted repeats becomes obvious; these are the well-known stem-loop structures of the tRNA cloverleaf molecular shape. They appear as clearly delineated diagonals. These diagonals are now perpendicular to an imaginary main diagonal running opposite to the previous case, since the orientation of the second sequence was reversed. For example, examine the middle stem; the region of the molecule centered at approximately base number 38 has a clear propensity to base pair with itself without creating a loop, since it crosses that imaginary main diagonal, and then just after a small unpaired gap, another stem is formed between the region from about base number 24 through 30 with approximately 46 through 40. (c) The middle stem described earlier most likely corresponds to the bottom-most stem represented here in a “ribbon” style model of the tRNA. (Drawn from Rotkiewicz, P., iMol molecular visualization program, <http://www.pirx.com/iMol>, 2007.) This loop is the anticodon region of the yeast phenylalanine tRNA deposited in the 3D PDB under access code 1TRA. (From Sundaralingam, M. et al., *Nucleic Acids Res.*, 10, 2471, 1976.)

TABLE 30.1 Dynamic Programming (One Point for Match, Zero Points for Mismatch, Less One Point for Creating a Gap, Plus Less One Point per Gap for Extending the Gap)

a. First complete the match matrix using whatever match/mismatch scoring scheme used:

	c	T	A	T	A	t	A	a	g	g
c	1	0	0	0	0	0	0	0	0	0
g	0	0	0	0	0	0	0	0	1	1
T	0	1	0	1	0	1	0	0	0	0
A	0	0	1	0	1	0	1	1	0	0
t	0	1	0	1	0	1	0	0	0	0
A	0	0	1	0	1	0	1	1	0	0
a	0	0	1	0	1	0	1	1	0	0
T	0	1	0	1	0	1	0	0	0	0

b. Now add and subtract points based on the best path through the matrix, working diagonally, left to right and top to bottom. However, whenever a box is jumped to make the path, subtract one point for doing so and an additional point per box jumped, except at the beginning or end of the alignment, so that end gaps are not penalized. Fill in all additions and subtractions, calculate the sums and differences along the way, and keep track of all the best paths. The score matrix is shown with all calculations in the following:

	c	T	A	T	A	t	A	a	g	g
c	1	0	0	0	0	0	0	0	0	0
g	0	0 + 1 = 1	0 + 0 = 0	0 + 0 = 0	0 + 0 = 0	0 + 0 = 0	0 + 0 = 0	0 + 0 = 0	1 + 0 = 1	1 + 0 = 1
T	0	1 + 0 = 1	0 + 1 = 1	1 + 0 = 1	0 + 0 = 0	1 + 0 = 1	0 + 0 = 0	0 + 0 = 0	0 + 0 = 0	0 + 1 = 1
A	0	0 + 0 = 0	1 + 1 = 2	0 + 1 = 1	1 + 1 = 2	0 + 0 = 0	1 + 1 = 2	1 + 0 = 1	0 + 0 = 0	0 + 0 = 0
t	0	1 + 0 = 1	0 + 0 = 0	1 + 2 = 3	0 + 1 = 1	1 + 2 = 3	0 + 0 = 0	0 + 2 = 2	0 + 1 = 1	0 + 0 = 0
A	0	0 + 0 = 0	1 + 1 = 2	0 + 0 = 0	1 + 3 = 4	0 + 1 = 1	1 + 3 = 4	1 + 3 - 2 = 2	0 + 2 = 2	0 + 1 = 1
a	0	0 + 0 = 0	1 + 0 = 1	0 + 2 = 2	1 + 3 - 2 = 2	0 + 4 = 4	1 + 4 - 2 = 3	1 + 4 = 5	0 + 2 = 2	0 + 2 = 2
T	0	1 + 0 = 1	0 + 0 = 0	1 + 1 = 2	0 + 2 = 2	1 + 2 = 3	0 + 4 = 4	0 + 3 = 3	0 + 5 = 5	0 + 5 - 2 = 3

c. Clean up the score matrix next. Just the totals are shown in each cell in the matrix in the following.

All best paths are highlighted:

	c	T	A	T	A	t	A	a	g	g
c	1	0	0	0	0	0	0	0	0	0
g	0	1	0	0	0	0	0	0	1	1
T	0	1	1	1	0	1	0	0	0	1
A	0	0	2	1	2	0	2	1	0	0
t	0	1	0	3	1	3	0	2	1	0
A	0	0	2	0	4	1	4	2	2	1
a	0	0	1	2	2	4	3	5	2	2
T	0	1	0	2	2	3	4	3	5	3

(continued)

TABLE 30.1 (continued) Dynamic Programming (One Point for Match, Zero Points for Mismatch, Less One Point for Creating a Gap, Plus Less One Point per Gap for Extending the Gap)

d. Finally, convert the score matrix into a trace-back path graph by picking the bottom-most, furthest right and highest scoring coordinate. Then choose the trace-back route that created that cell, to connect the cells all the way back to the beginning using the same “over-your-left-shoulder” rule. Only the best trace-back route is now highlighted with an outline font in the trace-back matrix in the following:

	c	T	A	T	A	t	A	a	g	g
c	1	0	0	0	0	0	0	0	0	0
g	0	1	0	0	0	0	0	0	1	1
T	0	1	1	1	0	1	0	0	0	1
A	0	0	2	1	2	0	2	1	0	0
t	0	1	0	3	1	3	0	2	1	0
A	0	0	2	0	4	1	4	2	2	1
a	0	0	1	2	2	4	3	5	2	2
T	0	1	0	2	2	3	4	3	5	3

e. The final alignment is shown here. It shows the random eukaryotic promoter TATA Box sequence, with a preferred region centered between -36 and -20 of the start codon, versus the random bacterial sequence that fits the consensus from the standard *Escherichia coli* RNA polymerase promoter “Pribnow” box -10 region. (Gap cost: 1, length cost: 1, match score: 1, mismatch: 0. Alignment score: 5, percent identity: 62.5.)

```
cTATAtAagg
      ||||
      .cgTAtAaT.
```

Another way to explore the dynamic programming solution space is to reverse the entire process. This can often discover alternative alignments. To recap, and for those people that like mathematics, an optimal pair-wise alignment is defined as an arrangement of two sequences, 1 of length i and 2 of length j , such that the following holds true:

1. The number of matching symbols between 1 and 2 are maximized.
2. The number of gaps within 1 and 2 are minimized.
3. The number of mismatched symbols between 1 and 2 are minimized. Therefore, the actual solution can be represented by the following recursion:

$$S_{ij} = s_{ij} + \max \left\{ \begin{array}{l} S_{i-1j-1} \\ \max S_{i-xj-1} + w_{x-1} \\ 2 < x < i \\ \max S_{i-1j-y} + w_{y-1} \\ 2 < y < i \end{array} \right. \left. \begin{array}{l} \text{or} \\ \text{or} \end{array} \right.$$

where

S_{ij} is the score for the alignment ending at i in sequence 1 and j in sequence 2

s_{ij} is the score for aligning i with j

w_x is the score for making a x long gap in sequence 1

w_y is the score for making a y long gap in sequence 2, allowing gaps to be any length in either sequence

However, just because dynamic programming guarantees an optimal alignment, it is not necessarily the only optimal alignment. Furthermore, the optimal alignment is not necessarily the “right”

or biologically relevant alignment! Significance estimators can provide some handle on this, but always question the results of any computerized solution based on what is known about the biology of the system. The example shown in Table 30.1 illustrates the Needleman and Wunsch (1970) global solution, as generalized by Gotoh (1982). Later refinements (Smith and Waterman, 1981) demonstrated how dynamic programming could also be used to find optimal local alignments. To solve dynamic programming using local alignment (without going into all the details) algorithms, do the following:

1. Scoring functions penalize mismatches by assigning negative numbers for them. Therefore, bad paths quickly become very bad. This leads to a trace-back path matrix with many alternative paths, most of which do not extend the full length of the graph.
2. The best trace-back within the overall graph is chosen. This does not have to begin or end at the edges of the matrix—it's the best segment of alignment.

30.3.1.3 Significance

A particularly common misunderstanding in this field regards the concept of homology versus that of similarity: there is a huge difference! Similarity and identity are merely statistical parameters that describe how much two sequences, or portions of them, are alike according to some set scoring criteria. It can be normalized to ascertain statistical significance, as is done in database searching, but it's still just a number. Homology, in contrast and by definition, implies an evolutionary relationship—but more than just the fact that all life on Earth evolved from some common ancestor. One needs to be able to demonstrate an evolutionary lineage between the organisms or genes of interest to claim homology. Better yet, provide experimental evidence, structural, morphological, genetic, or fossil, that corroborates the assertion. There really is no such thing as percent homology; something is either homologous or it's not. Walter Fitch (personal communication) explains with the joke: "Homology is like pregnancy—you can't be 50% pregnant, just like something can't be 50% homologous. You either are or you are not." Do not make the mistake of calling any old sequence similarity homology. Highly significant similarity can argue for homology, but not the other way around.

So, how does one tell if a similarity, in other words, an alignment discovered by some program, means anything? Is it statistically significant, is it truly homologous, and, even more importantly, does it have anything to do with real biology? Many programs generate percent similarity scores; however, as seen earlier, these really don't mean a whole lot. Don't use percent similarities or identities to compare sequences except in the roughest way. They are not optimized or normalized in any manner. Alignment quality scores mean more but are difficult to interpret. At least they take the length of similarity, all of the necessary gaps introduced, and the matching of symbols all into account; however, quality scores are only relevant within the context of a particular comparison or search and are relative to the particular scoring matrix and gap penalties used.

A traditional way of ascertaining alignment significance relies on an old statistics trick—Monte Carlo simulations. This type of significance estimation has implicit statistical problems; however, few practical alternatives exist when just comparing two sequences, and they are fast and easy. Monte Carlo randomization options in dynamic programming alignment algorithms compare an original alignment score against the distribution of scores from alignments where one of the sequences is repeatedly shuffled, at least 100 times after the initial alignment, each with its own alignment score. A standard deviation is calculated based on that distribution. Comparing the mean of the randomized sequence alignment scores to the original score using a "Z-score," calculation can help decide significance. A "rule of thumb" is if the actual score is much more than three standard deviations above the mean of the randomized scores, the analysis may be significant; if it is much more than five, than it probably is significant; and if it is above ten, than it definitely is significant. Many Z-scores measure this distance from the mean using a simplistic Monte Carlo model assuming a normal Gaussian distribution, in spite of the fact that

“sequence space” actually follows an “extreme value distribution”; however, this simplistic approximation actually estimates significance quite well:

$$Z\text{-score} = \frac{[(\text{Actual score}) - (\text{Mean of randomized scores})]}{(\text{Standard deviation of randomized score distribution})}$$

When the two TATA sequences from the previous dynamic programming example are compared to one another using the same scoring parameters as before, but incorporating a Monte Carlo Z-score calculation, their similarity is found not at all significant. The mean score based on 100 randomizations is around 42, with a standard deviation around 8. Therefore, the Z-score is only one, so there is no significance to the match in spite of 62.5% identity! Composition can make a huge difference—the similarity seen here is merely a reflection of the relative abundance of A’s and T’s in both sequences!

The FastA (Pearson and Lipman, 1988; Pearson, 1990, 1998), Basic Local Alignment Search Tool (BLAST) (Altschul et al., 1990, 1997), Profile (Gribskov et al., 1987, 1989), and HMMer (Eddy, 1996, 1998) database search algorithms and their extensions all use a similar approach but base their statistics on the distance of the query matches from the actual, or a simulated, extreme value distribution of the rest of the, “insignificantly similar,” members of the database being searched. The statistics are well characterized for alignments without gaps. The number of ungapped alignments to be expected between any two sequences of length m and n , with a score greater than or equal to a particular score S , is generalized such that the expectation value E relates to S through the function $E = Kmne^{-\lambda S}$ (Karlin and Altschul, 1990, and see <http://www.ncbi.nlm.nih.gov/BLAST/tutorial/Altschul-1.html>). This is called the E -value for score S . In a database search, m is the length of the query and n is the size of the database in residues, so $N = mn$ is the complete search space size. K and $-\lambda$ are supplied by statistical theory, dependent on the scoring system and the background amino acid or nucleotide frequencies, calculated from actual or simulated database alignment distributions. These two parameters define the statistical significance of an E -value. Expectation values are given in scientific notation; the smaller the number, that is, the closer it is to zero, the more significant the match. In other words, the less likely a particular alignment is due to chance alone. Expectation values provide evidence for the inference of homology, or not, by showing how often to expect a particular alignment to occur as a random phenomenon in a search of that size database. Rough, conservative guidelines to Z-scores and expectation values from a typical protein search are shown in Table 30.2.

Be very careful with guidelines such as these, though, because they are entirely dependent on both the size and content of the database being searched as well as how often the search is performed! Think about it: the odds are very different for rolling dice depending on how many dice are rolled at a time, whether they are “loaded” or not and how many times they are rolled. Another very powerful empirical method of determining significance is to repeat a database search with an entry of questionable significance discovered by the previous search. If the new entry finds more significant “hits” of the same biochemical “family” of sequence as the original search did, then the entry in question is undoubtedly homologous to the original entry. That is, homology is transitive. If it finds entirely different types of sequences, then it probably is not homologous. Modular proteins with distinctly separate domains confuse issues

TABLE 30.2 Rough, Conservative Guidelines to Z-Scores and Expectation Values from a Typical Protein Search

~Z-Score	~E Value	Inference
≥ 3	≤ 0.1	Little, if any, evidence for homology, but impossible to disprove!
≈ 5	$\approx 10^{-2}$	Probably homologous, but may be due to convergent evolution
≤ 10	$\geq 10^{-3}$	Definitely homologous

considerably, but the principles remain the same and can be explained through domain swapping and other examples of non-vertical transmission. And, finally, the “gold standard” of homology is shared structural folds—if two proteins have the same structural fold, then, regardless of similarity, at least that particular domain is homologous between the two.

30.3.1.4 Scoring Matrices

This is all fine, but what about protein sequences—conservative amino acid replacements, as opposed to identities? The scoring functions discussed so far only allow match or mismatch.

Allowing similarities is certainly an additional complication that would seem important. Particular amino acids are very much alike, structurally, chemically, and genetically. How can the similarity of amino acids be taken advantage of in alignments? People have been struggling with this problem since the late 1960s.

Dayhoff (Schwartz and Dayhoff, 1979) unambiguously aligned closely related protein datasets (no more than 15% difference, and in particular cytochrome c) available at that point in time and noticed that certain residues, if they mutate at all, are prone to change into certain other residues. As it turns out, these propensities for change fell into the same categories that chemists had known for years—those same chemical and structural classes mentioned earlier—conserved through the evolutionary constraints of natural selection. Dayhoff’s empirical observation quantified these changes. Based on the multiple-sequence alignments that she created, the empirical amino acid frequencies within those alignments, and the assumption that estimated mutation rates in closely related proteins can be extrapolated to more distant relationships, she was able to empirically specify the relative probabilities at which different residues mutated into other residues through evolutionary history, as appropriate within some level of divergence between the sequences considered. This is the basis of the famous PAM (corrupted acronym of “accepted point mutation”) 250 (meaning that the matrix has been multiplied by itself 250 times) log-odds matrix.

Since Dayhoff’s time, other biomathematicians (e.g., Henikoff and Henikoff’s [1992] BLOSUM [BLOcks SUBstitution Matrix] series of matrices and the Gonnet et al. matrix [1992]) have created matrices regarded more accurate than Dayhoff’s original, but the concept remains the same. Plus, the PAM series remains a classic as historically the most widely used. Confusingly these matrices are known variously as symbol comparison, log-odds, substitution, or scoring tables or matrices, but they are fundamental to all sequence comparison techniques. The default amino acid scoring matrix for most protein similarity comparison programs is now the BLOSUM62 table (Henikoff and Henikoff, 1992). The “62” refers to the minimum level of identity within the ungapped sequence blocks that went into the creation of the matrix. Lower BLOSUM numbers are more appropriate for more divergent datasets. The BLOSUM62 matrix is shown in Table 30.3.

30.3.1.5 Database Searching

Database searching programs use elements of all the concepts discussed earlier; however, classic dynamic programming techniques are far too slow when used against an entire sequence database. Therefore, the algorithms use tricks to make things happen faster. These tricks fall into two main categories, that of hashing and that of approximation. Hashing is the process of breaking a sequence into small “words” or “k-tuples” of a set size and creating a “lookup,” “hash” table with those words keyed to numbers. Then when any of the words match part of an entry in the database, that match is saved. In general, hashing reduces the complexity of the search problem from N^2 for dynamic programming to N , the length of all the sequences in the database.

Approximation techniques are collectively known as “heuristics.” Webster’s (1973) defines heuristic as “providing aid or direction in the solution of a problem, but otherwise unjustified or incapable of justification.” In database searching techniques, the heuristic usually restricts the necessary search space by calculating some sort of a statistic that allows the program to decide whether further scrutiny of a particular match should be pursued. This statistic may miss things depending on the

TABLE 30.3 BLOSUM62 Amino Acid Scoring Matrix

	A	B	C	D	E	F	G	H	I	K	L	M	N	P	Q	R	S	T	V	W	X	Y	Z

Values whose magnitude is ≥ 4 are drawn in shadowed characters to make them easier to recognize.

parameters set—that’s what makes it heuristic. The exact implementation varies between the different programs, but the basic ideas follow in all of them.

Two predominant versions exist: the Fast and BLAST programs. Both return local alignments. Both are not a single program but rather a family of programs with implementations designed to compare a sequence to a database every which way imaginable: a DNA sequence against a DNA database (not recommended unless forced to do so because of dealing with a nontranslated genomic region), a translated (where the translation is done “on-the-fly” in all six frames) version of a DNA sequence against a translated (“on-the-fly”) version of a DNA database (not available in Fast), a translated (“on-the-fly”) version of a DNA sequence against a protein database, a protein sequence against a translated (“on-the-fly”) version of a DNA database, or a protein sequence against a protein database. Many implementations allow the recognition of frame shifts in translated comparisons. In more detail:

30.3.1.5.1 *FastA and Family* (Pearson and Lipman, 1988; Pearson, 1990, 1998)

1. Works well for DNA against DNA searches (within limits of possible sensitivity)
2. Can find only one gapped region of similarity per search
3. Relatively slow, should often be run in the background
4. Does not require specially prepared, preformatted databases

The Fast programs are older than BLAST. They were the first widely used, powerful sequence database searching programs available. Pearson continually refines the algorithms such that they remain a viable alternative to BLAST, especially if one is restricted to searching DNA against DNA without translation. The Fast programs also may be more sensitive than BLAST in situations where BLAST finds no significant alignments.

30.3.1.5.1.1 Algorithm The Fast programs build words of a set k -tuple size, by default two for peptides. The program then identifies all exact word matches between the sequence and the database members. Scores are assigned to each continuous, ungapped, diagonal by adding all of the exact match BLOSUM values. The 10 highest scoring diagonals for each query–database pair are then rescored using BLOSUM similarities as well as identities, and ends are trimmed to maximize the score. The best of each of these is called the *Init1* score.

Next the program “looks” around to see if nearby off-diagonal *Init1* alignments can be combined by incorporating gaps. If so, a new score, *Initn*, is calculated by summing up all the contributing *Init1* scores, penalizing gaps with a penalty for each. The program then constructs an optimal local alignment for all *Initn* pairs with scores better than some set threshold using a variation of dynamic programming “in a band” (Pearson and Lipman, 1988). A sixteen residue band centered at the highest *Init1* region is used by default with peptides. The score generated from this step is called the *opt* score.

Then Fast uses a simple linear regression against the natural log of the search set sequence length to calculate a normalized z -score for the sequence pair (Pearson, 1998). It compares the distribution of these z -scores to the actual extreme value distribution of the search. Using this distribution, the program estimates the number of sequences that would be expected to have, purely by chance, a z -score greater than or equal to the z -score obtained in the search. This is reported as the expectation value. Unfortunately, the z -score used in the Fast programs and the Monte Carlo style Z -score discussed previously are quite different and cannot be directly compared; however, the expectation values between Fast and other programs are equivalent. Finally, the program uses full Smith–Waterman local dynamic programming, not “restricted to a band,” to produce its final alignments.

30.3.1.5.2 *BLAST: Basic Local Alignment Search Tool* (Altschul et al., 1990, 1997)

1. Normally not a good idea to use for DNA against DNA searches (not optimized)
2. Prefilters repeat and “low complexity” sequence regions by default
3. Can find more than one region of gapped similarity
4. Very fast heuristic and parallel implementation
5. Restricted to precompiled, specially formatted databases

30.3.1.5.2.1 Algorithm After BLAST has sorted its lookup table, it tries to find all double-word hits along the same diagonal within some specified distance using a discrete finite automaton (DFA) (NCBI). Word hits of size W do not have to be identical; rather, they have to be better than some threshold value T . To identify double-word hits, the DFA scans through all strings of words (typically $W = 3$ for peptides) that score at least T (usually 11 for peptides). Each double-word hit that passes this step then triggers a process of ungapped extension in both directions, such that each diagonal is extended as far as it can, until the running score starts to drop below a predefined value X within a certain range A . The result of this pass is called a high-scoring segment pair (HSP). HSPs then, are those stretches of sequence pairs that cannot be further improved by extension or trimming. Those HSPs that pass this step with a score better than S then begin a gapped extension step utilizing dynamic programming. Those gapped alignments with expectation values better than the user specified cutoff are reported. The extreme value distribution of BLAST expectation values is pre-computed against each precompiled database available to the program—this is one area that speeds up the algorithm considerably.

30.3.1.5.3 Database Searching Conclusions

In review, both the Fast and BLAST family of programs calculate their Expectation “ E ” values on a more realistic “extreme value distribution,” based on either real or simulated “not significantly similar” database alignments, than do most Monte Carlo style Z-scores, since Monte Carlo techniques are often based on the normal distribution, although they do parallel Monte Carlo style Z-scores fairly well. Regardless, the higher an E -value, the more probable that the observed match is due to chance in a search of that size database, and the lower its Z-score will be. Conversely, the smaller an E -value, that is, the closer it is to zero, the more significant it is, and the higher its Z-score will be. The E -value is the number that really matters. A value of 0.01 is usually a decent starting point for significance in most typical searches.

Furthermore, all database searching, regardless of the algorithm, is far more sensitive at the amino acid level than at the DNA level. This is because proteins have twenty match criteria, the 20 naturally occurring amino acids, versus DNA’s four nucleotides, and those four DNA nucleotides can only be identical or not, not similar, to each other. Furthermore, many DNA base changes (especially third position changes) do not change the encoded protein at all because of the redundancy of the genetic code. All of these factors drastically increase the “noise” level of a DNA against DNA search and give protein searches a much greater “look-back” time, typically five to ten times longer back in evolutionary history. Therefore, whenever dealing with coding sequence, it is always prudent to search at the protein level. Furthermore, even without a protein sequence query, one can use programs that take a DNA query, translate it in all six frames, and then compare protein databases.

30.3.2 Multiple-Sequence Analysis

The power and sensitivity of sequence-based computational methods dramatically increase with the addition of more data. More data yield stronger analyses—if done carefully! Otherwise, it can confound the issue. The patterns of conservation become ever clearer by comparing the conserved portions of sequences among a larger and larger dataset. Those areas most resistant to change are most important to the molecule. The basic assumption is that those portions of sequence of crucial structural and functional value are most constrained against evolutionary change. They will not tolerate many mutations. Not that mutation doesn’t occur in these regions, it is just that most mutation in the area is lethal, so it is never seen. Other areas of sequence are able to drift more readily, being less subject to this evolutionary pressure.

Therefore, sequences end up a mosaic of quickly and slowly changing regions over evolutionary time.

However, a big problem exists. As we've seen, dynamic programming reduces the pair-wise alignment problem's complexity down to order N^2 —the solution of a 2D matrix, so the complexity of the solution is equal to the length of the longest sequence squared. But how are more than just two sequences at a time aligned? It becomes much harder. Sequences can be manually aligned with an editor, but some type of an automated solution is desirable, at least as a starting point to manual alignment. Solving the dynamic programming algorithm for more than just two sequences rapidly becomes intractable. Dynamic programming's complexity, and hence its computational requirements, increases exponentially with the number of sequences in the dataset being compared (complexity = [sequence length]^{number of sequences}), an N -dimensional matrix. So a three-sequence dynamic programming alignment would require the solution of a three-axis matrix, with complexity equal to the length of the longest sequence cubed, and so forth. A 3D matrix can at least be drawn, but more dimensions than that quickly become impossible to even visualize!

Several different heuristics have been employed over the years to simplify the complexity of the problem. One classic program, multiple sequence alignment (MSA) (Gupta et al., 1995), attempts to globally solve the N -dimensional matrix recursion using a bounding box trick. However, the algorithm's complexity precludes its use in most situations, except with very small datasets. Another way to globally solve the algorithm, and yet reduce its complexity, is to restrict the search space to only the most conserved "local" portions of all the sequences involved. This approach is used by the program pattern-induced multi-sequence alignment (PIMA) (Smith and Smith, 1992). Neither program ever really caught on though, as both require relatively small datasets.

30.3.2.1 Heuristic Solutions: How the Algorithms Work

Most multiple-sequence alignment implementations do not attempt to globally solve the algorithm; they modify dynamic programming by establishing a pair-wise order in which to build the alignment. This heuristic modification is known as pair-wise, progressive dynamic programming. Originally attributed to Feng and Doolittle (1987), this variation of the dynamic programming algorithm creates a global alignment but restricts its search space to a local neighborhood of the full length of only two sequences, at any one time. Consider a dataset of sequences. First all are compared to each other, pair-wise, using some quick variation of standard dynamic programming. This establishes an order for the dataset, most to least similar, known as the "guide tree." The algorithm then takes the top two most similar sequences and aligns them. It creates a quasi-consensus of those two and aligns that to the third sequence. Next it creates the same sort of quasi-consensus of the first three sequences and aligns that to the fourth most similar. Subgroups are clustered together similarly. The way the various implementations make and use this "consensus" is one of the biggest differences between them. This process, all using standard, pair-wise dynamic programming, continues until it has worked its way through all of the sequences and/or sets of clusters, to complete the full multiple-sequence alignment. The pair-wise, progressive solution is implemented in several programs. Perhaps the most popular is ClustalW of Thompson et al. (1994) and its graphical user interface ClustalX (Thompson et al., 1997). This program achieved the first major advances over the basic Feng and Doolittle algorithm by incorporating variable sequence weighting, dynamically varying gap penalties and substitution matrices, and a neighbor-joining (NJ, Saitou and Nei, 1987) guide tree. Several more variations on the theme have come along since ClustalW. Tree-based consistency objective function for alignment evaluation (T-Coffee) (Notredame et al., 2000) was one of the first and has gained much favor. Its biggest innovation is the use of a preprocessed, weighted library of all the pair-wise global alignments between the sequences in a dataset plus the ten best local alignments associated with each pair of sequences. This helps build both the NJ guide tree and the progressive alignment. Furthermore, the library is used to assure consistency and help prevent errors, by allowing "forward thinking" to see whether the overall alignment will be better one way or another after particular segments are aligned one way or another. Notredame (2006) uses the analogy of school schedules—everybody, students, teachers, and administrators, with some folk being more important than others, that is, the weighting factor, puts the schedule they desire in a big pile, that is, T-Coffee's library, and

the trick is to best fit all the schedules to one academic calendar, so that everybody is happiest, that is, T-Coffee's final multiple-sequence alignment. The M-Coffee version (Wallace et al., 2006) can even tie together multiple methods as external modules, making consistency libraries from the results of each. T-Coffee is one of the most accurate multiple-sequence alignment methods available because of this consistency-based rationale, but it is not the fastest.

Muscle (Edgar, 2004; Edgar and Batzoglou, 2006) is another multiple-sequence alignment program that came after ClustalW. It is incredibly fast, yet nearly as accurate as T-Coffee with protein data. Muscle is an iterative method that uses weighted log-expectation profile scoring along with a slew of optimizations. It proceeds in three stages—draft progressive using k -tuple counting, improved progressive using a revised tree from the previous iteration, and refinement by sequential deletion of each tree edge with subsequent profile realignment. Two other programs that claim speed and accuracy beyond standard progressive multiple-sequence alignment are partial order alignment (POA) and profile consistency multiple-sequence alignment (PCMA). POA (Lee et al., 2002) uses graph theory to represent an alignment as a partial order graph and allows for a new edit operator, homologous recombination. PCMA (Pei et al., 2003) combines Clustal-style progressive alignment of very similar sequences with a T-Coffee-like strategy of profile–profile consistency comparison. Perhaps the most accurate multiple-sequence alignment program is ProbCons (Do et al., 2005). It uses HMM techniques and posterior probability matrices that compare random pair-wise alignments to expected pair-wise alignments. Probability consistency transformation is used to reestimate the scores, and a guide tree is then constructed, which is used to compute the alignment, which is then iteratively refined.

The MAFFT (Kato et al., 2002, 2005) multiple-sequence alignment suite is also quite powerful. It can be run many different ways—a couple of progressive, approximate modes, using a fast Fourier transform (FFT); a couple of iteratively refined methods that add in weighted-sum-of-pairs (WSP) scoring; and several iterative methods that use the WSP scoring combined with a T-Coffee-like consistency-based scoring scheme. Speed and accuracy are inversely proportional for these from fast and rough, to slow and accurate, respectively. MAFFT's FFT provides a huge speedup over most previous methods. Homologous regions are quickly identified by converting amino acid residues to vectors of volume and polarity, thus changing a 20-character alphabet to six, rather than by using an amino acid similarity matrix. Similarly, nucleotide bases are converted to vectors of imaginary and complex numbers. The FFT trick then reduces the complexity of the subsequent comparison to order $N \log N$. FFT identifies potential similarities though, without localizing them; a sliding window step using the BLOSUM62 matrix is used for this. Then MAFFT constructs a distance matrix, and hence a progressive guide tree, on the number of shared six-tuples from this Fourier transform, rather than on a ranking based on full-length, pair-wise sequence similarity. The user can specify how many times a new guide tree is subsequently recalculated from a previous alignment as many times as desired; the alignment is reconstructed using the Needleman–Wunsch algorithm for each pass.

The iterative refinement modes build on this foundation by adding steps that adjust the alignment back and forth until there is either solely no improvement in the WSP score (or the number of cycles has reached a set limit), or it adds both this WSP score and a T-Coffee-like consistency score between pair-wise and multiple alignments to the refinement procedure. Differences in the iterative methods that combine WSP and consistency scores are based on how the pair-wise scores are calculated, globally, locally with affine gap costs, or locally with generalized affine gap costs. Knowing which to choose, especially when dealing with sequences too diverged for the fast methods to work well, depends on the nature of the data. MAFFT's algorithm page (<http://mafft.cbrc.jp/alignment/software/algorithms/algorithms.html>) explains where and when each mode is most appropriate. If sequences have full-length, but low, similarity, then the global option is appropriate (ginsi); if sequences have one similar domain among a bunch of “junk,” then the local affine gap option works best (linsi); whereas if sequence data are composed of multiple, yet alignable domains, then the local generalized affine gap scheme is appropriate (einsi).

MAFFT's capability to handle large datasets and its speed is similar to or greater than Muscle's in its faster modes; its results and capabilities are similar to T-Coffee in its slow, iteratively refined, optimized modes.

30.3.2.2 Coding DNA Issues

As discussed in the database searching section, all alignment algorithms, be they pair-wise, multiple, or database similarity searching, are far more sensitive at the amino acid level than at the DNA level. The signal-to-noise ratio is just so much better with amino acids, for all the reasons previously described. Therefore, database searching and sequence alignment both should always be done at the protein level, unless forced otherwise by dealing with noncoding DNA, or if the sequences are so very similar as to not cause any problems. Therefore, usually, if dealing with coding sequences, translate DNA to its protein counterpart, before performing multiple-sequence alignment. Even if dealing with very similar coding sequences, where the DNA can be directly aligned, it is often best to align the DNA along with its corresponding proteins. In addition to the much more reliable alignment, this also insures that alignment gaps are not placed within codons, which would not make sense biologically. DNA indels in coding regions need to be in multiples of three to avoid frameshift errors. Phylogenetic analysis can then be performed on the DNA rather than on the proteins, if desired. This is especially important when dealing with datasets that are quite similar, since the proteins may not reflect differences hidden in the DNA. Furthermore, many people prefer to run phylogenetic analyses on DNA rather than protein regardless of how similar they are—the multiple substitution models have a long and well-accepted history, and yet are far simpler. However, the more diverged a dataset becomes, the more random third and eventually first codon positions become, which introduces noise (error) into the analysis. Therefore, often third positions and sometimes first positions are masked out of datasets for phylogenetic analysis. Just like in most of computational molecular biology, one is always balancing signal against noise. Too much noise or too little signal, both degrade the analysis to the point of nonsense.

Several scripts and programs, as well as some web servers, can perform this sort of codon-based alignment, but they can be a bit tricky to run. Examples include mrtrans (Pearson, 1990) (also available in EMBOSS [Rice et al., 2000] as `tranalign` and in BioPerl [Stajich et al., 2002] as `aa_to_dna_aln`), transAlign (Bininda-Emonds, 2005), RevTrans (Wernersson and Pedersen, 2003), PAL2NAL (Suyama et al., 2006), and TranslatorX (Abascal et al., 2010). Some multiple-sequence alignment editors, such as SeaView (Galtier et al., 1996), can also help with this process.

Multiple-sequence alignment is much more difficult if forced to align nucleotides because a sequence does not code for a protein. Automated methods may be able to help as a starting point, but they are certainly not guaranteed to come up with a biologically correct alignment. The resulting alignment will probably have to be extensively edited, if it works at all. Success will largely depend on the similarity of the nucleotide dataset.

30.3.2.3 Reliability?

One liability of most global, progressive, pair-wise methods is they are entirely dependent on the order in which the sequences are aligned. Fortunately, ordering them from most similar to least similar makes biological sense and works well. However, most of the techniques are very sensitive to the substitution matrix and gap penalties specified. Some programs allow “fine-tuning” areas of an alignment by realignment with different scoring matrices and/or gap penalties; this can be extremely helpful. Regardless, any automated multiple-sequence alignment program should be thought of only as a tool for offering a starting alignment that can be improved upon, not the “end-all-to-meet-all” solution, guaranteed to provide the “one-true” answer. Although, in this post-genomics era, especially when dealing with giga-bases of data, it does make sense to start with the “best” solution possible. This is the premise of using a very accurate multiple-sequence alignment package, such as T-Coffee (Notredame et al., 2000), ProbCons (Do et al., 2005), POA (Lee et al., 2002), PCMA (Pei et al., 2003), or MAFFT (Katoh et al., 2002, 2005).

Whichever program used to create an alignment, always use comparative approaches to help assure its reliability. After the program has offered its best guess, try to improve it further. Think about it—a sequence alignment is a statement of positional homology—it is a hypothesis of evolutionary history. It establishes the explicit homologous correspondence of each individual sequence position,

each column in the alignment. Therefore, insure that it is as good as it can be. Be sure that it makes biological sense—align things that make sense to align! Beware of comparing “apples and oranges.” Be particularly suspect of sequence datasets found through text-based database searches such as NCBI’s Entrez (Schuler et al., 1996) or the EMBL/EBI sequence retrieval system (SRS) (Etzold and Argos, 1993). For example, don’t try to align receptors and/or activators with their namesake proteins or with each other. Be wary of trying to align genomic sequences with cDNA when working with DNA; the introns will create big problems, unless using software specifically designed for the task. Similarly, aligning mature and precursor proteins, or alternate splicing forms, from the same organism and locus, doesn’t make evolutionary sense, as one is not evolved from the other, rather one is the other. Watch for redundant sequences; there are lots of them in the databases. Some programs can automatically cull them from a dataset. If creating alignments for phylogenetic inference, make either paralogous comparisons (evolution via gene duplication) to ascertain gene phylogenies within one organism or orthologous (within one ancestral loci) comparisons to ascertain gene phylogenies between organisms (which should imply organismal phylogenies). Try not to mix the two without complete data representation. Otherwise, confusion can mislead interpretation, especially if the sequences’ nomenclature is inconsistent. These are all easy mistakes to make; try to avoid them.

Devote considerable time and energy toward developing the best alignment possible. Use biological understanding to help guide judgment. Look for conserved functional, enzymatic, regulatory, and structural elements and motifs—they should all line up. Searches of the *PROSITE database of protein families and domains* (Bairoch, 1992) for cataloged structural, regulatory, and enzymatic consensus patterns or “signatures” can help, as can searches of the Pfam protein family database of HMM profiles (Eddy, 1996, 1998), and *de novo* motif discovery tools like MEME (Bailey and Elkan, 1994) and MotifSearch (Bailey and Gribskov, 1998). Look for columns of strongly conserved residues such as tryptophans, cysteines, and histidines; important structural amino acids such as prolines, tyrosines, and phenylalanines; and conserved isoleucine, leucine, and valine substitutions. The conservation of covarying sites in ribosomal and other structural RNA alignments can be very helpful in refining RNA alignments. That is, as one base in a stem structure changes, the corresponding Watson–Crick paired base will change in a corresponding manner. This principle has guided the assembly of ribosomal RNA (rRNA) structural alignments at the Ribosomal Database Project at Michigan State University (RDP, Cole et al., 2007), at the University of Gent, Belgium European Ribosomal RNA database (Wuyts et al., 2004), and at the German SILVA database system (Pruesse et al., 2007).

Editing alignments to insure that all columns are truly homologous should be encouraged, not discouraged. Dedicated sequence alignment editing software such as the genetic data environment (GDE) (Smith et al., 1994), Jalview (Clamp et al., 2004), Se-AL (Rambaut, 1996), and SeaView (Galtier et al., 1996) are great for this, but any editor will do, as long as the sequences end up properly formatted afterward. Structural alignment is the “gold standard,” but the luxury of having homologous, experimentally solved structures is often not available. Even with a structural alignment, there’ll often be questionable regions of sequence data within it.

These highly saturated regions have the property known as “homoplasy.” This is a region of a sequence alignment where so many multiple substitutions have occurred at homologous sites that it is impossible to know if those sites are properly aligned and, thus, impossible to ascertain relationships based on those sites. The primary assumption of all phylogenetic inference algorithms is most violated in these regions, and this phenomenon increasingly confounds evolutionary reconstruction as divergence between the members of a dataset increases.

Therefore, only analyze those sequences and those portions of an alignment that assuredly do align. This often means trimming down or somehow excluding those homoplastic regions, some of the internal gaps, and, minimally, the alignment’s extreme amino- and carboxy-termini (5’ and 3’ in DNA), which seldom align well. Sequence editors such as SeaView can do this. Those portions excluded will not be used in subsequent analyses. These decisions are somewhat subjective by nature, experience helps,

and some software, such as Gblocks (Talavera and Castresana, 2007), ASaturA (Van de Peer et al., 2002), and T-Coffee (Notredame et al., 2000), has the ability to evaluate the quality of particular regions of an alignment. If, after all else, some region, or an entire sequence, just can't be aligned, if there is any doubt, then do not use it. Cutting an entire sequence out of an alignment may leave columns of gaps across the entire alignment that will need to be removed. Most alignment editors have a function for closing these common gaps. The validity of all subsequent analyses is absolutely dependent upon the quality and accuracy of the input multiple-sequence alignment. Remember the old adage "garbage in—garbage out!" Some general guidelines to remember (Olsen, 1992) include the following:

- If the homology of a region is in doubt, then throw it out
- Avoid the most diverged parts of molecules; they are the greatest source of systematic error
- Do not include sequences that are more diverged than necessary for the analysis at hand

Biocomputing is always a delicate balance—signal against noise—and sometimes it can be quite the balancing act!

30.3.2.4 Applicability

So what's the big deal about multiple-sequence alignment; why would anyone want to bother?

Multiple-sequence alignments can be

- Extremely useful in the development of PCR primers and hybridization probes
- Great for producing annotated, publication quality, graphics, and illustrations
- Required for building HMM profiles for remote homology similarity searching and alignment
- Invaluable for structural and functional analyses via homology inference
- Absolutely necessary for molecular evolutionary phylogenetic inference

Multiple-sequence alignments can be very helpful for designing phylogenetic-specific probes and primers by allowing for the clear visualization and localization of the most conserved and the most variable regions within an alignment. Depending on the dataset being analyzed, any level of phylogenetic specificity can be achieved. Areas of high variability in the overall dataset that correspond to areas of high conservation in phylogenetic category subset datasets can differentiate between universal and phylo-specific potential probe sequences. Any of several primer discovery programs, such as MIT's Primer3 (Rozen and Skaletsky, 2000) or the commercial Oligo program (National Biosciences, Inc.), can be used to find and test the best primers within the target areas localized by this method.

Graphics prepared from multiple-sequence alignments can dramatically illustrate functional and structural conservation as it relates to sequence similarity. These can take many forms of all or portions of an alignment—shaded or colored boxes or letters for each residue or base (e.g., BoxShade [Hofmann and Baron] and PrettyPlot in EMBOSS [Rice et al., 2000]), cartoon representations (e.g., WebLogos [Schneider and Stephens, 1990]), running line graphs of overall similarity (as displayed by ClustalX [Thompson et al., 1997] and others), overlays of attributes, various consensus representations, etc.—all can be printed with high-resolution equipment, usually in color or gray tones. These can make a big difference in a poster or manuscript presentation.

Profiles are position-specific scoring matrices (PSSM) that describe a sequence alignment or a portion of an alignment. These powerful tools are created from an existing alignment of similar sequences and can be used to perform the most sensitive database remote similarity search possible. Another advantage of profile techniques is they can be used to build ever-larger multiple-sequence alignments much faster and more accurately than any of the progressive multiple-sequence alignment methods. This ability to easily create larger and larger multiple-sequence alignments is incredibly powerful and much faster than starting all over each time another sequence needs to be added to an alignment. Originally described by Gribskov et al. (1987, 1989), and then automated by NCBI's PSI-BLAST (Altschul et al., 1997), later refinements have added more statistical rigor (see, e.g., Eddy's HMM HMMer profiles and

Pfam profile database [1996, 1998] and Bailey and Elkan's Expectation Maximization [1994]). Briefly described profiles upweight conserved regions such that the more highly conserved a residue is, the more important it becomes, and, in those profiles that allow gaps, gap insertions are penalized more heavily in conserved areas of the alignment than in variable regions.

Conserved sequence really does matter. In addition to the conservation of primary sequence, structure and function are also conserved in these crucial regions. In fact, recognizable structural conservation between true homologues extends way beyond statistically significant sequence similarity. The serine protease superfamily contains a good example. *Streptomyces griseus* protease A shows remarkably little sequence similarity when compared to the rest of the superfamily (expectation values $10^{1.8}$ in a typical protein database search), yet it clearly is a serine protease as its 3D structure can be superimposed over most other members of the family with a root mean square deviation (RMSD) of less than 3 Å (Pearson, W.R., personal communication). These comparative principles are the premise of "homology modeling," which works remarkably well. One of the best applications of these principles is PredictProtein, which uses weighted dynamic programming multiple-sequence alignment methods (MaxHom, Sander and Schneider, 1991), along with neural net technology, to predict protein secondary structure by the profile network method (PHD, Rost and Sander, 1993, 1994) at an expected 70.2% average accuracy for the three states helix, strand, and loop. Furthermore, even 3D modeling without crystal coordinates is possible, if a sequence is similar enough to an experimentally solved structure. In fact, the SWISS-MODEL (Guex and Peitsch, 1997; Guex et al., 1999) system at the ExPASy server in Switzerland, supported by SIB and GlaxoSmithKline, automates the homology modeling process, given similar enough sequence data to at least one solved structure, though as in most cases, a multiple-sequence alignment of solved structure sequences makes the theoretical model even more probable.

Finally, multiple-sequence alignments are required for phylogenetic inference. Many different computational methods can estimate the most reasonable evolutionary tree for a sequence alignment based on the assertion of homologous positions within that alignment. Computational tools that incorporate these methods include Phylogenetic Analysis Using Parsimony (PAUP*) (and other methods) (Swofford, 1989–2012), PHYLogeny Inference Package (PHYLIP) (Felsenstein, 1980–2012), MrBayes (Ronquist and Huelsenbeck, 2003), GARLI (Zwickl, 2006), and RAXML (Stamatakis, 2006). This is a huge and complicated field of study and will not be discussed further here. However, always remember that regardless of the algorithm used—any form of parsimony, all of the distance methods, all maximum likelihood techniques, and even all types of Bayesian phylogenetic inference—all make the absolute validity of the input alignment matrix their first and most critical assumption (but see, e.g., Lunter et al., 2005). The famous Darwinian evolutionist Theodosius Dobzhansky summarized the importance of phylogenetic analyses in 1973, provided as an inscription on the inner cover of the classic organic evolution text *Evolution*: "Nothing in biology makes sense except in the light of evolution" (Dobzhansky et al., 1977). Evolution provides the single, unifying, cohesive force to explain all life.

30.4 Complications

Sequence data format is a huge problem in bioinformatics. The major databases all have their own distinct format, plus many of the different programs and packages require their own. Clustal (Higgins et al., 1992) has a specific format associated with it. The Fast package (Pearson and Lipman, 1988) uses a very basic sequence format that many programs recognize. NCBI uses a library standard called Abstract Syntax Notation One (ASN.1), plus it provides GenBank flat file format for all sequence data. PAUP* (Swofford, 1989–2012), MrBayes (Ronquist and Huelsenbeck, 2003), and many other phylogenetic analysis packages have a required format called the NEXUS file (Maddison et al., 1997). Even PHYLIP (Felsenstein, 1980–2012) has its own unique data format. Standards have been argued over for years, such as using XML for everything, but until everybody agrees, which is not likely to happen, it just won't happen. Fortunately several programs are available to convert formats back and forth between

the required standards; however, it can all get quite confusing. BioPerl's SeqIO system (Stajich et al., 2002) and ReadSeq (Gilbert, 1990–2008) are two very helpful tools for format conversion. T-Coffee (Notredame et al., 2000) comes with one built in, and the SeaView (Galtier et al., 1996) editor recognizes NEXUS, Clustal, FastA, PHYLIP, and MASE format. Alignment gaps are still another problem. Different program suites may use different symbols to represent them. Most programs use hyphens “-” but some do not. Furthermore, not all gaps in sequences should be interpreted as deletions. Interior gaps are probably okay to represent this way, as regardless of whether a deletion, insertion, or a duplication event created the gap, logically they are the same. These are the indels mentioned previously. However, end gaps should not be represented as indels, because a lack of information before or beyond the length of any given sequence may not be due to a deletion or insertion event. It may have nothing to do with the particular stretch being analyzed at all. It just may not have been sequenced! These gaps are just placeholders for the sequence. Therefore, it is safest to manually edit an alignment to change leading and trailing gap symbols to “x”s, which mean “unknown amino acid,” or “n”s, which mean “unknown base,” or “?”s, which is supported by many programs, but not all, and means “unknown residue or indel.” This will assure that incorrect assumptions are not made, though most phylogenetic inference algorithms treat indels and missing data equivalently by default.

30.5 Conclusions

The comparative method is a cornerstone of the biological sciences. Multiple-sequence alignment and database searching are the comparative method on a molecular scale and are a vital prerequisite to some of the most powerful computational biology techniques available. Understanding something about the algorithms and the program parameters of each is the only way to rationally know what is appropriate. Knowing and staying well within the limitations of any particular method will avert much frustration. One point that needs to be emphasized is sequence analysis techniques generally have appropriate default parameters. This will usually work just fine, but it is a good idea to think about what these default values imply and adjust them accordingly, especially if the results seem inappropriate after a first pass with the default parameters intact.

Furthermore, the dramatic importance of a multiple-sequence alignment cannot be understated. All subsequent analyses are absolutely dependent upon it, especially phylogenetic inference. Also, if building multiple-sequence alignments for phylogenetic inference, do not base an organism's phylogeny on just one gene. Many complicating factors can produce weird phylogenies: bad alignments, insufficient data, abjectly incorrect models, saturated positions (homoplasy), compositional biases, and/or horizontal gene transfer. Therefore, use several genes—the Ribosomal Database Project (Cole et al., 2007) provides a good, largely accepted alignment and phylogenetic framework with which other phylogenies can be compared. Anytime the orthologous phylogenies of organisms based on two different genes do not agree, there is either some type of problem with the analysis, or lateral gene transfer has occurred. Paralogous gene phylogenies are another story altogether and should be based, if at all possible, on sequences all from the same organism.

Gunnar von Heijne (1987) in his quite readable but very dated treatise, *Sequence Analysis in Molecular Biology; Treasure Trove or Trivial Pursuit*, provides an appropriate conclusion:

Think about what you're doing; use your knowledge of the molecular system involved to guide both your interpretation of results and your direction of inquiry; use as much information as possible; and do not blindly accept everything the computer offers you.

He continues:

... if any lesson is to be drawn ... it surely is that to be able to make a useful contribution one must first and foremost be a biologist, and only second a theoretician We have to develop better algorithms, we have to find ways to cope with the massive amounts of data, and above all we have to become better biologists. But that's all it takes.

Key Terms

Affine: An affine function is a linear function, described by the algebraic formula $y = mx + b$.

Expectation value (E-value): The likelihood that a particular sequence alignment is due to chance. The value is dependent on sequence and database composition and size and on how often a researcher performs database searches. Most modern sequence database similarity programs such as BLAST and FastA provide this statistic based on the extreme value distribution. The closer the value is to zero, the more significant the match.

Exon: A defined stretch of DNA within a gene that is transcribed into a corresponding complimentary message RNA molecule and that is maintained after RNA processing into mature mRNA, such that only those portions not excised follow the relevant genetic code to be translated into corresponding amino acids.

Gap penalties: In the context of affine gap penalties, the creation or opening penalty is how many points a dynamic programming algorithm is penalized for imposing a gap in an alignment (the b in the previous equation).

The extension or lengthening penalty describes how many additional points the algorithm is penalized for each additional gap added to the first one after it is introduced (the x in the previous equation).

Gene: A defined stretch of DNA nucleotides that encodes either a protein, with or without introns and exons, or a structural or regulatory RNA (e.g., tRNAs, rRNAs, microRNAs, siRNAs, and snRNAs), which is inherited from one generation to the next.

Global alignment: As opposed to local alignment, which is the alignment of only the best regions within sequences, global alignment is the alignment of the full length of a sequence set and generally applies to the multiple-sequence alignment problem. However, it should be realized that global alignment can be restricted to subsequences within sequences, the distinction being that local alignment “picks” the best regions, whereas global alignment uses the full length of whatever is specified.

HMM: In sequence analysis, HMMs contain the statistical description of a recognized functional unit of some particular biological gene family or superfamily, assembled under the probabilistic model of hidden Markov chains (see profile).

Homology: An organ, trait, gene, or even DNA nucleotide position shared with a common ancestor. Homology, as opposed to sequence identity and similarity, can have no level.

A sequence and, in fact, a position within an alignment, is either demonstrably related via evolution to another or not. Statistically significant similarity can argue for homology; however, a lack of statistically significant similarity cannot be used to argue against homology.

Homology modeling: The secondary and often tertiary, 3D structure of proteins can be inferred by alignment with proteins whose 3D structure has been experimentally determined. Obviously the more similar the sequences are, the more successful the theoretical model will be.

Homoplasy: A region of a sequence alignment where so many multiple substitutions have occurred at homologous sites that it is impossible to know if those sites are properly aligned and, thus, impossible to ascertain relationships based on those sites.

Indel: An indel is a gap introduced into a sequence alignment necessary to reconcile differing lengths due to differing evolutionary histories. It is impossible to ascertain whether an insertion or a deletion event created the discrepancy, hence the term indel.

Intron: A defined stretch of DNA within a gene that is transcribed into a corresponding complimentary message RNA molecule, but that is not retained after RNA processing into a mature mRNA and, therefore, is not translated into amino acids.

Matrices: A match matrix is the first step in dot plot techniques and in the visualization of the dynamic programming algorithm illustrated. Its cells contain the value each position receives for matching (aligning) respective X- and Y-axis characters.

A score matrix also has two meanings. In the context of dynamic programming, it is the matrix in which cell values have received initial match values adjusted by gap penalties and trace-back paths. The alternative meaning describes the values that amino acid residues or nucleotide bases receive for aligning with one another, also known as symbol substitution tables, or log-odds matrices, for example, the PAM and BLOSUM matrix series.

The trace-back path matrix delineates the alignments discovered by the dynamic programming algorithm; it illustrates the optimal paths through the matrix.

Motif: A motif is a described and cataloged region of a sequence, usually shorter than a domain and often, but not always, associated with some biological structural, functional, or regulatory role. Motifs are commonly represented as consensus patterns but are often described by HMM profiles as well.

Orthology and paralogy: Two major classes of sequence homology exist. Orthology describes homologous sequences present in different organisms as a result of speciation processes. Paralogy describes homologous sequences within the same organism as a result of gene duplication. Major confusion can result from mixing paralogues and orthologues in the same analysis.

Profile: A profile is a statistical description of a multiple-sequence alignment, commonly of a region or a motif within a multiple-sequence alignment. Profiles take many forms associated with the particular programs that create them, for example, ProfileBuild, HMMer, MEME, but always increase the importance of conserved residues or bases and decrease the importance of variable areas.

z-score and Z-score: The Z-score is usually based on a normal Gaussian distribution and describes how many standard deviations a particular score is from the distribution's mean, though it may be based on the extreme value distribution. This is confusingly in contrast to Bill Pearson's z-score in the FastA programs that is a linear regression of the opt score against the natural log of the search set sequence length. The two values, Z and z, have entirely different magnitudes and should not be correlated.

31.1 Introduction

Terrain models are used for many purposes in a variety of hydrological, geomorphological, and biological applications. Examples include estimation of river networks and watersheds, soil moisture and runoff behavior, soil erosion, long-term water availability, delineation of land slide areas, and land cover classification [68]. In the past decades, it has become increasingly easy to collect high-precision elevation samples of the Earth surface and the floors of water bodies. However, many other types of terrain properties are not as easy to collect, because they are not readily observed or measured from above. Examples include the flow of water across the surface or the daily amount of sunlight per square meter. To make maps of such properties across a terrain, scientists use models to compute an estimation of the required data from the available elevation data. Other uses of elevation data include computations for planning purposes, such as computing a least-cost path to construct a road between two given points or to find a location for a building that minimizes or maximizes its visual impact. The increasing availability of ever-higher-resolution elevation data poses an ever-increasing computational challenge, since higher resolutions come with more noise, and the data sets grow too big to be loaded into the main memory of a computer at once.

Terrains have been studied in many different research areas including computational geometry, computational topology, computer graphics, geomatics engineering, civil engineering, hydrology, oceanography, and other earth sciences. It is practically impossible to produce a complete survey of terrain models and applications including results from all these disciplines. On top of that, terrain data are often provided in the form a regular grid of elevation samples, and thus, it is very similar to a large

gray-scale image. Therefore, it is not surprising that many of the problems in terrain data processing are similar to problems in image processing. For example, to estimate the slope and aspect at any point on a terrain, one may first have to smoothen the terrain; otherwise, small bumps in the terrain (whether real or the result of errors in the data) would dominate the results; image smoothing techniques can be applied. In this chapter, we highlight algorithmic approaches and challenges that concern some of the most important problems in terrain processing and that are typical to geographic terrain data: removal of noise from light detection and ranging (LiDAR) and sound navigation and ranging (SONAR) data, model construction, the computation of contour maps, water flow analysis, and visibility analysis.

Since terrain data sets acquired with recent technology may be as large as hundreds of gigabytes, they often do not fit in the main memory of a computer at once. Working with such data requires efficient algorithms that scale well and are designed to minimize the I/O: the swapping of data between a fast main memory (or cache) and a larger but slower memory such as a disk. The efficiency of such algorithms is assessed not only by studying the computational complexity (see Chapter 4) and by measuring running times in practical experiments but also by studying how the number of I/O operations grows with the input size. The standard model to do so was defined by Aggarwal and Vitter [5]. In this model, a computer has a memory of size M and a disk of unbounded size. The disk is divided into blocks of size B . Data are transferred between memory and disk by transferring complete blocks: transferring one block is called an I/O operation or, simply, an I/O. Algorithms can only operate on data that are currently in main memory; to access the data in any block that is not in main memory, it first has to be copied from the disk. The I/O efficiency of an algorithm can be assessed by analyzing the number of I/O's it needs as a function of the input size n , the memory size M , and the block size B . Fundamental building blocks for I/O-efficient algorithms are *scanning* and *sorting*: scanning n consecutive records from disk takes $scan(n) = \frac{n}{B}$ I/O's; sorting takes $sort(n) = \frac{n}{B} \log_{M/B} \frac{n}{B}$ I/O's in the worst case [5]. A more restrictive model for algorithms for large data is the *streaming model* [57]. Algorithms that conform to this model make only a small number of sequential passes over the data while processing the data using a small memory buffer.

In Section 31.2, we describe the sources and formats of terrain elevation data, the problem of cleaning and filtering raw elevation data, common interpolation methods used on such data, and how to construct terrain models in the most common formats. In Sections 31.3 through 31.5, we review the state of the art in three applications of terrain models: computing contour maps, computing water flow and watershed hierarchies, and computing viewsheds (visibility maps).

31.2 Data Collection and Model Construction

In this section, we discuss how terrain models are obtained. Section 31.2.1 describes sources of terrain elevation data and in particular LiDAR data, which have recently become the best source of terrain data because of its high resolution and accuracy. We overview cleaning and filtering raw LiDAR data in Section 31.2.2. Next, we describe the most commonly used terrain data formats and interpolation methods (Sections 31.2.3 and 31.2.4). Finally, we overview methods for converting LiDAR data to the main terrain formats (Sections 31.2.5 and 31.2.6).

31.2.1 Digital Elevation Data Sources

Most digital elevation data are obtained from stereoscopic interpretation of aerial photographs and satellite imagery. Elevation data can also be obtained by ground survey, by digitizing the contour lines on existing topographic maps, and, more recently, from technology like LiDAR. The LiDAR technology is one of the most accurate and cost-effective ways to collect elevation data for large areas. The LiDAR technology is based on sending laser signals from an aircraft down to a point on earth and measuring the time it takes for the pulse to reflect back. The reflection time, together with the exact position and orientation of the aircraft, allows us to compute the elevation of that point on the earth. LiDAR

measurements can be collected at .5–3 m resolution and are very accurate (15–30 cm) [56]. The resulting product is a densely spaced collection of three-dimensional points, often called a point cloud.

A technology similar to LiDAR, called SoNAR, can be used in water to measure the elevation of the seafloor. The SoNAR technology operates in a similar way as LiDAR, except that, instead of laser, it uses sound. Seafloor data is used for applications such as searching for oil or maintaining pipes.

In the recent years LiDAR and SoNAR data have become increasingly available. Data from LiDAR and SoNAR are usually massive, have high resolution, high redundancy and contain noise. To be useful, they need to be cleaned and thinned/simplified, and the algorithms for doing so need to be efficient and able to handle huge inputs.

31.2.2 Cleaning and Filtering LiDAR and SoNAR Data

Raw LiDAR and SoNAR data contain a point cloud of elevation measurements representing the surface. In fact, several returns may be collected for each pulse emitted. The last return of a pulse may be associated with reflection of the bare ground (or ocean floor), while the first returns may represent reflections of birds, fish, tree tops, etc. Furthermore, the data may contain noise resulting from, for example, refraction in gas bubbles, influences of the ship's propeller or differences in sound speed.

Applications usually need a digital terrain model, that is, a model of the bare ground. Such a model is obtained from the raw data by *cleaning* the data, that is, detecting and eliminating noise, and *filtering* the data, that is, distinguishing and removing all features such as vegetation and buildings. The criteria and approaches used for cleaning and filtering may differ depending on the morphology of the data (seafloor vs. surface, urban vs. agricultural or forested) and the density of points.

For a review of cleaning and filtering algorithms for LiDAR data we refer to Sithole and Vosselman [61] and Meng et al. [50] and the references therein.

A common method for cleaning SoNAR data is through the use of the CUBE algorithm (Combined Uncertainty and Bathymetry Estimator) developed by Calder and Mayer [18]. The CUBE algorithm computes depth estimates at the vertices of a grid laid over the terrain, and in doing so it gives a mechanism to remove noise in the data. The method attributes to each point an estimate of uncertainty, propagates these uncertainties in the local neighborhood, and based on them it estimates the true depth at the points in the grid. The CUBE algorithm is implemented by most hydrographic software. It has a low memory footprint, it is fast on large data sets and is suitable for real-time use. However, according to Arge et al. [11], CUBE works well for isolated outliers, but not so well for clustered noise. Their solution is to define a graph that represents the topology of the data, and to clean the data by removing connected components of the graph that appear to represent noise clusters. To construct the graph they start with the Delaunay triangulation of the points,* for each edge they add its corresponding diagonal, and then they remove all edges of which the elevations of the endpoints differ by more than a user-specified threshold τ . Thus, areas that are delineated by abrupt changes in depth, for example the back of a fish that swims at a height at least τ above the seabed, will be disconnected from the rest. The largest connected component in the resulting graph is assumed to represent the seabed, while the others represent noise. Using I/O-efficient algorithms and under realistic assumptions on the size of the graph ($n = O(M^2)$), the algorithm runs in $O(\text{sort}(n))$ I/O's on a SoNAR data set of n points. The authors analyse the accuracy of the algorithm and compare it to a manually cleaned data set [11].

31.2.3 Data Models/Representation

Digital elevation data can be structured in several ways: the most common data formats are regular grids and triangulated irregular networks (TINs) of elevation samples.

* The Delaunay triangulation is the triangulation in which the interiors of the circumcircles of the triangles do not contain any vertices, see Chapter 6.

Grid data consists of a set of elevation values in a regular pattern, typically the intersection points of a regular grid of squares formed by equally spaced longitudinal and latitudinal lines. Thus, the data is essentially a matrix of elevation values. When the surface covered is not too large, each pair of neighboring elevation samples can be considered to have equal distance between them; otherwise algorithms will have to include corrections to account for the curvature of the earth surface and the decreasing distance between samples as one moves away from the equator. Grid data is most commonly stored in row-major order: row by row, and in each row, from west to east. This makes it easy to convert between coordinates of a grid point and its position in the file, and it guarantees that neighboring grid points are stored relatively close to each other in the file. Alternatively, Z-order (also known as Morton layout) could be used: the terrain is subdivided into an NW, NE, SW and SE quadrant, which are stored one by one in that order, each ordered recursively in the same way [64]. This order tends to optimize the number of cache misses (accesses to main memory or disk) needed when arbitrary long paths through the grid need to be traversed. Grids with sample points on the vertices of a grid of equilateral triangles have also been considered but do not seem to have found their way into common practice in the geosciences. There does not seem to be an inherent algorithmic reason for this: all algorithms for grid terrains discussed in this survey can easily be adapted to triangular grids.

A more flexible alternative to grid formats is provided by triangulated irregular networks (TINs). Here the elevation samples lie in an irregular pattern, and a triangulation on these points is provided. Typically the triangulation forms a Delaunay triangulation when projected on the horizontal plane (or rather, the reference ellipsoid of the Earth). For high-quality flow and visibility computations it may be advantageous to make sure that known valley and ridge lines are approximated by paths that are composed of edges of the triangulation. This can be done by using a *constrained Delaunay triangulation* (see Section 31.2.5). While for grid formats it suffices to store the elevation data itself, for TINs one also needs to store the horizontal coordinates of the sample points and the topology, that is, what are the edges and the triangles of the triangulation. To allow the TIN to be traversed efficiently, a non-trivial data structure is needed, for example a doubly-connected edge list or half-edge structure [30], or a more efficient data structure specifically designed for triangulations [20,49].

The choice between a grid format or a TIN format is not obvious. On one hand, grid models are very restrictive: they require an exact spacing of sample points, and equal spacing everywhere. Elevations that have actually been measured cannot be used since the measured elevation samples seldom lie exactly on a grid point, so the whole grid has to be constructed by interpolation. Furthermore, if high-resolution data is required or available to model any part of the terrain, then the complete terrain model must be given at high resolution, even where high-resolution data is unavailable or simply not required. Thus, grid formats may carry a substantial storage overhead in the form of interpolated sample points that do not carry any information from actual measurements. On the other hand, algorithms operating on TINs tend to be more complicated than algorithms on grid formats. Furthermore, one should choose the data structure to store the topology information of a TIN carefully. Commonly used data structures store at least seven pointers per vertex on average [49], plus the coordinates of each vertex: thus the total amount of storage needed for a TIN is at least an order of magnitude more than what is needed for the mere elevation data. Recently, Castelli Aleardi and Devillers published a data structure that uses only four pointers and, in our case, three coordinates per vertex [20]—I/O-efficient construction has not been studied yet. Theoretically, data structures exist that use as little as 2 bits per vertex to store the topology [21], but construction and navigation of such data structures is much more difficult and time-consuming and researchers in the field consider them to be of “mainly theoretical interest” [20]. In the end, because of their simple structure, grids are probably the most commonly used and most widely available format in geographic information systems.

Naturally, researchers have been researching the possibilities to overcome the disadvantages of grid and TIN formats. As an alternative to regular grids, grids based on quadtrees could be used: starting from a single square grid cell, we keep subdividing cells into four quadrants recursively until each cell is small enough to allow the morphology of the local terrain to be captured adequately [30]. Thus, the cell size may vary across the terrain. However, algorithms for applications such as those mentioned in the remaining sections of this chapter, have generally not been adapted to work with such formats.

31.2.4 Spatial Interpolation

Terrain elevation data must be considered, either explicitly or implicitly, with an interpolation method that describes how to obtain the elevation values for points other than the sampled points. More precisely, let $P = \{p_1, p_2, \dots, p_n\}$ be a set of points, each specified by their latitude and longitude, and denote the measured elevation of p_i by $z[p_i]$. To be able to construct and interpret a terrain model, we need to define an elevation function z that gives an elevation value for *any* two-dimensional point p , also for points p that are not in P . This function z should respect the data, that is, $z(p)$ should be (approximately) equal to $z[p]$ for all $p \in P$. In this section we discuss several common methods to define such a function z . For a more thorough survey, see Mitas and Mitášová [51].

Interpolation by Thiessen polygons or nearest neighbors: With this technique, the interpolated elevation $z(q)$ of any point q is the elevation $z[p]$ of the point $p \in P$ that is nearest to q , when distances are measured in the projection on the horizontal plane. This leads to a partitioning of the terrain into regions called Thiessen polygons. The region $T(p)$ containing a point p of P is exactly the set of points that are closer to p than to any other point of P , and within each region, each point has the same elevation. Interpolation with Thiessen polygons is often used for grids; in that case the Thiessen polygons are simply rectangular cells centered at the grid points. This interpolation method is simple, but has the problem that the (interpolated) values change sharply across polygon boundaries, which is not necessarily plausible. The partitioning in Thiessen polygons is also known as a Voronoi diagram; it is the dual of the Delaunay triangulation that usually underlies a TIN [30].

Interpolation on triangular facets: This interpolation method models the surface as a tessellation of triangular facets. To be able to apply this technique, we first compute a triangulation of the elevation samples P . The elevation of any other point q is then obtained by linear interpolation between the three vertices of the triangular facet that contains q . Although simple, linear TIN interpolation is not accurate; see Mitas and Mitášová [51] and the references therein. Variants of this method use non-linear interpolation functions for each triangle to ensure additional continuity across boundaries and the existence of derivatives.

Inverse-distance-weighting (IDW): This method is reported to be the most commonly used method in geographic information systems [48]. The value $z(q)$ is defined as a weighted average of all points $p \in P$, where the weights depend on q , that is, $z(q) = \sum_i w_i(q) z[p_i] / \sum_i w_i(q)$. More precisely, we define $w_i(q)$ as $1/|p_i, q|^2$, where $|p_i, q|$ is the distance between p_i and q . The IDW technique produces a smooth surface but can produce counterintuitive results like fake pits and peaks, that is, peaks that are higher than any elevation that was actually measured in its neighborhood [48]. Applications that use IDW often give the option to ignore points that are further away than a specified distance, or to consider only a specified number of nearest points, or to average only over the closest points in each of a number of directions [48].

Natural-neighbor interpolation: Like IDW, the value of $z(q)$ is defined as a weighted average of all points $p \in P$. Each weight $w_i(q)$ is now defined as the size of the part of the Thiessen polygon $T(p_i)$ that would be lost to the Thiessen polygon $T(q)$ when q would be inserted in P . In other words, $w_i(q)$ is the size of the intersection of $T(p_i)$ in the Voronoi diagram of P and $T(q)$ in the Voronoi diagram of $P \cup \{q\}$. An implementation that exploits the parallel processing power of a graphics processing unit was recently presented by Beutel et al. [16].

Kriging: This is another method in which the value of $z(q)$ is defined as a weighted average of all points $p \in P$. The weights are now derived from a geostatistical analysis of the data. The structural variation in the data is captured by the *variogram*, which is the function that gives an estimate of the average squared elevation difference between p_i and p_j as a function of their horizontal distance. More precisely, if $N(h)$ is set of pairs (i, j) such that $|p_i, p_j| = h$, then the variogram is obtained by fitting a certain type of function (for example, a Gaussian, spherical, or exponential function) to the function

$\sigma(h) = \frac{1}{|N(h)|} \sum_{(i,j) \in N(h)} |z[p_i] - z[p_j]|^2$. The variogram is then determined to define the weights. For a detailed discussion of Kriging see Longley et al. [48] and Burrough and McDonnell [17].

Regularized spline with tension (RST): Proposed by Mitášová and Mitas [52], this method consists in defining and minimizing a certain smoothness function. It includes a tension parameter which changes the character of the resulting surface from a thin metal plate to a membrane, which is pinned to the data points. The value of the tension has to be determined empirically in each application. The method enables the computation of local derivatives of all orders, which is useful in various applications. The authors report that RST is more accurate than alternative methods, such as thin plate spline, Hardy quadric, etc. [52]. The authors implemented RST in GRASS [53]; an implementation that can handle larger data sets was recently presented by Danner et al. [27].

31.2.5 From Point Cloud to TIN

As discussed above, terrain data often comes in the form of a point cloud obtained by LiDAR or other means. For further processing, this data is usually transformed to a grid or a TIN. As LiDAR data tend to be very large (hundreds of millions of points), the grid or TIN construction algorithm needs to be *I/O*-efficient in order to handle such data sets. Below we focus on algorithms that have been proposed for and/or tested on very large data sets. In this subsection we discuss algorithms to construct TINs; in the next subsection we discuss algorithms to construct grid models.

To construct a TIN from a point cloud, one needs to triangulate the point set. Typically a Delaunay triangulation based on the horizontal coordinates of the points—the elevation values are not taken into account—is used. Several $O(n \lg n)$ -time, but not necessarily *I/O*-efficient, algorithms for Delaunay triangulations are known [13]. A state-of-the-art implementation is *Triangle*, developed by Shewchuck [59]. Several *I/O*-efficient algorithms to compute Delaunay triangulations have been proposed as well [3,26,40].

The first *I/O*-efficient algorithm accompanied by an experimental evaluation is by Agarwal et al. [3], based on Crauser et al. [26]. The implementation actually solves a more general problem, the *constrained Delaunay triangulation*: given a set V of vertices in the plane together with a set S of predetermined edges, compute the triangulation of V that includes all predetermined edges in S and is “as close as possible” to the Delaunay triangulation (for a more precise definition, see the original publication). This allows us to ensure that the triangulation respects, for example, valley and ridge lines that are known from other sources. The algorithm works in rounds which triangulate increasingly bigger sets of points from the input, in each round using the results of the previous round to divide the problem into sub-problems that are solved with the *Triangle* package mentioned above. The algorithm remains efficient if V is huge as long as S is modest: if S does not require more storage than a certain constant fraction of the main memory, the expected number of *I/O*'s required by the algorithm is $O(\text{sort}(n))$. The authors report that their algorithm can process 10 GB of LiDAR data (about 500 million points from the Neuse river basin of North Carolina) using 128 MB of main memory in roughly 7.5 h.* This is several orders of magnitude faster than a direct application of Shewchuck's *Triangle*.

A different approach is described by Isenburg et al. [44]. They advocate processing large datasets using the *streaming paradigm*. Streaming algorithms make only a few sequential passes over the data, do not create intermediate files, and perform computations only on the part of the data that is in memory. During each pass, as more data and more partial results are computed, the algorithm needs to decide which previously read data and previously computed results still need to be retained in memory and which data and results can make place for new data and results. The Delaunay triangulation algorithm by Isenburg et al. does this as follows. The algorithm first reads the input point cloud to determine its bounding box. Next the algorithm divides the bounding box in a regular grid of rectangular cells such

* Considering machines with so little RAM is done to illustrate the scalability of the algorithm to data that is much larger than main memory.

that one can easily keep a counter for each cell in memory. The input is then read once more to count the number of points in each cell. Finally the input is read a third time. This time the points of each cell are collected in memory. As soon as all points of a cell have been read, the whole cell is triangulated using the *Triangle* package. Triangles whose circumcircles lie entirely inside the current and previously processed cells are written to the output immediately. The remaining triangles may still change, subject to the contents of the unprocessed cells: only these triangles and their vertices are retained in memory. Isenburg et al. report that the algorithm can process the above mentioned data set of the Neuse river basin in 48 min using 70 MB of memory on a laptop, using a slower processor and slower disk than Agarwal et al. [3]. However, the implementation by Isenburg et al. does not take a set of predetermined edges into account.

Note that the approach taken by Isenburg et al. is very fast in practice, but its worst-case complexity is not. The algorithm exploits the natural spatial coherence of raw LiDAR data sets: points that are close to each other in space tend to be close to each other in the file. Thus the algorithm does not need to keep many points of incomplete cells in memory. Furthermore, the algorithm by Isenburg et al. requires that most triangles do not span many regions: thus the algorithm will not need to keep many triangles that may still change in memory. It seems that this requirement is met in practice. Thus the memory footprint of the algorithm by Isenburg et al. stays small and I/O remains limited to sequentially reading the input and sequentially writing the output.

31.2.6 From Point Cloud to Grid Model

Different approaches to compute a grid model from a point cloud I/O-efficiently were again proposed by Agarwal et al. [1] and Isenburg et al. [45].

The solution proposed by Agarwal et al. [1] is a standard I/O-efficient algorithm, designed and analyzed in the I/O-model. Their approach is based on Mitášová and Mitas [52] and has three steps: first, they process the point cloud into a quadtree (the *segmentation* phase) with at most a user-specified number of points in each leaf; second, for each leaf in the quadtree they find out which cells are its neighbors (the *neighbor finding* phase); and third, they interpolate elevations for the grid points within each cell using the points in the cell and its neighboring cells (the *interpolation* phase). In their implementation, interpolation with regularized splines with tension (RST) is used, but other interpolation methods might be substituted. The complete algorithm runs in $O\left(\frac{N}{B} \frac{h}{\log M/B}\right)$ I/O's, where h is the height of the quadtree. Agarwal et al. implemented and evaluated their approach on some practical examples. A grid of 1300 million points is reported to be constructed from a LiDAR data set of 390 million points (the Neuse river basin data set from <http://www.ncfloodmaps.com>) in 53 h on an Intel 3.4 GHz Pentium 4 with 1 GB of main memory. This is reported to be faster than two popular geographic information system packages, ArcGIS and GRASS. Of the three phases of the algorithm, interpolation is by far the most time-consuming, accounting for 50%–80% of the running time, with the bottleneck being the required computational effort for RST interpolation, rather than I/O. A new implementation of this approach has been recently described by Danner et al. [27]. This version, designed to take advantage of a modern platform containing multi-core processors and modern graphics processors, is at least an order of magnitude faster than the implementation by Agarwal et al. [1].

Isenburg et al. [45] again adopt the streaming paradigm. Their algorithm is based on the point-cloud-to-TIN algorithm described in Section 31.2.5, which is extended as follows. Instead of writing the triangles produced by the algorithm to an output file, the triangles and the vertices are piped through to another process, the *rasterizer*. The rasterizer receives each triangle and each vertex exactly once and uses the triangles to estimate the elevation at the grid points by linear interpolation. The stream of triangles and vertices that is fed to the rasterizer is interleaved with vertex tags that mark when all the triangles incident on a vertex have appeared in the stream: thus the rasterizer knows when a vertex still needs to be retained in memory and when it can be discarded. More advanced interpolation methods,

in which the interpolation within a triangle also depends on the neighboring triangles, may be implemented by keeping triangles in memory until all neighboring triangles of its neighboring triangles have been received. The elevations of grid points as computed by the rasterizer, are immediately written to a file and are not kept in memory. Upon completion of the algorithm, the output is sorted into row-major order to obtain the grid model. The overall process is extremely fast: a grid of 1500 million points is constructed by linear interpolation from a 10 GB LiDAR data set of 500 million points from the Neuse river basin of North Carolina in 67 min on a laptop using less than 100 MB of memory and with a 5400 RPM disk. Although this is much faster than the 53 h of Agarwal et al. [1], a direct comparison cannot be made because Agarwal et al. implement a more complex interpolation method (RST), while Isenburg et al. report running times for linear interpolation.

31.3 Computing Contours and Contour Maps

One of the main applications on terrain models is computing contours and contour maps. A *contour* (or *isoline*) of a terrain T at a given level (elevation) is a connected component of a level set of T , that is, the set of points of T at a given elevation. A *contour map* consists of contours at regular elevation intervals. Contour maps have been used historically in cartography to represent terrains; recently they are used for visualization, where isosurface extraction in general is one of the most effective techniques for the investigation of volume datasets [22].

A straightforward way to compute a contour is to start from a cell intersecting the contour (for example a triangle, if the terrain is represented as a TIN) and trace the contour from cell to cell until coming back to the starting point. The question is how to find a start cell. Traversing the entire dataset to construct a single contour is not efficient, since the size of contours is usually small. Therefore research has focused on finding data structures that can be queried for contours and report them efficiently.

One solution is to associate each cell in the data set (grid cell or triangle) with an interval representing the elevation range of the cell; for example, if the terrain is represented as a TIN, each triangle is associated with the interval bounded by the elevations of its lowest and highest vertices. Computing contours now reduces to an interval search problem, namely finding all intervals that contain a given query elevation h . In the first phase of contour extraction one finds all cells whose elevation range includes h ; such cells are called active. In the next phase one can apply an algorithm to actually generate the contours from the active cells. An algorithm based on this idea was given by Cignoni et al. [24], using interval trees to store the intervals corresponding to the dataset. After preprocessing in $O(n \lg n)$ time, contours at a given elevation can be found in optimal $O(\lg n + k)$ time, in internal memory, where k is the size (total number of edges) of the contours. In external memory the same approach was used by Chiang and Silva to propose an I/O-efficient algorithm [22,23]. Using the I/O-efficient interval tree developed by Arge and Vitter [12], Chiang and Silva describe a linear-size data structure to store a TIN on disk such that all edges in the contours at elevation h can be reported in $O(\log_B n + k/B)$ I/O's, where k is the size of the contours. Agarwal et al. [2] note that this algorithm does not sort the edges along a contour. Using standard techniques (list ranking) this would require another $O(\text{sort}(k))$ I/O's (possibly with relatively high constant factors hidden in the O -notation) in the worst case, but as long as the contours at any given elevation fit in memory, it is not a problem.

A different approach uses the *contour tree*, which is a data structure that encodes the starting point(s) for each contour and can be used to compute contours and contour maps efficiently. Van Kreveld et al. [67] gave an $O(n \lg n)$ time algorithm for constructing a contour tree of a terrain represented as a TIN. In the I/O-model, an algorithm to compute the contour tree efficiently in $O(\text{sort}(n))$ I/O's was proposed by Agarwal et al. [4]. This can be used to find the starting points for a contour efficiently, however it is not clear how to efficiently trace the contour in the I/O-model, since a naive implementation would require one I/O per segment, and thus $O(k)$ I/O's in total.

Agarwal et al. proposed a different I/O-efficient data structure for answering contour queries on TINs [2]. They show how to construct a linear-size data structure in $O(\text{sort}(n))$ I/O's, so that all contours

at a given elevation can be reported using $O(\log_b n + k/B)$ I/O's, where k is the size of the contours. Each contour is reported with its segments in sorted order. Their solution is based on exploiting the topology of the contours as analyzed by Edelsbrunner et al. [36], and computing a certain ordering of the triangles in the TIN such that for any contour, the segments in the contour are in order and contours do not interleave.

Unfortunately, none of the I/O-efficient algorithms mentioned above come with experimental results.

When a complete contour map needs to be produced, one may be able to afford to scan the complete input. In this case one can simply scan all cells of the data set to find all edges of the contours. Again, this does not generate the edges of the contours in sorted order. Arge et al. [9] describe an algorithm and implementation to compute and simplify contour maps of massive terrain data sets. As a first step, their algorithm indeed generates the (unsimplified) contours by simply scanning all triangles of a TIN and generating the contour segments that intersect them. For further processing, the contour segments need to be sorted by and along each contour. Arge et al. implement an algorithm that does this I/O-efficiently as long as certain assumptions can be made, such as that each contour by itself is not larger than a certain constant fraction of main memory.

31.4 Flow Analysis

One important application of terrain models is in predicting the flow of water on terrains, for example to predict the risks of floods and the impact of pollution, or, in combination with other parameters, to predict rates of erosion, vegetation cover, or suitability for agriculture. The *catchment area* or *watershed* of a location on a terrain is the region from where water flows to that location. The size of the catchment area of a location (possibly weighted according to variations in rainfall) is also known as the location's *flow accumulation*. The *specific catchment area* or *specific flow accumulation* would be the flow accumulation of a section of a contour, divided by the length of the section. The specific catchment area can be defined at any single point of the terrain by estimating the limit value for a contour section that contains that point and shrinks to zero length. Typically a terrain drains through a network of streams and rivers, which are exactly the locations that have relatively high flow accumulation. The watersheds on a terrain form a hierarchical structure, in which the watershed of each location in the river network is contained in the watershed of all locations downstream of it. In particular, watersheds of rivers are composed of watersheds of tributaries. Efficient computation of a (specific) flow accumulation map of a terrain, possibly together with a representation of the watershed hierarchy, is at the core of many applications of water flow analysis on terrains. Furthermore, many other computational problems related to the drainage structure of a terrain can be solved with similar algorithmic techniques.

In this section we will first give an overview of the state of the art in the computation of flow accumulation maps and watershed hierarchies, assuming a perfect terrain model that is nowhere horizontal. Two main approaches can be distinguished: the continuous-surface approach and the discrete-surface approach. The first approach, discussed in Section 31.4.1, treats the terrain as a continuous surface, of which the exact shape is estimated by interpolating between sample points for which an elevation is given. The second approach, discussed in Section 31.4.2, treats the terrain as a network of cells, in which each cell is treated as an atomic unit, and water that arrives in any cell continues its course down-hill to one or more neighboring cells. Both approaches can produce reasonable results only if water always follows a course that, according to the terrain model, leads strictly downhill. However, in practice this is not always the case, due to the presence of sampling or interpolation errors in the model and the presence of flat areas in the actual terrain. To make a terrain model suitable for flow accumulation computations, it needs to be *hydrologically corrected* and one needs to compute how water may find its way on flat surfaces. This is discussed in Section 31.4.3. Finally, in Section 31.4.4, we discuss the main challenges for further development of flow analysis algorithms: how to deal with imprecision, how to improve hydrological correction, and how to take into account the limited capacities of drainage channels and the passing of time.

31.4.1 Flow in the Continuous-Surface Model

In the continuous-surface model, water is usually assumed to follow the exact direction of steepest descent on the interpolated terrain. Thus, water is not bound to flow from sample point to sample point, but it can also flow across the surface between sample points. This approach allows for a relatively precise representation of valley and ridge lines with relatively few sample points, and it avoids certain artifacts that result from the representation of the terrain. For example, streams are not limited to follow the edges of a triangulation, or to follow strictly the eight cardinal and ordinal directions in a grid. Continuous-surface models can be based on elevation samples in a grid, in a triangulated irregular network, or without structure, and the interpolation may produce a smooth surface (without discontinuities in the gradients) or one with sharp folds (with discontinuities in the gradients).

In the context of geographic information science, research has mostly focussed on the setting where the continuous surface is defined by a triangulation on the sample points and linear interpolation within each triangle—resulting in a surface with sharp folds at the edges of the triangulation. In this setting we can distinguish valley edges, transfluent edges, and ridge edges. Valley edges receive water from both incident triangles. On transfluent edges, water arrives from one incident triangle and continues its course down the other incident triangle. All other edges are ridge edges: on both incident triangles, the gradient is directed away from the edge, so that no water ever flows across or along the edge. In this model, two categories of points in the terrain can be distinguished: those that lie on a steepest-descent path starting from a valley edge, and those that do not. The first category of points form the skeleton of the drainage network. They have non-zero flow accumulation and infinite specific flow accumulation. Each point p of the second category only catches water from an infinitely thin course that can be traced back up from p by following the direction of steepest ascent until reaching a ridge. Thus, such points p all have zero flow accumulation, but they may still have meaningful, non-zero *specific* flow accumulation.

Steepest-ascent paths starting at ridges form a skeleton that encodes the boundaries between watersheds [69]. The drainage network and the watershed boundary skeletons, together with the steepest-ascent and steepest-descent paths from other vertices in the terrain, decompose the terrain into *strips*. This decomposition, called a *strip map*, can be stored in a data structure from which the catchment area, the flow accumulation and the specific flow accumulation of any point on the terrain can be retrieved efficiently [29]. Unfortunately, the whole structure has relatively high complexity. Theoretically, by linear interpolation of a triangulated irregular network on n sample points, one can construct a surface that has a drainage network skeleton and a strip map consisting of $\Theta(n^3)$ line segments—even when the triangulation is a Delaunay triangulation [29]. When all triangles are equilateral triangles of the same size, the complexity is still $\Theta(n^2)$ in the worst case [29]. In practice, it has been reported that the drainage network skeleton has size only $O(n)$ [69]. However, De Berg and Tsirogiannis found that explicit computation and storage of the strip map is a major bottleneck, with the computation requiring at least 16 KB of working memory per input vertex and 8 KB per input vertex in the final result [32].

Flow structures in the continuous-surface model have also been studied for smooth surfaces. Paths of steepest ascent/descent between peaks (local maxima), pits (local minima) and saddle points form a structure known as a *Morse-Smale complex* in computational topology [42], or a *surface network* in geographic information science. On a linearly interpolated surface, paths of steepest ascent or descent do not usually cross many edges before they meet a ridge or valley edge, but in a smooth terrain, such paths may extend a long way, slowly converging towards valley lines without actually meeting them. Thus, a generalization of the approach discussed above for linearly interpolated terrains is unlikely to be practical.

31.4.2 Flow in the Discrete-Surface Model

In practice, usually a discrete-surface model is used. In its simplest form (the D8 model), the model consists of elevation samples arranged in rows and columns. Each sample point represents a cell of unit size. Water arriving in any cell continues to one of the eight neighbors of the cell; more precisely, from

a cell c it continues to the lower neighbor c' such that the elevation difference between c and c' , divided by the distance between the center points of c and c' , is largest. This approach is also called *single-directional flow*. A disadvantage of this approach is that it is prone to artifacts, such as a tendency for streams to follow the ordinal or cardinal directions of the grid model, even on slopes that have a different orientation. More advanced models use *multi-directional flow*: they distribute the water that arrives in a cell among multiple lower neighbors to model dispersion on convex slopes, or to model directions of steepest descent that are not exactly one of the cardinal or ordinal directions [41]. The latter may also be achieved by routing flow over the edges of a TIN that is constructed such that all known valley and ridge lines approximately follow edges of the TIN.

In the discrete-surface model, the difference between flow accumulation and specific flow accumulation is subtle. To compute the specific flow accumulation in a cell from its flow accumulation, one should divide by the length of the contour section that is covered by the cell—but this is not well-defined. Gruber and Peckham [41] discuss some of the subtleties to consider.

In this section, we focus on the algorithmic aspects of flow accumulation computation, rather than the modeling aspects. From an algorithmic point of view, the challenge is not how to distribute flow of a single cell to its multiple lower neighbors, but rather how to visit all cells in the most efficient order. As long as the full terrain model fits in memory, computation of flow accumulation for all cells is relatively easy. Here is just one example of a linear-time algorithm to do so. We start the computation by giving each cell one unit of water and marking each cell as unprocessed. Then we go through all cells one by one, calling a flow distribution algorithm on each cell. When called on a cell that has already been processed, or on a cell that is still to receive flow from unprocessed higher neighbors, the flow distribution algorithm does not process the cell and it returns immediately. Otherwise, it marks the cell as processed, distributes its water to its neighbors, and makes a recursive call on each of the neighbors.

When processing large grids that are stored on a hard disk and do not fit in the main memory of a computer at once, computation becomes more complicated. The simple algorithm sketched above may access the cells of the terrain model in an order that requires many accesses to each block of data on disk and renders caching ineffective, making the computation prohibitively slow. Haverkort and Janssen showed that in practice, the simple algorithm can still be very fast when processing a 28 GB terrain model on a computer with only 1 GB of memory, provided the D8 model is used and a regular grid model. The grid model is best stored and traversed in Z-order, that is, recursively subdivided in square blocks, instead of row by row [43]. Haverkort and Janssen also present a more complicated algorithm that has theoretically optimal performance in terms of disk I/O (even on a worst-case input) and that is equally fast in practice. The algorithm first divides the terrain into square blocks that fit in memory one by one, and computes a small “summary” of each block: this summary captures, for each point on the boundary of the block, how much water flows to that point from the interior of the block, and which other points on the boundary of the block are upstream of it. The summaries are then processed together and used to compute the flow of water between blocks; finally the blocks are processed one by one once more, to distribute the incoming water from the boundary into each block. The amount of disk I/O needed is proportional to the amount needed to scan the input.

When multi-directional flow models or triangulated network models are used, the results of Haverkort and Janssen are not applicable. Instead, one can use algorithms based on *time-forward processing*: here cells are processed in order of decreasing elevation; when a cell is processed, it receives messages that say how much flow comes in from each upstream neighbor, and it sends a message to the downstream neighbors, saying how much flow they will receive. If the message passing is handled by a data structure such as an I/O-efficient priority queue, the total amount of disk I/O needed is proportional to the amount needed to sort the input. The approach has successfully been implemented in the *TerraFlow* [7] and *TerraStream* [28,55] packages. The algorithms appear to be an order of magnitude slower than the algorithms of Haverkort and Janssen [43], but they allow a far wider range of flow models.

When a single-directional flow model is used, it is also possible to compute the hierarchical watershed structure: each cell can be given a decimal label such that, given two cells, one can decide if one

cell is in the other cell's watershed by only examining their labels. Under the reasonable assumption that in practice, the number of significant digits of a label is bounded by a small constant, the labeling can be computed efficiently with the algorithm of Arge et al. [8], which has also been implemented in *TerraStream* [28]. Unfortunately, the results are not applicable to multi-directional flow models, because multi-directional flow results in unbounded overlap between watersheds: two cells p and q could have partially overlapping watersheds even when none is inside the watershed of the other.

Thus, while discrete-surface models are attractive because of the availability of efficient algorithms, they also have inherent limitations: single-directional flow is prone to artifacts; multi-directional flow may mitigate the worst artifacts but renders the analysis of watershed hierarchies problematic.

31.4.3 Hydrological Correction and Routing

The flow models and algorithms described above are all based on the assumption that water always flows downhill. However, there are two problems with this assumption. First, due to the presence of sampling or interpolation errors, the course that water follows in the real terrain may not always lead downhill in the model. Problematic areas in the model are characterized by the presence of local minima that one would not expect to find in the real terrain. Second, the real terrain may actually contain flat areas or even local minima from which water still finds a way out, for example because these areas are actually flooded (such as lakes), because they drain slightly below the surface, or because they are the result of man-made structures (such as bridges) under which water actually passes through. The last is especially a problem with high resolution terrain models, where small features become visible; in this case bridges appear as elevated areas which, if not removed, can block the flow of water under the bridge and produce unrealistic river networks.

To make a terrain model suitable for flow accumulation computations, small local minima and bridges have to be removed, and flat areas (such as lakes) have to be preprocessed so that the algorithms of Sections 31.4.1 and 31.4.2 can deal with them. In this section we discuss algorithms that can be used to preprocess terrain models so that they can be used for flow analysis under the discrete-surface model, or under the linearly-interpolated continuous-surface model. The removal of local minima and bridges is known as *hydrological correction* or *hydrological conditioning*. Hydrological correction typically removes local minima by filling them up (known as *flooding*), by carving a way out into the terrain (known as *breaching*), or by a combination of these approaches.

Indiscriminate *flooding* raises the elevation of every point of a terrain until for each point there is a path to the edge of the terrain and that never leads up-hill. In practice, one should not always flood all local minima—typically, larger local minima correspond to real features in the terrain, such as quarries, where water does indeed collect, and only smaller local minima should be removed. *TerraStream* [28,55] implements a method to automatically flood (and thus remove) all local minima smaller than a user-defined threshold. The size of a local minimum is defined based on volume and/or topological persistence [36], that is, the height difference between the lowest point in the local minimum and the lowest point on its boundary. *TerraStream* also works for large triangulated models that do not fit in main memory.

As noted by Carlson and Danner [19], not all spurious local minima have small persistence. In particular, local minima behind bridges in a terrain model may have large persistence—and these are particularly problematic because they tend to arise exactly along locations of water flow. Carlson and Danner [19] describe a system for automatically detecting bridges and bridge-like features using supervised learning. Once identified, the bridges are cut out. Both the detection and the cutting algorithms process the data using small neighborhood windows and the whole process is efficient and scalable. The authors give an extensive analysis of the accuracy of their method including cross-validation. Their method modifies the terrain model significantly less as compared to a flooding approach.

When parts of the drainage network are known from other data sources, one may also correct the terrain model by changing the elevation of points along known streams such that these streams follow an always-descending path in the model. When elevations are only lowered, this approach is known as *stream burning*. Van Kreveld and Silveira discuss how to minimize the total amount of elevation change

(up and down), using a linear-programming approach that is fast enough for terrains of moderate size, and they discuss what side-effects of the process to watch out for [66].

After hydrological correction, the terrain model may still contain flat areas: groups of vertices at the same elevation. Typically, only one or some of these vertices have a lower neighbor. Flow from the other vertices in a flat area must somehow find its way across the flat area to one of the vertices that have a lower neighbor. Several heuristics have been developed to direct the edges in a flat area such that from each point in the flat area, all directed paths eventually lead to a point that has a lower neighbor. One approach is to simply compute a breadth-first search tree, starting from a point that has a lower neighbor, and direct all edges of the tree towards the root, but heuristics that result in more natural-looking flow networks have also been proposed [62] and implemented in *TerraStream* [55]. Depending on the algorithms used to compute flow accumulation, the directed edges can be given directly to the flow accumulation algorithm, or flow in the right direction can be enforced by (symbolically) modifying the elevations of the vertices, so that each edge is directed down-hill.

31.4.4 Challenges

31.4.4.1 Imprecision

A major challenge with flow analysis on terrain models, is that small differences in elevation can have large consequences. A small error is sufficient to divert a river that passes close to a natural or artificial saddle point into the wrong valley. One way to deal with this, is to make many (hundred or more) different versions of the terrain model, each constructed from the original model by applying random noise according to some probability distribution. Flow accumulation and watershed hierarchy computations are then performed on each version of the model, and results are considered more reliable when they are consistent across the different versions of the model [58,63]. A disadvantage of this approach is that it is computationally expensive (not only flow accumulation but also hydrological correction needs to be computed for each version of the model), it is sensitive to the distribution of noise and the dependencies between the errors on different vertices, and results come without any guarantees even if bounds on the error of the terrain model are known.

Alternatively, one may try to compute the smallest and the largest possible flow accumulation values (and watersheds) for each point in the terrain. Theoretically, it is NP-hard to do so for a linearly-interpolated continuous-surface model, but it can be done in $O(n \lg n)$ time for single-directional discrete-flow models of n vertices, provided bounds on the elevation error of each vertex are known [35]. The algorithm has not been evaluated in practice and raises several questions for further research. One of its shortcomings may be that it gives extreme lower and upper bounds on flow accumulation values without any probability distribution on the range between these extremes. Furthermore, multi-directional flow has not been investigated.

31.4.4.2 Hydrological Correction

Automated hydrological correction still remains a challenge. To our knowledge, bridge detection algorithms have not been implemented for triangulated irregular networks. A natural optimization criterion for hydrological correction could be to apply a combination of raising vertices (flooding) and lowering vertices (breaching) that minimizes the total change in elevation and removes all spurious local minima. Thus, one would avoid flooding large areas where a breach would be the more natural solution. Unfortunately, hydrological correction under this optimization criterion is NP-hard [60] (for a description of NP-hardness see Chapter XXX). Approximation algorithms (see Chapter 7) and/or (i/o-efficient) algorithms that work well under realistic conditions still remain to be developed.

31.4.4.3 Volume and Time

All the techniques discussed above ignore the fact that water has volume: narrow and/or shallow pits and channels cannot process unlimited amounts of water without flooding and diverting flow onto other paths than the path of steepest descent on the surface. In particular, when the purpose of

analyzing the flow of water on a terrain is to predict risks of floods, the limited capacity of pits and channels cannot be ignored. In addition, the time component becomes essential: many floods are not the result of structural undercapacity of a channel over a large time span, but rather the result of too much water from one big shower reaching the same location in the landscape at the same time. Such floods could, for example, be prevented by selectively slowing down or speeding up the drainage from some areas, but the effects of this are not captured by steady-state flow accumulation computations as described in Sections 31.4.1 and 31.4.2. Algorithmic techniques that take volume and time into account and can handle high-resolution terrain models—necessary to capture essential features such as dikes and other barriers adequately—are still in an early stage of development. Arge et al. [10] published an algorithm that can compute the flooding times of all terrain vertices in the discrete-surface model, under the assumption that channels have unlimited capacity but pits fill up as more water arrives. Their algorithm is asymptotically I/O-efficient (running in roughly $O(\text{sort}(n))$ I/O's), but there are no reports on implementations and experiments.

31.5 Visibility Analysis

Another application of terrain models is the computation of visibility. Visibility computations are at the core of many applications, such as planning the placement of communication towers or watchtowers, planning of buildings such that they do not spoil anybody's view, finding routes on which you can travel while seeing a lot or without being seen, and computing solar irradiation maps—which can in turn be used in predicting vegetation cover. A variety of problems pertaining to visibility have been researched in computational geometry and computer graphics, as well as in geographic information science and geospatial engineering.

Two points a and b are visible to each other if the interior of their *line of sight* \overline{ab} (the line segment from a to b) lies entirely above the terrain. Given a terrain and an arbitrary (view)point v (not necessarily on the terrain), the *visibility map* or *viewshed* of v is the set of all points of the terrain that are visible from v . As discussed in Section 31.2.3, the standard terrain models are the grid and the TIN. Viewshed algorithms can be grouped in two classes: *discrete* approaches mark each vertex of a grid or TIN as visible or invisible; *continuous* approaches compute the exact boundaries of the viewshed. Both approaches can be used with both terrain models (grid or TIN), although the discrete approach is usually used on grids, while the continuous approach is usually used on TINs.

Since terrain datasets may be as large as tens and even hundreds of gigabytes, they may not fit in the main memory of a computer all at once and most of the data may have to reside on disk during computations. Hence, computing visibility requires I/O-efficient algorithms. In this section we give an overview of I/O-efficient algorithms for computing viewsheds on terrains, with emphasis on algorithms for grids (Section 31.5.1). We also present some results and considerations for TINs in Section 31.5.2, and end with a set of challenges and open problems in Section 31.5.3.

There are other visibility-related problems on terrains, such as answering point-to-point and region-to-region intervisibility queries, computing horizons, computing depth-under-horizon maps, computing a map that shows the size of each point's viewshed, etc. For brevity, in this chapter we only discuss viewsheds. For other visibility problems and results we refer the interested reader to the surveys by De Floriani and Magillo [33,34] and the references therein.

31.5.1 Visibility on Grids

Viewsheds on grids are usually modeled in a discrete way: each point in the grid is marked as visible or invisible, and the viewshed of v is defined as the set of all grid points that are visible from v . To decide whether a point p is visible, one needs to interpolate the elevation of the terrain along the line of sight \overline{pv} between p and v (more precisely, along the projection of the line of sight on the horizontal plane) and check whether the interpolated elevations are below the line of sight. Various algorithms differ in what and

how many points they select to interpolate along the line of sight, and in the interpolation method used. These choices crucially affect the efficiency and accuracy of the algorithms. Below we discuss a number of viewshed algorithms. For simplicity, we assume that the grid is square and has size \sqrt{n} by \sqrt{n} .

Some of the early algorithms for computing viewsheds have been described by Franklin and Ray [39]. The method called *R3* calculates the intersections between the horizontal projection of the line of sight and the grid lines, and computes the elevation at these intersection points by linear interpolation. Since a line of sight intersects $O(\sqrt{n})$ grid lines, determining the visibility of a point takes $O(\sqrt{n})$ time, and determining the visibility of all points in the grid takes $O(n\sqrt{n})$ time. Franklin and Ray also describe two algorithms that are faster, running in $O(n)$ time, at the expense of accuracy. The algorithm known as *R2* examines lines of sight as above but *only* for the $O(\sqrt{n})$ grid points on the boundary of the grid; a grid point that is not on the boundary is considered to be visible if and only if the nearest point of intersection between a grid line and one of the examined lines of sight is determined to be visible. The other algorithm, *XDraw*, computes the visibility of the grid points incrementally in concentric layers around the viewpoint, starting at the viewpoint and working its way outwards. For a grid point v in layer i , the algorithm computes whether v is visible, and what is the maximum height above the horizon along the line of sight to v . To do so, it determines which are the two grid points q and r in layer $i-1$ that are nearest to \overline{pv} , and then it estimates the maximum height above the horizon along \overline{pv} by interpolating between the lines of sight to q and r . Thus, the visibility of each point is determined in constant time per point. *XDraw* is the fastest of the three algorithms, due to the simplicity of the calculations, but it is also the least accurate. Izraelevitz [46] presented a generalization of *XDraw* that allows to user to set a parameter k , which is the number of previous layers that are taken into account when computing the visibility of a grid point. Thus the user can choose how much speed he is willing to sacrifice for accuracy. For $k = 1$ Izraelevitz's algorithm becomes *XDraw*, and for $k = \sqrt{n}$ it becomes *R3*.

A different approach for computing viewsheds was described by Van Kreveld [65]. In his model, the terrain is seen as a tessellation of square cells, where each cell is centered around a grid point and has the same view angle as the grid point throughout the cell, that is, the cell appears as a horizontal line segment to the viewer—somewhat similar to *R3* if nearest-neighbor interpolation is used instead of linear interpolation. Van Kreveld describes how to compute the viewshed by a radar-like algorithm, rotating a ray around the viewpoint while maintaining a data structure that stores the cells that intersect the ray. This data structure supports insertions of cells, deletions of cells, and visibility queries for a point along the ray in $O(\lg n)$ time per operation, and thus the whole viewshed can be computed while rotating the ray in $O(n \lg n)$ time. Unfortunately the data structure functions correctly only under the assumption that each cell appears as a horizontal segment to the viewer, so that it is not readily adapted to use linear interpolation or other interpolation methods.

None of the algorithms mentioned above are I/O-efficient. I/O-efficient viewshed algorithms have been proposed by Fishman et al. [37] and Andrade et al. [6]. The algorithm by Andrade et al. [6], based on Franklin et al. [38], runs in $O(n \lg n)$ time and $O(\text{sort}(n))$ I/O's in the worst case. As in *R2*, the idea is to evaluate lines of sight only to the points on the perimeter of the grid. To do this I/O-efficiently, the algorithm first copies all grid points from the input file row by row, annotating each point p with the endpoints of the lines of sight whose evaluation requires the elevation of p . Next, all annotated points are sorted by line of sight. The algorithm then evaluates each line of sight, determining for each point on a line of sight whether it is visible or not, and writes the results to a file, in order of computation. As a result, the file contains the visibility map, ordered by line of sight. The algorithm finishes by sorting this file into row-by-row order. The algorithm is very fast in practice. For example, using at most 1.0 GB of memory and a 7200 RPM hard drive, viewsheds on grids of 1600 million points (6.0 GB, using 4 bytes per elevation value) are computed within 2 h, that is, in 4.4 μ s per point.

Fishman et al. describe two I/O-efficient viewshed algorithms based on Van Kreveld's approach [37]. A direct implementation of Van Kreveld's algorithm would result in inefficient I/O-behavior. This can be solved by first sorting all grid cells by the time at which they will be hit by the rotating ray—similar to the sorting by line of sight in the algorithm of Andrade et al. To save on the time needed for sorting, Fishman et al. sort

the grid cells only partially, but still enough to make the evaluation phase run i/o-efficiently. Two solutions are considered: sorting into concentric bands around the viewpoint, or sorting into sectors. Both solutions run in $O(n \lg n)$ time and $O(\text{scan}(n))$ i/o's on inputs of reasonable size, and can be extended to run in $O(\text{sort}(n))$ i/o's on larger inputs. The algorithms are very fast in practice and scale up to terrains that are more than order of magnitude larger than the available memory. For example, on a machine with 512 MB of memory and a laptop-speed (5400 RPM) hard drive, the viewshed of a terrain of 7600 million points (28.4 GB using 4 bytes per elevation value) is computed in 430 min, that is, in 3.4 μ s per point.

Fishman et al. also describe a different, faster approach, which runs in $O(n)$ time and $O(\text{scan}(n))$ I/Os with a cache-oblivious algorithm, that is, an algorithm that is i/o-efficient even if not tuned explicitly to a specific memory and block size. It is somewhat similar to XDraw: it grows a region around the viewpoint, while maintaining the horizon of the terrain within the region seen so far. The horizon is represented by a grid model itself: the algorithm maintains the maximum elevation angle (the “height”) of the horizon for a discrete set of regularly spaced azimuth angle intervals. The horizontal resolution of the horizon model is chosen to be similar to the horizontal resolution of the original terrain model, so that elevation angles are maintained for $\Theta(\sqrt{n})$ azimuth angle intervals. Note that this gives the algorithm the potential for higher accuracy than XDraw, which represents the horizon up to a given layer by only as many grid points as there are in that layer—which can be quite inaccurate close to the viewpoint. Another difference with XDraw is that the algorithm of Fishman et al. does not proceed layer by layer, but instead grows the region in a recursive, more i/o-efficient way. This results in a significant speed-up and makes the algorithm of Fishman et al. the fastest of the i/o-efficient algorithms presented here (provided it is tuned to the available amount of memory, like the algorithms mentioned above). For example, on a machine with 512 MB of memory and a laptop-speed (5400 RPM) hard drive, the viewshed of a terrain of 7600 million points (28.4 GB using 4 bytes per elevation value) is computed in only 200 min, that is, in 1.6 μ s per point.

A proper comparison of viewshed algorithms needs to include both efficiency and accuracy. While efficiency is easy to compare, even accounting for different platforms, comparing accuracy is much harder. The straightforward way to assess accuracy is to compare the results of the computations with ground truth data. Ideally one would consider a large sample of viewpoints, compute the viewshed from each one in turn, compare it with the real viewshed at that point, and aggregate the differences. Unfortunately, ground truth viewsheds are hard, if not impossible, to obtain for larger grids. Thus one needs to define accuracy in relative terms, with respect to a base algorithm that is considered exact. An experimental evaluation of the accuracy of the various viewshed algorithms proposed so far remains an open problem.

31.5.2 Visibility on TINs

Visibility on TINs is usually modeled with a continuous model, in which the elevation of any point p on the terrain is defined by linear interpolation between the vertices of the triangle that contains p . Given a point v , the goal of a viewshed computation is to determine, for each triangle τ in the TIN, what part of τ is visible. Several algorithms are known for computing viewsheds on a TIN. The algorithm with the best known theoretical bounds on the number of computational steps is by Katz et al. [47] and runs in $O((n\alpha(n) + k)\lg n)$ time, where n is the number of triangles of the TIN, k is the size of the output and $\alpha()$ is the inverse Ackermann function.*

In the worst case, the size of the output could be quite big. The boundary of the visible part of a triangle is basically the boundary of the shadow cast by other, possibly many, triangles of the TIN when a light source is placed at v . In the worst case, in a TIN of size n there may be $\Theta(n)$ triangles such that the boundary of the visible part of each of them consists of $\Theta(n)$ line segments, and thus a complete visibility map may have size $\Theta(n^2)$ [25]. Such high complexity of the viewshed would make its computation unfeasible, especially on large TINs.

* We note that $\alpha(n) \leq 4$ as long as n is at most the estimated number of atoms in the observable universe; therefore $\alpha(n)$ can be considered constant for all practical purposes.

Fortunately, in practice the complexity of viewsheds seems to be close to linear. Moet et al. [54] and De Berg et al. [31] give a theoretical explanation based on assumptions on the shape of the terrain. Given arbitrary constants $\alpha > 0$, $\theta < \frac{\pi}{2}$, $\sigma \geq 1$, we say that a set of terrain triangles is *fat* if all angles (in the projection on the plane) are at least α ; the set is *non-steep* if the angle of each triangle with the horizontal plane is at most θ ; the set has *bounded scale factor* if the length ratio of the longest and the shortest edge is at most σ . Furthermore, given an arbitrary constant $\rho \geq 1$, we say a terrain has *bounded aspect ratio* if its projection on the horizontal plane is a rectangle with aspect ratio at most ρ . Moet et al. [54] prove that the worst-case complexity of the viewshed is $\Theta(n\sqrt{n})$ if the terrain has bounded aspect ratio and its triangles are fat and have bounded scale factor (the constants in the asymptotic bound depend on α , σ , and ρ). De Berg et al. [31] prove that the expected complexity of any viewshed on any terrain is $O(n)$ provided all except $O(\sqrt{n})$ triangles are fat, non-steep and of bounded scale factor and the elevation of each TIN vertex is subject to random noise that is proportional to the length of the longest edge.

Many applications need to compute viewsheds from many viewpoints, for example an application that tries to find a small number of locations that can together oversee a complete terrain. Such applications cannot afford to spend linear time on each viewshed. The complexity of the output can be reduced by only reporting the boundary of the complete viewshed and not the visible parts of each triangle, but in the worst case this will not help (even under the assumptions of De Berg et al.). To be sure to obtain a viewshed in sublinear time, one needs to resort to approximations. In many cases the digital terrain model itself is not completely accurate, so an algorithm that gives good approximations fast is a good trade-off.

Several algorithms to compute an approximation of the viewshed on a TIN together with an experimental analysis are described by Ben-Moshe et al. [14]. Their best algorithm works by dividing the area around the viewpoint into a number of slices: each slice is bounded by two rays from the viewpoint. The algorithm computes a one-dimensional visibility map along each ray. If the visibility maps of the two rays bounding a slice are similar enough, the visibility map of the whole slice is constructed by interpolation between the bounding rays; otherwise the slice is subdivided into smaller slices.

Another approach to approximating visibility is to simplify the terrain to reduce its size and compute visibility on the simplified terrain; see, for example, Ben-Moshe et al. [15]. Standard simplification methods typically simplify the terrain such that the vertical distance between the simplified terrain and the original terrain is within a user defined margin ϵ . The idea of Ben-Moshe et al. [15] is that vertical distance does not matter much for visibility: the most important features that need to be preserved are the ridges. Their algorithm computes the ridge network and simplifies it (by keeping only a small number of its vertices); this induces a subdivision of the terrain into “patches,” which they simplify, one at a time, using one of the standard methods. To compare visibility on the original terrain T and simplified terrain T' , they compute, given a set of points X , the fraction of pairs of points in X that have the same visibility in T and T' (i.e. they are both visible or both invisible). Their experimental analysis shows that this approach preserves visibility better (according to their metric) than standard simplification methods.

31.5.3 Challenges

As already mentioned, a question that remains to be addressed is how various viewshed algorithms proposed so far compare with respect to accuracy. Without such a comparison the relative merits and tradeoffs of the algorithms cannot be judged.

Another question is how to compute viewsheds of sublinear complexity in sublinear time, that is, can we preprocess grids and TINs such that we can compute a viewshed of k grid points, or a viewshed bounded by k line segments, in time linear in k but sublinear in n ? In practice viewsheds tend to be very small compared to the size of the terrain, especially on very large terrains. An output-sensitive (and preferably I/O-efficient) algorithm with running time sublinear in n , may significantly improve the overall running time in practice.

Although the I/O-efficient viewshed algorithms proposed by Andrade et al. and by Fishman et al. are fast, their running times are still too high to make them suitable for the computation of many viewsheds of the same terrain, or for online calculations. A challenge is to develop viewshed approximation algorithms that trade off speed and accuracy, and for which the error can be quantified and bounded in some way.

Viewsheds on TINs have been less studied from a practical point of view, probably because continuous viewsheds are more complex and therefore less appealing in practice. Exploring viewsheds on TINs, testing the scalability of the algorithms to very large TINs and developing I/O-efficient algorithms for TINs are problems yet to be considered.

31.6 Concluding Remarks

In this chapter we discussed some basic problems and solutions regarding the analysis of terrain data. We have seen a number of efficient and effective algorithms that have been implemented in commercial and academic geographic information systems. However, there are also many problems for which satisfactory solutions do not exist yet.

Dealing with increasingly high-resolution data means dealing with increasing amounts of noise and errors that cannot be corrected by hand. This requires increasingly better techniques for cleaning, filtering and hydrological correction. Dealing with increasingly high-resolution data also means running into the limits of the simplifying assumptions that were made in the past—such as ignoring the volume of water; new algorithmic techniques need to be brought to the geosciences to deal with this in an efficient way. Last but not least, dealing with increasingly high-resolution data means that we need increasingly fast algorithms. It is therefore important to take full advantage of the parallel computing power that is becoming increasingly available, for example in the form of graphics processing units.

A shortcoming of many of the algorithms presented in this chapter, is that it is not clear what exactly they compute. There is no analysis of how accurate the output of the algorithms is as compared to a ground truth. Algorithms do not take the error margins on the input into account and do not output error margins with their results. This holds for algorithms on grid models as well as for algorithms on (usually linearly interpolated) TIN models, both of which are just approximations of an actual terrain. This leads not only to inherently unreliable results, but also to a wasteful use of computational resources. Lacking a thorough analysis of what errors in the input may cause what errors in the output, we may run hundreds of computations on ever-higher-resolution terrain models, requiring ever-more-sophisticated noise removal techniques, but the extent of uncertainty remains unknown.

32.1 Introduction

Geometric primitives are the basic building blocks for creating sophisticated objects in computer graphics and geometric design. They provide familiarity, uniformity, and standardization and also enable hardware support.

Initially, the definition of geometric primitives was driven by the capabilities of the hardware. Only simple primitives were available, for example, points, line segments, and triangles. In addition to hardware constraints, other driving forces in the development of geometric primitives have been either general applicability to a broad range of needs or wide applicability in restricted domains. The triangular facet is an example of a primitive that is simple to generate, easy to support in hardware, and widely used to model many graphics objects. The sphere is included in the primitive set of most software libraries and software products, for example, AutoCAD, Maya, Rhinoceros, SketchUP, and CATIA. More specialized primitives have also been developed, for example, in architectural modeling where a door might be considered as a primitive in a building information model (BIM) or in chemical modeling where a particular molecule configuration would be considered as primitive. So, what is a geometric primitive? Here we qualify the definition based on simplicity of the object and frequency of use based on computer-aided design (CAD)/computer-aided manufacturing (CAM), computer-aided engineering (CAE), computer graphics, animation, and industrial styling systems. We are cognizant that other readers may choose a somewhat different set of primitives based on their experiences, for example, editing operations like push/pull, but we have strived to select the most comprehensive base available in current software.

As hardware, central processing unit (CPU), and the number of specialized applications increased in capability, sophistication of primitives grew as well. Primitives became somewhat less dependent on hardware and subsequently software primitives became more common. For raw speed, however,

hardware primitives still dominate, for example, it is widespread practice in computer graphics engines to partition any primitive object into triangles.

One direction for the expansion of graphics primitives has been in the geometric order of the primitive. Initially, primitives were discrete or first-order approximations of objects, that is, collections of points, lines, and planar polygons. This has been extended to higher-order primitives represented by polynomial or rational curves and surfaces in any direction. The other direction for the expansion of primitives has been in attributes that are assigned to the geometry. Color, transparency, associated bitmaps and textures, surface normals, and labels are examples of attributes attached to a primitive for use in its display. Since the focus of this chapter is on geometry, attributes are beyond the scope of this discussion.

This summary of graphics primitives will first describe representative examples used in practice. We then draw upon these examples to discuss the fundamental principles underlying primitives. Finally, we highlight some future directions in the field of geometric primitives being pursued in academia and industry.

32.2 Examples in Practice

32.2.1 Screen Specification

Screen specification is closely related to object geometry and is the coordinate frame wherein all primitives lie. The problem of rendering a graphics primitive on a raster screen is called *scan conversion*. It is the scan conversion method that is embedded in hardware to accelerate and improve the display of graphics in a system.

32.2.2 Simple Primitives

The primitives are described here in roughly the chronological order of their development, which basically corresponds to their increase in complexity. This chapter concentrates on common primitives. We will distinguish between *design primitives* and *database primitives*. A *design primitive* is input data that form an integral part of the geometric model, whereas a *database primitive* is a tool that is used to assist in the design process or the way in which it is saved in memory, but does not form part of the model (Figure 32.1).

32.2.2.1 Points

A *point* represents a zero-dimensional object. A point can be part of a bitmap representation of an object, for example, line and text, or used as a construction tool, for example, control vertex (CV). The classic example of point as design primitive is its use in text. There are two standard ways to represent

FIGURE 32.1 Example of database primitive vs. design primitive. The design primitive is the sphere, deformed here, for example. Database primitives are seen in each screen capture: (a) CVs and isocurves, (b) universal manipulator frame, (c) normals to surfaces, and (d) underlying triangulated surface tessellation. Model created in Autodesk Maya.

FIGURE 32.2 The drawing in (a) represents the Arabic letter hamza (e). Details show the effect of (b) anti-aliasing to smooth out jagged edges; (c) bitmap pixilation, jagged edges, as the result of aliasing; and (d) rotation on pixilation; note how transformation changes the pixilation.

textual characters for graphics purposes. The first method is to save a representation of the characters as a bitmap, called a *font cache*. This method allows fast reproduction of the character on-screen. Usually the font cache has more resolution than needed, and the characters are pixelated. Even on high-resolution devices such as a quality laser printer, the discrete nature of the bitmap can be apparent, creating jagged edges. When transformations are applied to bitmaps such as rotations or shearing, aliasing problems can also be apparent. See the examples in Figure 32.2.

To improve the quality of transformed characters and to compress the amount of data needed to transfer text, a second method for representing characters was developed using polygons or curves. When the text is displayed, the curves or polygons are scan-converted; thus, the quality is constant regardless of the transformation. The transformation is applied to the curve or polygon basis before the scan conversion. PostScript is a well-known product based on text transferal (see Adobe Systems Inc., 1999). In a PostScript printer, for instance, the definition of the fonts resides in the printer where it is scan-converted. Transfer across the network requires only a few parameters to describe font size, type, style, etc. Those printers that do not have resident PostScript databases and interpreters must transfer bitmaps with a resulting loss of quality and time. PostScript is based on parametrically defined curves called Bézier curves (see Section 32.3).

An important trend in 3D surface representation is using points instead of polygons, that is, a *point cloud* may be used where a dense set of points defines the surface of an object (Figure 32.3a). Unlike triangular meshes, points do not require connectivity data. For further information see Levoy and Whitted (1985), Rockwood (1986), Rockwood (1987), and Pauly et al. (2003).

FIGURE 32.3 Three renderings of a camel head model: (a) point cloud model (rendered in MeshLab), (b) triangulated mesh model with bounding box (rendered in SketchUP), and (c) triangulated mesh model with CVs shown (ghosted rendering in Rhinoceros). Open source model “camello” by robertttitto in SketchUP 3D Warehouse (<http://sketchup.google.com/3dwarehouse> [accessed October 23, 2013]).

32.2.2.2 Lines and Polylines

Together with points, one of the most prevalent graphics primitives is the *line segment*, typically specified by “move to (x_1, y_1) ” and then “draw to (x_2, y_2) ” commands, where (x_1, y_1) and (x_2, y_2) are the end points of the line segments. The end points can also be given as 3D points and then projected onto the screen through viewing transformations.

A line segment can be easily extended to a *polyline* graphics primitive, that is, to a piecewise polygonal path. It is usually stored as an array of 2D or 3D points. The first element of the array tells how many points are in the polyline. The remaining array elements are the arguments of the line drawing commands. The first entry invokes the “move to” command; successive array entries use the “draw to” command as an operator.

Because of the discrete, pixel-based nature of the raster display screen, lines are prone to alias; that is, they may break apart or merge with one another to form distracting *moiré* patterns (Creath and Wyant 1992). They are also susceptible to jagged edges, a signature of older graphics displays. Advanced line drawing systems found it therefore important to add hardware that would *anti-alias* their lines while drawing them (Freeman 1974; Crow 1977) (Figure 32.2b). Where aliasing produces false artifacts by under sampling, anti-aliasing reduces those artifacts either by more intelligent or higher resolution sampling.

32.2.2.3 Polygons

Closing a polyline by matching start and end points creates a polygon, for example, quadrangle and triangle (see Appendices 32.A and 32.B). It is probably the most commonly employed primitive in graphics, because it is easy to define an associated surface. Because of their usefulness for defining surfaces, polygons almost always appear as 3D primitives that subsume the 2D case.

The most sophisticated polygon primitive allows non-convex polygons that contain other polygons, called *holes* or *islands* depending on whether they are filled or not. A complex polygon is often made as a macro out of simple polygon primitives for example, in Open Graphics Library (OpenGL) it would be written as a strip of triangles (Figure 32.4). There are many triangulation routines to reduce polygons to simple triangular facets.

Associated surfaces, or faces, can be created with a polygon where the edges form the boundaries of the surface. Vertices represent the positions where the end points of surface edges meet.

32.2.2.4 Triangular Facet

If the polygon is the most popular primitive, the simple triangle is certainly the most popular polygon. Figure 32.3b and c shows a model of a camel composed of triangular facets.

FIGURE 32.4 Strip of triangular facets: lead triangle (thick lines), successive triangles (thin lines); vertices of start triangle indicated as v_1 , v_2 , and v_3 ; “path” (lines that connect vertices 1–3); and bounding box of triangle (lines that form a square around the triangle and intersect with vertices).

The triangular facet is fast to draw and supports more complex polygons as well as many more diverse and powerful operations. Another major advantage is that they are always flat; their vertices do not have to leave the plane and avoid numerical problems, data errors, or non-planar preserving transformations. Currently, graphics cards are designed to handle raw triangles in the order of millions, where the limit is given by the memory size of the graphics card and time required for the render process (measured in frames per second); the current limit in memory size is around 6GB.

In order to increase the performance of polygon rendering and decrease the size of the file database, triangular and quadrilateral facets can be stored and processed as meshes, that is, collections of facets that share edges and vertices. The triangular mesh, for instance, is given by defining three vertices for the “lead” triangle and then giving a new vertex for each successive triangle (Figure 32.4). The succeeding triangles use the last two vertices in the list with the newly given one to form the next triangle. Such a mesh contains about one-third the data and uses the shared edges to increase processing speed. Most graphics objects have large contiguous areas that can take advantage of meshing, which turns out to be a compression technique. The quadrilateral mesh requires two additional vertices be used, with the last two given, and therefore has less savings.

Because of its benefits and ubiquity, many other primitives are defined in software as configurations of the triangular facet. One example is the faceted sphere. With enough facets the sphere will look smooth (see Figure 32.9). It is commonly encountered in engineering applications and molecular modeling.

32.2.2.5 Elliptical Arcs

Elliptical arcs in 2D may be specified in many equivalent ways. One way is to give the center position, major and minor axes, and start and end angles. Both angles are given counterclockwise from the major axis. It should be mentioned that arcs can also be represented by a polyline with enough segments; thus, a software primitive for the arc that induces the properly segmented and positioned polyline may be a cost-effective *macro* for elliptical arcs (Figure 32.5). This macro should consider the effects of zoom and perspective to avoid revealing the underlying discretization of the arc. It is surprising how small a number of line segments, properly chosen, can give the impression of a smooth arc. One of the most commonly used elliptical arcs is, of course, the circular arc.

32.2.2.6 Curves: Bézier, Splines, and NURBS

The four most common design primitives for drawing more complex curves are the polynomial and rational *Bézier*, *B-spline*, nonuniform rational B-spline (*NURBS*), and *interpolating splines*, that is, *fit*

FIGURE 32.5 Ellipse with decreasing discretization of curve, that is, 226, 24, and 8 line segments, from right to left. Inset shows typical user interface for drawing ellipses using alternative input data options, that is, center point, axis direction and end point, or arc length. (Screen capture from AutoCAD.)

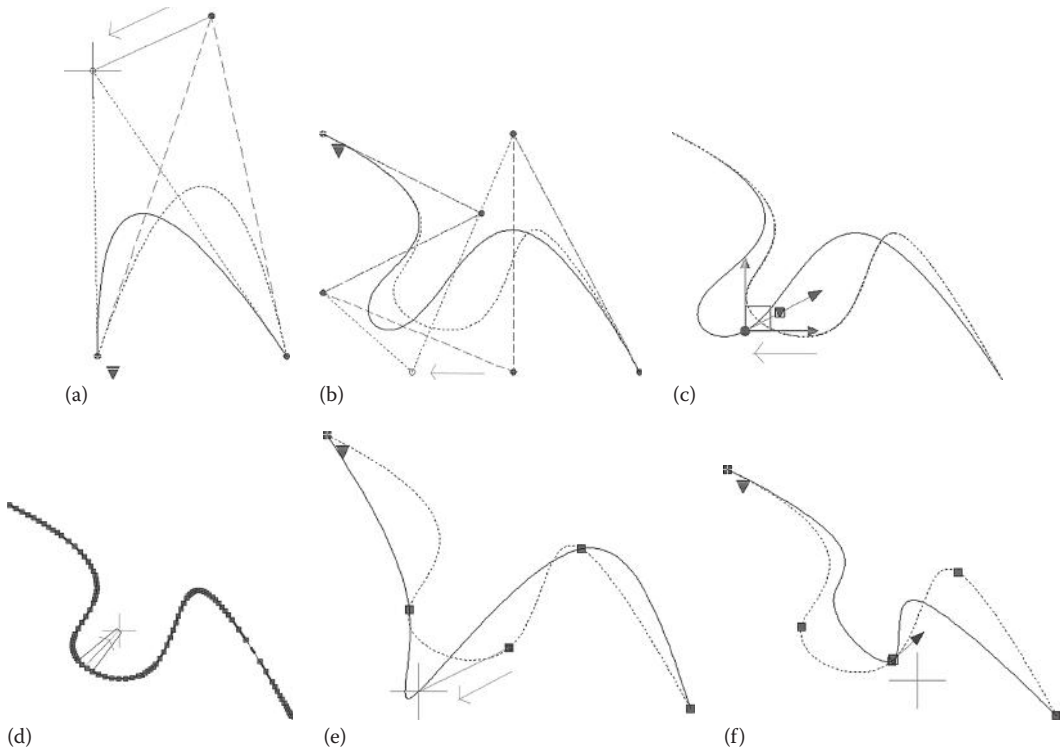

FIGURE 32.6 Typical curve types and effect of editing: (a) Bézier (dashed lines represent the curve’s control polygon); (b) Bézier converted to polyline; (c) NURBS, with moved point; (d) B-spline; and (e) fit points (Lagrange interpolation); and (f) NURBS, with moved tangent.

points (AutoCAD) (Figure 32.6). See Section 32.3 for the theory underlying parametric modeling of curves. All polynomial curve types possess a specified degree (the degree implies the number of control points that influence any given point on the curve). Characteristics, such as editability, computational complexity, and ease of use, vary (see Table 32.1).

The *Bézier* method has a strict relation between degree and number of CVs (see Rockwood and Chambers 1996, p.55). End points are fixed and the other CVs lie off the curve. Each curve has generating functions and all CVs affect the curve. The Bézier curve is more difficult to edit due to the fact that moving a single CV changes the global shape of the curve. There is a generating (basis/blending) function for each CV, and at a particular parameter value, the basis functions yield the blending factor for the CV, for example, at $t = 0$, the basis function for $C^0 = 1$ and the others are 0, which produces the interpolation. More details will follow.

The *B-spline* method (Birkhoff and de Boor 1965) concatenates Bézier curves in a succinct user interface. Bézier end points automatically connect and tangents align, achieving continuity of curve, that is, if degree is n , we get $n - 1$ continuity.

TABLE 32.1 Curve Types and Characteristics

Curve Type		Characteristics		
Bézier	Partition of unity	Uniform	Global influence	End point interpolation
B-spline	Partition of Unity	Uniform	Local influence	Noninterpolating
NURBS	Partition of unity	Nonuniform	Local influence	Noninterpolating
Fit points	Non-POU	Nonuniform	Local influence	Interpolates every point

Good editability requires that curves and surfaces allow options of degree and CV weight (influence) together with automatic curvature continuity when concatenating or adding new segments. *NURBS* stands for nonuniform rational B-spline, and the input required are degree, weighted CVs, and knot vectors (a knot vector is a way to specify the weighting factors with a visually convenient sequence of points on the domain line; see Figure 32.12). Nonuniform means that the knots are not evenly spaced. Rational indicates that the CVs are weighted by a rational factor. Adding or removing interior control points, which requires adding or removing a corresponding knot, on a curve allows local refinement. This allows nonuniform subdivision of *NURBS* curves and surfaces making it a good way to add local complexity. Nonrational splines or Bézier curves may approximate a circle, but they cannot represent it exactly. Rational splines can represent any conic section exactly, including the circle (Piegl and Tiller 1987).

The *fit point* method uses Lagrange interpolation (Berrut and Trefethen 2004) to create an interpolatory B-spline. A special case of the fit point method includes two tangent controls at each point, for example, the “paths” in Adobe (see also Hermite interpolation, e.g., Bartels et al. 1987).

The optimal work flow for modeling curves would be to design and save in B-splines but operate in Bézier form, which provides greater stability and speed, and restore curves in B-spline or *NURBS* since these are more compact to store.

32.2.3 Solid Geometry Primitives

Before describing each solid geometry primitive, it is worth mentioning the importance of the *Euler characteristic* (see Richeson 2008). In mathematics and computer graphics, one can create objects that could never be built, for example, self-intersecting surfaces. The Euler characteristic is one way of identifying whether or not an object is buildable. The *Euler characteristic*, usually denoted as *chi* χ , was classically defined for the surfaces of polyhedra, according to the formula

$$\chi = V - E + F$$

where V , E , and F are, respectively, the numbers of vertices, edges, and faces in the given polyhedron. Any deformation of the ball without self-intersection, including all convex polyhedra, has Euler characteristic $\chi = 2$, whereas with a torus, for example, $\chi = 0$.

The most widely accepted solid geometry primitives are cube, pyramid, cylinder, cone, sphere, ellipsoid, and torus, as briefly described in the following (Figure 32.7).

FIGURE 32.7 The most fundamental solid geometry primitives: cube, sphere, pyramid, cylinder, ellipsoid, cone, and torus. The paraboloid and truncated cone are often considered primitives in many modeling software packages. Software used to create these images include Autodesk Maya, AutoCAD, Adobe Photoshop, SketchUP, MeshLab, and Rhinoceros.

(continued)

FIGURE 32.7 (continued) The most fundamental solid geometry primitives: cube, sphere, pyramid, cylinder, ellipsoid, cone, and torus. The paraboloid and truncated cone are often considered primitives in many modeling software packages. Software used to create these images include Autodesk Maya, AutoCAD, Adobe Photoshop, SketchUP, MeshLab, and Rhinoceros.

32.2.3.1 Cube

A *cubeoid* or *rectangular box* is bounded by six rectangular faces, three of which meet at each vertex. The special case is the cube, a platonic solid, which is bounded by six equal faces (Figure 32.7a).

32.2.3.2 Pyramid

A *pyramid* is formed by connecting a polygonal base, often a square, and a point, or apex. Each base edge and apex forms a triangle. A pyramid with an n -sided base will have $n + 1$ vertices, $n + 1$ faces, and $2n$ edges. A tetrahedron is a special type of pyramid with triangular base, often referred to as a “triangular pyramid” (Figure 32.7c). The generalization of the tetrahedron is the “simplex.” A simplex is the extension of a triangle into higher dimensions and always contains the minimum number of vertices, edges, faces, and hyperfaces for its dimension. See Boole Stott (1910), Coxeter (1988), and Grünbaum (2003) for more on polyhedra.

32.2.3.3 Cylinder and Cone

A cylinder is a solid of circular cross section in which the centers of the circles all lie on a single straight line (Figure 32.7d). A cone is a pyramid with a circular base and cross section (Figure 32.7f). Intersecting a double cone with an inclined plane is particularly instructive since the resultant conic sections represent the quadratic curves, that is, circles, ellipses, parabolas, and hyperbolas (Figure 32.8).

32.2.3.4 Sphere, Ellipsoid, and Torus

A sphere is defined as the set of all points in 3D Euclidean space \mathbb{R}^3 that are located at a fixed distance, r (radius), from a given center point or origin (see Coxeter 1942) (Figure 32.7b). Figure 32.9d shows a

FIGURE 32.8 Conic sections; when a cone is cut through by a plane, depending on the angle of the plane, the resultant section cut is a circle, ellipse, parabola, or hyperbola. (Adapted from Weissten, E.W., MathWorld—A wolfram web resource <http://mathworld.wolfram.com/ConicSection.html> [accessed October 23, 2011].)

FIGURE 32.9 (a)–(d) Loop subdivision of tetrahedron results in triangular faceted sphere; (e)–(h) first three steps of Catmull–Clark recursive subdivision algorithm applied to simple polyhedral. (Models created by Yongliang Yang.)

faceted sphere resulting from a process of *recursive subdivision* (see the following) that started from a double pyramid. The problem of structuring the surface of a sphere and curved shapes, for example, with triangles, quadrilaterals, combination, or pentagons and hexagons, continues to be a challenging research issue in the field of geometric modeling. A *torus*, a closed surface with a single handle, is the only example thus far of a primitive higher than second order (Figure 32.7g).

32.2.3.5 Polygonal Extrusions (Prisms)

Modeling often starts with a geometric primitive, or combination of primitives, that is then modified according to design intent, for example, recursive subdivision shown in Figure 32.9e–h. When a polygonal plane is extruded, it will form a *prism* or a *polysolid*. It should be noted here that as part of the 3D modeling working method, wireframe models are often used, particularly in engineering and drafting applications, because of their visual precision (pyramid in Figure 32.7c). Additional advantages with wireframe are improved working speeds and the ability to see parts of the object that would otherwise be obscured by surface attributes. Wireframe objects do not support realism, however, and most objects have a surface that is assigned attributes such as material, color, and reflectance.

32.3 Underlying Principles of Geometric Representation

32.3.1 Fundamental Theorem of Geometric Modeling

There are three ways of mathematically expressing geometric objects, namely, *explicit*, *implicit*, and *parametric*. An *explicit* representation of an object is an algebraic expression that associates an input from an arbitrary dimension to another quantity also known as the output such as

$$f(x, y) = x^2 + y^2, \text{ mapping from } \mathbb{R}^2 \rightarrow \mathbb{R}$$

This form is probably the most familiar to the reader, but it has a caveat for geometric design because its shape requires multiple values, but it is a single value function, for example, in the definition of a circle:

$$x = \pm\sqrt{r^2 - y^2}$$

In general, another issue with this form is that derivatives cannot always be defined, for instance, at the intersection with the x-axis (see Figure 32.10).

The *implicit* form can be seen as an extension of the explicit form in one dimension higher, with an additional equation that is set equal to a constant and therefore limits the space, for instance,

$$f(x, y) = z = x^2 + y^2 - r^2$$

$$x^2 + y^2 - r^2 = 0$$

FIGURE 32.10 Diagram showing caveats for explicit representation of geometric design; undefined derivatives (points shown left and right on circle); vertical line test (dotted line through undefined derivative); multiple-valued function (solid vertical line intersecting two points on circle).

This yields a system of 2 equations and 3 unknowns. A major advantage of this representation is that it allows us to determine where a point lies relative to the surface, that is,

$$F(x) > 0, \text{ if } x \text{ is "outside" the surface}$$

$$F(x) = 0, \text{ if is "on" the surface}$$

$$F(x) < 0, \text{ if } x \text{ is "inside" the surface}$$

The *parametric* representation is a system of variables and constraints in which some of the variables, known as *parameters*, are used as generators and the other variables sweep out the object; this representation is helpful when the objective is to easily find points in a plot or to sweep a curve with an additional variable such as time. For example, the parametric equation of a unit circle is

$$x = \cos(t)$$

$$y = \sin(t)$$

with t varying across the interval $[0, 2\pi]$.

In this example x, y specify the object, and t is the generating parameter. This representation also yields a system of equations that has 3 unknowns (x, y, t) and 2 constraints. Note that in order to transform between implicit and explicit forms, the forms must satisfy certain conditions; see implicit and inverse function theorems (Spivak 1965).

32.3.1.1 Degrees of Freedom

If you subtract the number of equations from the number of variables, you can get the intrinsic dimension of the object (Table 32.2). Position in space given by a cubic Bézier curve at a certain time t can be represented as follows:

$$P(t) = (1-t)^3 P_0 + 3(1-t)^2 t P_1 + 3(1-t) t^2 P_2 + t^3 P_3$$

$$P_0 = \begin{pmatrix} x_0 \\ y_0 \\ z_0 \end{pmatrix}, P_1 = \begin{pmatrix} x_1 \\ y_1 \\ z_1 \end{pmatrix}, P_2 = \begin{pmatrix} x_2 \\ y_2 \\ z_2 \end{pmatrix}, P_3 = \begin{pmatrix} x_3 \\ y_3 \\ z_3 \end{pmatrix}$$

P represents a 3-tuple. This parametric form has 4 variables (x, y, z, t), described by 3 equations in x, y , and z , and the degree of freedom is then 1, which implies a curve.

TABLE 32.2 Dimension of Shape Can Be Deduced from Number of Unknowns and Equations

1 unknown	1 equation	0 dimension	Point
3 unknowns	2 equations	1 dimension	Curve
4 unknowns	2 equations	2 dimension	Surface
5 unknowns	2 equations	3 dimension	Volume
6 unknowns	2 equations	4 dimension	Hypervolume

32.3.2 Implicit Modeling

32.3.2.1 Implicit Primitives

The need to model mechanical parts drove the definition of implicitly defined primitives. These modeling primitives naturally became graphics primitives to serve the design industry. They have since been used in other fields such as animation and architecture.

An implicit function f maps a point x in \mathbb{R}^n to a real number, that is, $f(x) = r$. Usually, $n = 3$. By absorbing r into the function, we can view the implicit function as mapping to zero, that is, $g(x) = f(x) - r = 0$. The importance of implicit functions in modeling is that the function divides space into three parts: $f(x) < 0$, $f(x) > 0$, and $f(x) = 0$, as mentioned earlier. The last case defines the surface of an *implicit object*. The other two cases define, respectively, the *inside* and *outside* of the implicit object. Hence, implicit objects are useful in *solid modeling* where it is necessary to distinguish the inside and outside of an object. A polygon does not, for instance, distinguish between the inside and outside. It is, in fact, quite possible to describe an object in which inside and outside are ambiguous. This facility to determine inside and outside is further enhanced by using Boolean operations on the implicit objects to define more complex objects (see CSG objects in the following) (Figure 32.11).

Another advantage of implicit objects is that the surface normal of an implicitly defined surface is given simply as the gradient of the function: $N(x) = \nabla f(x)$. Furthermore, many common engineering surfaces are easily given as implicit surfaces; thus, the plane (not the polygon) is defined by $n \cdot x + d = 0$, where n is the surface normal and d is the perpendicular displacement of the plane to the origin. The ellipsoid is defined by $(x/a)^2 + (y/b)^2 + (z/c)^2 - r^2 = 0$, where $x = (x, y, z)$. General *quadratics*, which include ellipsoids, paraboloids, and hyperboloids, are defined by $x^T M x + b \cdot x + d = 0$, where M is a 3-by-3 matrix and b and d are vectors in \mathbb{R}^3 . The quadrics include such important forms as the cylinder, cone, sphere, paraboloids, and hyperboloids of one and two sheets. Other implicit forms used are the torus, blends (transition surfaces between other surfaces), and *superellipsoids* defined by $(x/a)^k + (y/b)^k + (z/c)^k - R = 0$ for any integer k .

32.3.2.2 CSG Objects

An important extension to implicit modeling arises from applying set operations such as union, intersection, and difference to the sets defined by implicit objects. The intersection of six half spaces defines

FIGURE 32.11 Boolean principles of subtraction ($-$), union (\cup), and intersection (\cap) are shown here using the primitives sphere and box.

a cube, for example. This method of modeling is called *constructive solid geometry* (CSG) (Foley 1990; Foley et al 1994). All set operations can be reduced to some combination of just union, intersection, and complementation (Figure 32.11). Because these create an algebra on the sets that is isomorphic to Boolean algebra, corresponding to multiply, add, and negate, respectively, the operations are often referred to as *Booleans*. Note that this is equivalent to directed acyclic graph (DAG) (Bang-Jensen and Gutin 2009). For example, an object could be made from Boolean parts of plane quadrics, a part torus, and blended transition surfaces. Unfortunately, implicit forms tend to be more expensive to render because algorithms for polygonizing implicit objects and CSG models tend to be quite complex (Bloomenthal 1988). The implicit object gives information about a point relative to the surface in space, but no information is given to tessellate into rendering elements such as triangular facets. In the case of ray tracing, however, the parametric form of a ray $x(t) = (x(t), y(t), z(t))$ composed with implicit function $f(x(t)) = 0$ leads to a root-finding solution of the intersection points on the surface, which are critical points in the ray-tracing algorithm. Determining whether points are part of a CSG model is simply exclusion testing on the CSG tree.

32.3.3 Parametric Modeling

32.3.3.1 Parametric Curves

When modeling with implicit equations, as described earlier, we know whether a point is inside or outside the model. When modeling with parametric equations, on the other hand, we know exactly where a point is on the surface. This makes parametric modeling more convenient for rendering compared to implicit since we can triangulate or texture map.

An important class of geometric primitives is formed by parametrically defined curves and surfaces. These constitute a flexible set of modeling primitives that are locally parameterized; thus in space, the curve is given by $P(t) = (x(t), y(t), z(t))$ and the surface by $S(u, v) = (x(u, v), y(u, v), z(u, v))$. In this section and the next one, we will give examples of only the most popular types of parametric curves and surfaces. There are many variations on the parametric forms (Farin 2002).

32.3.3.1.1 Bézier Curves

A Bézier curve is a parametric curve widely used in computer graphics (De-Casteljau 1959; Bézier 1974). Bézier curves are used to model smooth curves that are not bound by the limits of rasterized images and that are intuitive to modify. In vector graphics software, Bézier curves are linked to form “paths” that are then used in image manipulation.

The general form of a Bézier curve of degree n is

$$f(t) = \sum_{i=0}^n b_i B_i^n(t)$$

where b_i are vector coefficients, the *control points*, and

$$B_i(t) = \binom{n}{i} t^i (1-t)^{n-i}$$

where

$\binom{n}{i}$ is the binomial coefficient
 $B_i(t)$ are Bernstein functions

They form a basis for the set of polynomials of degree n . Bézier curves have a number of characteristics, which are derived from the Bernstein functions and which define their behavior. Figure 32.12 shows examples of B -spline basis functions.

FIGURE 32.12 Comparison of basis functions with uniform and nonuniform knot vectors. (a) The uniform case; each basis function is an identical translated copy of all the others and knots are equally spaced; (b) nonuniform basis functions; the first three knots and the last three knots have zero spacing between them, the remaining knots are equally spaced; (c) and (d) cubic B-splines using the same control points but two different knot vectors, as seen in (a) and (b), respectively. (Adapted from Cashman, T.J., NURBS-compatible subdivision surfaces, Ph.D. University of Cambridge, Computer Laboratory, Queen’s College, Cambridge, U.K., p. 21, 2010.)

End point interpolation: The Bézier curve interpolates the first and last control points, b_0 and b_n . In terms of the interpolation parameter t , $f(0) = b_0$ and $f(1) = b_n$.

Tangent conditions: The Bézier curve is cotangent to the first and last segments of the control polygon (defined by connecting the control points) at the first and last control points; specifically $f'(0) = (b_1 - b_0)n$ and $f'(1) = (b_n - b_{n-1})n$.

Convex hull: The Bézier curve is contained in the convex hull of its control points for $0 \leq t \leq 1$ (note: the convex hull can be thought of as enclosing a rubber band around the control points of a curve).

Affine invariance: The Bézier curve is affinely invariant with respect to its control points. This means that any linear transformation or translation of the control points defines a new curve, which is just the transformation or translation of the original curve.

Variation diminishing: The Bézier curve does not undulate any more than its control polygon; it may undulate less.

Linear precision: The Bézier curve has linear precision: If all the control points form a straight line, the curve also forms a line.

32.3.3.1.2 B-Spline Curves

A single B-spline curve segment is defined much like a Bézier curve. It is defined as

$$d(t) = \sum_{i=0}^n d_i N_i(t)$$

where d_i are control points, called *de Boor points*. The $N_i(t)$ are the basis functions of the B-spline curve. The degree of the curve is n . Note that the basis functions used here are different from the Bernstein basis polynomials. Schoenberg first introduced the B-spline in 1949. He defined the basis functions using integral convolution (the “B” in B-spline stands for “basis”). Higher-degree basis functions are

given by convolving multiple basis functions of one degree lower. Linear basis functions are just “tents”; when convolved together they make piecewise parabolic “bell” curves.

The tent basis function (which has a degree of one) is nonzero over two intervals, the parabola is nonzero over three intervals, and so forth. This gives the region of influence for different degree B-spline control points. Note also that each convolution results in higher-order continuity between segments of the basis function. When the control points (*de Boor* points) are weighted by these basis functions, a B-spline curve results.

32.3.3.1.3 NURBS

NURBS curves and surfaces are generalizations of both B-splines and Bézier curves, the primary difference being the weighting of the control points, which makes NURBS curves rational and admits circles, spheres, cylinders, etc., which are rational. NURBS have become industry standard tools for the representation and design of geometry. Some reasons for the extensive use of NURBS are that they offer one common mathematical form for both standard analytical shapes, for example, conics, and free-form shapes; provide the flexibility to design a large variety of shapes; can be evaluated reasonably fast by numerically stable and accurate algorithms; are invariant under affine as well as perspective transformations such as rotations and scaling; and are generalizations of nonrational B-splines and nonrational and rational Bézier curves and surfaces (Piegl 1991; Rogers and Earnshaw 1991; Farin 2002). One drawback for NURBS is the extra storage required to define traditional shapes, for example, circles. This results from parameters in addition to the control points but finally allows the desired flexibility for defining parametric shapes.

32.3.3.2 Parametric Surfaces

32.3.3.2.1 Bézier and B-Spline Surfaces

Imagine moving the control points of the Bézier curve in three dimensions. As they move in space, new curves are generated. If they are moved smoothly, then the curves formed create a surface, which may be thought of as a bundle of curves (see Figure 32.13). If each of the control points is moved along a Bézier curve of its own, then a Bézier surface patch is created; the result of extruding a B-spline curve is a Bézier surface.

All operations used for B-spline curves carry over to the surface via the nesting scheme implied by its definition. We recall that B-spline curves are especially convenient for obtaining continuity between polynomial segments. This convenience is even stronger in the case of B-spline surfaces; the patches meet with higher-order continuity depending on the degree of the respective basis functions. B-splines define quilts of patches with “local support” design flexibility. Finally, since B-spline curves are more compact to store than Bézier curves, the advantage is “squared” in the case of surfaces. These advantages are tempered by the fact that operations are typically more efficient on Bézier surfaces. Conventional wisdom says that it is best to design and represent surfaces as B-splines and then convert to Bézier form for operations.

FIGURE 32.13 The sweeping of a curve to make a surface.

32.3.3.2.2 NURBS Surfaces

NURBS surfaces are functions of two parameters mapping to a surface in 3D space. The shape of the surface is determined by control points. A surface under construction, for example, the head of a camel, is usually composed of several NURBS surfaces known as *patches*. Continuity at the patch boundaries will determine the smoothness or otherwise of surface junctions (refer Wiki NURBS; Piegl 1991).

32.4 Standards

Several movements have occurred to standardize primitives. In academia, an early attempt at standardization resulted in Programmer's Hierarchical Interactive Graphics System (PHIGS) + (ISO/IEC 9592-2:1997). Although it has never become the principle standard, many of the ideas were absorbed into later standards. Many standards grew out of the mechanical CAD/CAM industry, because of the early connection with graphics. One such prominent standard is the Initial Graphics Exchange Specification (IGES) (US PRO 1996). Because of its portability, the 3D ACIS format has become a standard in solid modeling (see ACIS Library Reference Documentation, R22). In industry each company has developed and lobbied for its particular set of graphics standards. In the computer graphics development area, the most widely used libraries are OpenGL developed by Silicon Graphics, Inc., and managed by the nonprofit technology consortium Khronos Group, and DirectX, a set of libraries owned and developed by Microsoft. For specific commands used by OpenGL and DirectX, refer to Appendices 32.A and 32.B, respectively.

In this chapter we have concentrated mostly on 3D primitives because they tend to be more complex and demanding. However, there has been great progress standardizing 2D graphics such as that epitomized by Flash, a format developed by Macromedia, now part of the Adobe suite (www.adobe.com/flashplatform/). Indeed, Flash has been so successful that as a standard it dominates 2D graphics.

32.5 Future Directions

There have been efforts to cast higher-order primitives like parametric surfaces into graphics hardware, but the best approach seems to be to convert these into polygons and then render. There may yet be hardware support for higher-order primitives, but the polygon processing remains at the heart of graphics primitives. This trend is likely to continue into the future if for no other reason than its own inertia. Special needs will continue to drive the development of specialized primitives.

One new trend that may affect development is that of volume rendering. Although it is currently quite expensive to render, hardware improvements that reduce memory needs, for example, in the architecture of GPUs and parallel processing languages, should make it increasingly more viable. As a technique it subsumes many of the current methods, usually with better quality, as well as enabling the visualization of volume-based objects. Volume-based primitives, that is, tetrahedral, cuboids, and curvilinear volume cubes, will receive more attention and be subject for additional research.

Recursive subdivision, a procedural modeling technique that begins with a polyhedral mesh in 3D and recursively chamfers the edges until a nicely smoothed object results (see Böhm et al 1984; Botsch et al 2010), continues to be a focus area. This approach is widely used in animation and conceptual modeling. Its input structure is polyhedral mesh and a set of parameters that inform the algorithm of how to chamfer. The algorithm itself is becoming a primitive residing on the graphics card. Fractals would be another example of a geometry form, which relies on a procedure and may be common enough to warrant the title of primitive.

In architecture and engineering, BIM is becoming the standard for modeling and information management. BIM systems represent a design model as a group of interrelated objects, each with its own geometry, relations, and attributes. Furthermore, specialized applications tailored to model dynamic, parametric designs will inevitably extend the definition and range of geometric primitives (see Pottmann et al 2012; Bury and Bury 2010).

Another example where primitives are currently evolving is in the area of 3D model compression akin to JPEG for images. There is a great need to visualize 3D models in a lightweight manner, for example,

through increased standardization. Unified Model Language (UML) has been developed jointly by industry and academia to develop 3D standards for model compression and communication of those models.

This cycle of innovative user application, hardware development, and software standardization is never more apparent than now. One of the strongest growing trends that will affect primitives is the further development of digital handheld devices such as smart phones and tablets. A big effort in this direction is to develop OpenGL for their use. This means optimizing OpenGL for the frenetic development in the hardware abilities and imaginative applications. In fact, this trend will only intensify as intelligent computing continues to miniaturize and finds its way into all aspects of our life. We see examples in controlling human implants, for example, digital cochlea, optical implants, and prosthetics. Also it will appear in everything from smart elevators to pilotless flight. Shape detection will play an increasing role, for example, in medicine such as early tumor and aneurism detection, MRI data, and echocardiograms. As in all previous developments, good standards will improve collaboration, efficiency, and further innovation.

Virtual Reality is perhaps the greatest known unknown at present. This is the area of research and development that will push our definition of reality, challenge our physical being, and blur the boundaries between the tangible and the perceptual.

32.6 Summary

Geometric primitives are the most fundamental components of computer visualization. They have been identified here as points, lines, polylines, polygons, triangular facets, elliptical arcs, and curves. Solid geometry primitives include the cube, pyramid, cone, sphere, ellipsoid, torus, and polygonal extrusions. A geometric primitive can be distinguished as either a design primitive or a database primitive, where a design primitive forms part of the final visualized model, for example, the curve that defines the edge of a sphere, and a database primitive is part of the working process and is not visible in the final model, for example, bounding box and CV. Although simple in themselves, geometric primitives can be combined and manipulated, for example, with Boolean operations and recursive subdivision, to form complex and sophisticated objects.

Finding usable implicit forms for quadratic parametric surfaces, for example, sphere, plane, or parabola, is easy and resolved in most software used today. However, the recurring challenge is to find intuitive and mathematically stable solutions for creating cubic patches and more complex shapes.

Key Terms

ACIS: The 3D ACIS Modeler is a geometric modeling kernel developed by Spatial Corporation

BIM: Building information modeling

Boolean: Booleans as used in CAD/CAM (distinguish from Boole's algebra)

CAD: Computer-aided design

CAE: Computer-aided engineering

CAM: Computer-aided manufacturing

CPU: Central processing unit

CSG: Constructive solid geometry

Implicit objects: Defined by implicit functions, they define solid objects of which outside and inside can be distinguished. Common engineering forms such as the plane, cylinder, sphere, and torus are defined simply by implicit functions.

Parametrically defined curves and surfaces: Higher-order surface primitives used widely in industrial design and graphics. Parametric surfaces such as B-spline and Bézier surfaces have flexible shape attributes and convenient mathematical representations.

Platonic solids: A convex solid composed of identical regular polygons. There are five in total.

Polygon: A closed object consisting of vertices, lines, and usually an interior. When pieced together it gives a piecewise (planar) approximation of objects with a surface. Triangular facets are the most common form and form the basis of most graphics primitives.

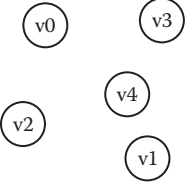

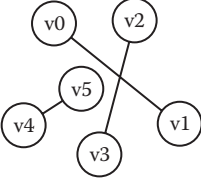

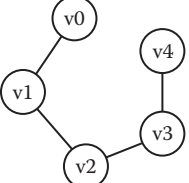

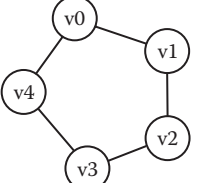

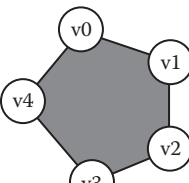

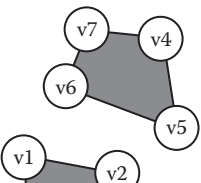

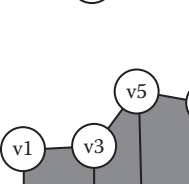

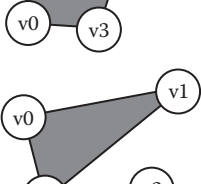

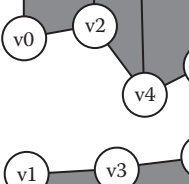

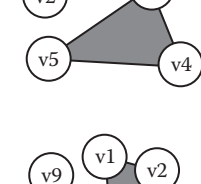

Polytope: A polytope is a geometric object with flat sides, which exists in any general number of dimensions.

Wireframe: Simplest and earliest form of graphics model, consisting of line segments and possibly elliptical arcs that suggest the shape of an object. It is fast to display and has advantages in precision and “see-through” features.

Zero-dimensional: An object with no volume, area, length, nor any other higher-dimensional analogue.

32.A Appendix A

The table that follows lists the geometric primitive specifications used in OpenGL. “GL” refers to *graphics library* and “v” represents a *vertex*.

GL_POINTS		GL_LINES	
GL_LINE_STRIP		GL_LINE_LOOP	
GL_POLYGON		GL_QUADS	
GL_QUAD_STRIP		GL_TRIANGLES	
GL_TRIANGLE_STRIP		GL_TRIANGLE_FAN	

Source: Adapted from <http://www.opentk.com/doc/chapter/2/opengl/geometry/primitives>.

32.B Appendix B

The table that follows lists the geometric primitive specifications used in DirectX. A *vertex* is represented by either “v” or x, y, z coordinates.

33.1 Introduction

Most virtual worlds are dynamic; they change over time: objects move, rotate, and transform themselves; in inhabited virtual worlds, virtual characters come to life. Object and character motion is an essential part of these virtual worlds. The main goal of computer animation is to synthesize the desired motion effects, which are a mixing of natural phenomena, perception, and imagination. The animator designs the object's dynamic behavior with his or her mental representation of causality. Animators imagine how each object moves, gets out of shape, or reacts when it is pushed, pressed, pulled, or twisted. So, the animation system has to provide the user with motion control tools that enable animators translate their wishes using their own language. Computer animation methods may also aid in the application of physical laws by adding motion control to data in order to show their evolution over time. Formally, any computer animation sequence may be defined as a set of objects characterized by state variables evolving over time. For example, a human character is normally characterized using its joint angles as state variables. To produce a computer animation sequence, the animator has several techniques available depending on the type of object to be animated. Our main focus will be character animation, which corresponds to the animation of articulated bodies (Magnenat-Thalmann 1987, 1991).

We will first explain a few basic animation methods, and then we discuss how to capture motion, which is the most popular technique today used in the production of movies and games. However, its main disadvantage resides in the lack of flexibility of recorded motions, especially when one wants to adapt the raw motion data to another human and/or environment. For this reason, motion editing methods have been developed and a key topic in this chapter. Then we will discuss two fundamental

problems for character animation, the deformation of the body and facial animation. Behavioral animation and autonomous characters (ACs) are very important aspects and will also be discussed. Finally, we will address two important topics that have attracted a lot of interest: crowd simulation and cloth simulation.

33.2 Basic Animation Methods

33.2.1 Key Frame

This is an old technique consisting of the automatic generation of intermediate frames, called *in-betweens*, based on a set of key frames supplied by the animator. Originally, the in-betweens were obtained by interpolating the key frame images themselves. As linear interpolation produces undesirable effects such as lack of smoothness in motion, discontinuities in the speed of motion, and distortions in rotations, spline interpolation methods are used. Splines can be described mathematically as piecewise approximations of cubic polynomial functions. Two kinds of splines are very popular: interpolating splines with C1 continuity at knots and approximating splines with C2 continuity at knots. For animation, the most used splines are the interpolating splines: cardinal splines, Catmull–Rom splines, and Kochanek–Bartels (1984) splines.

A way of producing better images is to interpolate parameters of the model of the object itself. This technique is called *parametric key frame animation*, and it is commonly found in most commercial animation systems. In a parametric model, the animator creates key frames by specifying an appropriate set of parameter values. Parameters are then interpolated, and images are finally individually constructed from the interpolated parameters. Spline interpolation is generally used for the interpolation.

33.2.2 Inverse Kinematics

This direct kinematics problem consists in finding the position of end points (e.g., hand, foot) with respect to a fixed-reference coordinate system as a function of time without regard to the forces or the moments that cause the motion. Efficient and numerically well-behaved methods exist for the transformation of position and velocity from joint-space (joint angles) to Cartesian coordinates (end of the limb). Parametric key frame animation is a primitive application of direct kinematics.

Basically, the problem is to determine a joint configuration for which a desired task, usually expressed in Cartesian space, is achieved. For example, the shoulder, elbow, and wrist configurations must be determined so that the hand precisely reaches a position in space. The equations that arise from this problem are generally nonlinear and are difficult to solve in general. In addition, a resolution technique must also deal with the following difficulties. For the positioning and animation of articulated figures, the weighting strategy is the most frequent difficulty: some typical examples are given by Zhao and Badler (1994) for posture manipulation and by Phillips et al. (1990, 1991) to achieve smooth solution blending.

33.2.3 Dynamic Simulation

A great deal of work exists on the dynamics of articulated bodies (Huston 1990), and efficient direct dynamic algorithms have been developed in robotics for structures with many degrees of freedom (Featherstone 1986). In computer animation, these algorithms have been applied to the dynamic simulation of the human body (MacKenna and Zeltzer 1996). Given a set of external forces (like gravity or wind) and internal forces (due to muscles) or joint torques, these algorithms compute the motion of the articulated body according to the laws of rigid body dynamics. Impressive animations of passive structures like falling bodies on stairs can be generated by this technique with little input from the animator. On the other hand, making adjustments is a tedious task as the animator has only indirect control over

the animation. Hodgins et al. (1995) achieved simulation of dynamic human activities such as running and jumping. Some controller architectures have also been proposed by Lazlo et al. (1996) to generate a wide range of gaits and to combine elementary behaviors (Faloutsos et al. 2001).

Dynamic approaches aim to describe motion by applying physics laws. For example, it is possible to use control algorithms based on finite state machine to describe a particular motion and proportional derivative servos to compute the forces (Wooten and Hodgins 2000). However, even if these methods produce physically correct animations, configuring their algorithms remains difficult. It is not easy to determine the influence of each parameter on the resulting motions. Many methods based on empirical data and biomechanical observations are able to generate walking (Boulic et al. 2004) or running patterns (Bruderlin and Calvert 1996), reactive to given user parameters. Other similar approaches take into account the environment, to walk on uneven or sloped terrains (Sun and Metaxas 2001) or to climb stairs (Chung and Hahn 1999). Despite their real-time capability, all these methods lack realism, as the legs' motion is considered symmetrical, for example.

33.2.4 Collision Detection and Response

In computer animation, collision detection and response are obviously more important. Hahn (1988) presents bodies in resting contact as a series of frequently occurring collisions. Baraff (1989) presents an analytical method for finding forces between contacting polyhedral bodies, based on linear programming techniques. He also proposed a formulation of the contact forces between curved surfaces that are completely unconstrained in their tangential movement. Bandi et al. (1995) introduced an adaptive spatial subdivision of the object space based on octree structure and presents a technique for efficiently updating this structure periodically during the simulation. Volino and Magnenat Thalmann (1994) described a new algorithm for detecting self-collisions on highly discretized moving polygonal surfaces. It is based on geometrical shape regularity properties that permit avoiding many useless collision tests. Vassilev and Spanlang (2001) propose to use the z-buffer for collision detection to generate depth and normal maps.

33.3 Motion Capture

Motion capture consists of measurement and recording of direct actions of a real person or animal for immediate or delayed analysis and playback. This technique is especially used today in production environments for 3D character animation, like in movies and games. It involves mapping of measurements onto the motion of the digital character.

We may distinguish between the main two kinds of systems: optical and magnetic.

Optical motion capture systems are often based on small reflective sensors called markers attached to an actor's body and on several infrared cameras focused on the performance space. By tracking positions of the markers, one can capture the locations for the key points in an animated model, for example, we attach the markers at joints of a person and record the position of the markers from several different directions. The 3D position of each key point is then reconstructed at each time point. The main advantage of this method is freedom of movement; it does not require any cabling. There is however one main problem: occlusion, that is, lack of data resulting from hidden markers, for example, when the performer lies on his or her back. Another problem is the lack of an automatic way of distinguishing reflectors when they get very close to each other during motion. These problems may be minimized by adding more cameras but at a higher cost, of course. Most optical systems operate with four to six cameras, but for high-end applications like movies, 16 cameras are usual. A good example of optical system is the VICON system (Figure 33.1). In recent years, the motion capture technology has matured with the use of active optical markers (e.g., PhaseSpace), and some recent systems are much more affordable.

Researchers in computer vision have tried to develop similar systems based on simple video cameras without markers. In 2010, Microsoft introduces the Kinect sensor, which is a horizontal bar connected

FIGURE 33.1 Optical motion capture based on markers at MIRALab.

to a small base with a motorized pivot, and it is designed to be positioned lengthwise above or below the video display. The device features an RGB camera, depth sensor, and multiarray microphone running proprietary software, which provide full-body 3D motion capture, facial recognition, and voice recognition capabilities. The depth sensor consists of an infrared laser projector combined with a monochrome CMOS sensor, which captures video data in 3D under any ambient light conditions. Although not very accurate, the Kinect (Figure 33.2) provides a cheap way of capturing motion that is becoming very popular.

Magnetic motion capture systems require a real actor to wear a set of sensors, which are capable of measuring their spatial relationship to a centrally located magnetic transmitter. The position and orientation of each sensor is then used to drive an animated character. One problem is the need for synchronizing receivers. The data stream from the receivers to a host computer consists of 3D positions and orientations for each receiver. For human body motion, eleven sensors are generally needed: one on the

FIGURE 33.2 The Kinect sensor.

head, one on each upper arm, one on each hand, one in the center of the chest, one on the lower back, one on each ankle, and one on each foot. To calculate the rest of the necessary information, the most common way is the use of inverse kinematics (IK).

33.4 Motion Editing

Motion retargeting or motion editing is simply editing existing motions to achieve the desired effect. Since motion is difficult to create from scratch using traditional methods, changing existing motions is a quicker way to obtain the desired motion. This means that motion editing is a well-known approach used to produce new motions from existing ones. With space-time constraints (Witkin and Kass 1988), to generate an animation, the user may specify pose constraints that must be satisfied by the resulting motion sequence and also specify an objective function that is a metric of performance such as the total power consumption of all of the character's muscles. Cohen (1992) constructed a more complete system and introduced the concept SpaceTime windows to enable the use of space-time constraints in an interactive framework, providing tools to the animator to examine and thus guide the optimization process. To achieve interactive editing, Gleicher (1997) provided a different formulation to the problem of space-time constraints, by combining displacement maps and space-time constraints. In Popović and Witkin (1999), Newton's laws were applied on a simplified character to minimize computational costs and to preserve the essential physical properties of the motion. Liu and Popović (2002) introduced a method for rapid prototyping of realistic motions. Starting from a simple animation generated using key framing, physical laws are enforced to produce a more realistic one.

Frequency-based methods consider the animation curve as a time-varying signal; by applying signal processing techniques, the input motion is modified. In the field of character animation, Bruderlin and Williams (1995) adapted multiresolution filtering, multitarget motion interpolation with dynamic time warping, wave shaping, and displacement mapping for editing motion data. Witkin and Popović (1995) presented the motion warping method built from the combination of time warping and displacement mapping techniques. Unuma et al. (1995) described a simple technique to represent periodic motions using the so-called rescaled Fourier functional model.

Gleicher (2001) proposed a taxonomy of constraint-based techniques. Constraint-based techniques enable the user to specify constraints over the entire motion or at specific times while editing an animation. An IK solver computes the "best" motion, pose by pose, so that each pose achieves the predefined constraints as much as possible. Boulic and Thalmann (1992) presented the first work in motion editing using IK on a per-frame basis to enforce constraints. They used a numerical IK solver in order to simultaneously handle two tasks: the primary and the secondary. The primary task is responsible for kinematics constraints. The latter is in charge of tracking the original motion so that the corrected motion does not deviate too much from the initial one. Lee and Shin (1999) introduced the first example of per-frame plus filtering class of motion editing techniques. Their interactive motion editing system addresses many common tasks such as retargeting, transitions, and/or editing. Huang et al. (2006) proposed a motion editing technique with collision avoidance to prevent the character's limbs to interpenetrate the body during editing. Callennec and Boulic (2006) proposed an off-line interactive motion editing technique with prioritized constraints. The characteristics of the original motion are preserved by adding the difference between the motion before and after editing as the lowest priority constraint by using an optimization vector.

Data-driven (or model-based) methods focus on the construction of a model from motion capture data and use the model to generate new motions from existing ones. Alexa and Muller (2000) used principal component analysis (PCA) to represent animations as a set of principal animation components, with the aim of decoupling the animation from the underlying geometry. Gardon et al. (2004) generate walking, running, and jumping motions by exploring the low-dimensional space constructed from a hierarchical PCA. This further decomposition of the PCA space was used to extract high-level parameters (e.g., walking speed) to provide user manipulation guiding a character through the virtual environment from a small set of well-understood parameters. Gardon et al. (2006a) also integrated

FIGURE 33.3 PCA-based walking models. (From Glardon, P. et al., *Visual Comput.*, 5(6), 194, 2006a.)

an optimization-based IK solver for preventing foot sliding by exploiting the predictive capability of the PCA motion model (Figure 33.3). Glardon et al. (2006b) developed a motion blending technique in parameter space, such as locomotion speed and jump length, to handle two PCA motion models in order to treat transitions from walking/running to jump motions while guiding a virtual character to avoid obstacles through an environment. Motion graphs and motion interpolation are used to produce new motions from a database (Kovar and Gleicher 2004, Kovar et al. 2002). A number of researches have also developed techniques to synthesize human motion in a low-dimensional space, by using both linear and nonlinear models. Safanova et al. (2004) proposed a motion synthesis framework able to synthesize new motions by optimizing a set of constraints within a low-dimensional space constructed with PCA.

Carvalho et al. (2007) recently proposed a new approach for interactive low-dimensional human motion synthesis, by combining motion models and prioritized IK. They developed a constrained optimization framework to solve the synthesis problem within a low-dimensional latent space. In this space, a movement enforcing a new set of user-specified constraints could be obtained in just one step (Figure 33.4).

FIGURE 33.4 Synthesized motions, from the swing motion shown in the left figure: (a) 7° down slope ground, (b) flat ground, and (c) 7° up slope ground. (From Carvalho, S. et al., *Comput. Anim. Virtual Worlds*, 18, 493, 2007.)

33.5 Character Deformations

Many different approaches have been proposed to connect a deformable skin to its underlying skeleton. They can be roughly subdivided into the following main categories: subspace deformations (SSDs), skin mapping, anatomically based deformations, physics-based approaches, and example-based approaches.

33.5.1 Subspace Deformations

The skeleton-driven deformation, a classical method for basic skin deformation, is probably the most widely used technique in 3D character animation. In the literature, an early version was presented by Magnenat-Thalmann et al. (1988) who introduced the concept of joint-dependent local deformation with operators to deform smoothly the skin surface. This technique has been given various names such as SSD, linear blend skinning, or smooth skinning. This method works by assigning a set of joints with weights to each vertex of the character. The deformation of a vertex is then computed by a weighted combination of the transformations applied to the influencing joints. Mohr et al. (2003) addresses a crucial issue related to linear blending skinning: setting the appropriate vertex weight values. Wang and Phillips (2002) propose an interesting extension of SSD-based approaches: the multiweighting approach assigns each vertex one weight for each coefficient of each influencing joint transformation matrix instead of a single weight per influencing joint. Mohr and Gleicher (2003) have presented an extension to SDD by introducing pseudojoints. The skeleton hierarchy is completed with extra joints inserted between existing ones to reduce the dissimilarity between two consecutive joints. Kavan and Zara (2005) are also aiming at addressing the intrinsic limitations of linear blending such as collapsing joints or twisting problem. To this end, they interpolate the transformations instead of the transformed vertex positions. Merry et al. (2006) proposed a framework called *animation space*, for generalizing SSD by keeping it linear and with the goal to reduce the initial shortcomings of SSD (especially collapses during bending).

33.5.2 Skin Mapping

An example of this approach is proposed by Thalmann et al. (1996) where ellipsoids are attached to the control skeleton to define a simplified musculature. Cani and Desbrun (1997) propose to use an automatic skinning algorithm based on swept surfaces. The skeleton is used as a path for extrusion of interpolating spline surfaces. More complex models include intermediate layers in order to improve and refine the control of the skin. For example, Chadwick et al. (1989) propose an intermediate muscle layer between the flexible skin and the rigid skeleton. This intermediate structure is made of free-form deformation (FFD) control boxes attached to the skeleton. Similar extended and optimized approaches have been proposed by Moccozet and Magnenat-Thalmann (1997) where the deformable skin is embedded inside a control lattice. Singh and Kokkevis (2000) propose an alternate intermediate structure that consists of a low-resolution mesh instead of a control lattice. Kho and Garland (2005) propose a technique for implicitly defining skeleton-based deformation of unstructured polygon meshes. The implicit skeleton is defined by interactively sketching curves onto the 3D shape in the image plane. Zhou et al. (2005) describe a deformation system providing a close interaction scheme: the designer initially specifies a curve on the mesh surface, called the original control curve. The resulting 3D curve is projected onto one or more planes to obtain 2D editable curves. Once edited, the modified 2D curves are projected back to 3D to get the deformed control curve, which is used to control the deformation.

33.5.3 Anatomically Based

Skeleton skinning has also been investigated to simulate anatomy and reproduce as closely as possible the anatomical behavior of characters, such as the work reported by Scheepers et al. (1997) and Wilhems and Vangelder (1997). Aubel and Thalmann (2001) define a two-layered muscle model suitable for

computer graphics applications. A muscle is decomposed into two layers: a skeleton and a surface mesh. The skeleton is simply defined by the action lines of the muscle. This idea is based on the work by Nedel and Thalmann (1998). Each vertex of the muscle mesh is parametrized by one or two underlying action lines so that the deformations of the muscle shape are driven by the associated action lines. It therefore reduces the 3D nature of the elasticity problem to 1D for fusiform muscles (one action line) and 2D for flat muscles (several action lines). Pratscher et al. (2005) propose a different approach for anatomical models. Rather than modeling internal tissues and attaching a skin to it, they generate a musculature from a skeleton and a skin mesh at a rest pose, with what they called an outside-in approach.

33.5.4 Physics-Based Approaches

Since Terzopoulos and Fleischer (1988) and Terzopoulos and Witkin (1988), various approaches have been proposed to introduce more realism by using dynamic-based deformations such as those proposed by Faloutsos et al. (1997). Capell et al. (2002) introduce a framework for skeleton-driven animation of elastically deformable characters. They use continuum elasticity and finite element method (FEM) to compute the dynamics of the object being deformed. Huang et al. (2006) presented a method that extends existing gradient domain name mesh deformation approaches. Larboulette et al. (2005) present flesh elements to add secondary dynamic effects to the skinning, while Guo and Wong (2005) propose a pseudoanatomical skinning method. In this chapter, their purpose is to provide a simple intermediate layer between the skeleton and the skin, namely, the chunks, to avoid the tedious design of the anatomical layers.

33.5.5 Example-Based Approaches

The idea of pose space deformation (PSD) (Lewis et al. 2000) approaches is to use artistically sculpted skin surfaces of varying posture that blend them during animation. Each vertex on the skin surface is associated with a linear combination of radial basis functions (RBFs) that compute its position, given the pose of the moving character. Recently, Kry et al. (2002) propose an extension of that technique by using PCA, allowing for optimal reduction of the data and thus faster deformation. These methods have been recently developed because of the full-body 3D scanners. The basic idea of these approaches is to use real data that cover the space of shape variation of the character to train a deformable model. The method proposed by Allen et al. (2002) is based on skin pose examples. Similarly to animation by target morph, they use a set of poses as targets or examples in order to produce the skinning information, whereas traditional approaches rely on much less information, namely, a skeleton and a template skin in a neutral posture. The approach proposed by James and Twigg (2005), named skinning mesh animations (SMAs), presents an original skin example-based scheme. The main difference is that it does not require any predefined skeleton. Sand et al. (2003) propose a method for the acquisition of deformable human geometry from silhouettes. The technique involves a tracking system to capture the motion of the skeleton and estimates skin shape for each bone using constraints provided by the silhouettes from one or more cameras. Anguelov et al. (2005) introduce a data-driven method for building a character shape model. The method is based on a representation that incorporates both skeletal and body deformations. Another recent approach is proposed by Der et al. (2006) extended from Sumner et al. (2005). It transforms a set of unarticulated example shapes into a controllable, articulated model, providing an IK method allowing the interactive animation of detailed shapes using a space learned from a few poses obtained from any source (scanned or hand sculpted).

33.6 Facial Animation

The goal of facial animation systems has always been obtaining a high degree of realism using optimum resolution facial mesh models and effective deformation techniques. Various muscle-based facial models with appropriate parameterized animation systems have been effectively developed for facial

animation (Parke 1982, Terzopoulos et al. 1990, Waters 1987). The Facial Action Coding System (Friesen 1978) defines high-level parameters for facial animation, on which several other systems are based. Most facial animation systems typically follow the following steps:

- Define an animation structure on a facial model by parameterization.
- Define “building blocks” or basic units of the animation in terms of these parameters, for example, static expressions and visemes (visual counterparts of phonemes).
- Use these building blocks as key frames and define various interpolation and blending functions on the parameters to generate words and sentences from visemes and emotions from expressions. The interpolation and blending functions contribute to the realism for a desired animation effect.
- Generate the mesh animation from the interpolated or blended key frames. Given the tools of parameterized face modeling and deformation, the most challenging task in facial animation is the design of realistic facial expressions and visemes.

The complexity of the key frame-based facial animation system increases when we incorporate natural effects such as coarticulation for speech animation and blending between a variety of facial expressions during speech. The use of speech synthesis systems and the subsequent application of coarticulation to the available temporized phoneme information are a widely accepted approach (Hill et al. 1988). Coarticulation is a phenomenon observed during fluent speech, in which facial movements corresponding to one phonetic or visemic segment are influenced by those corresponding to the neighboring segments. Two main approaches for coarticulation are the ones by Pelachaud (1991) and Cohen and Massaro (1993). Both these approaches have been based on the classification of phoneme groups and their observed interaction during speech pronunciation. Pelachaud arranged the phoneme groups according to the deformability and context dependence in order to decide the influence of the visemes on each other. Muscle contraction and relaxation times were also considered, and the facial action units were controlled accordingly.

For facial animation, the MPEG-4 standard is particularly important (MPEG-4). The facial definition parameter (FDP) set and the facial animation parameter (FAP) set are designed to encode facial shape, as well as animation of faces, thus reproducing expressions, emotions, and speech pronunciation. The FDPs are defined by the locations of the feature points and are used to customize a given face model to a particular face. They contain 3D feature points such as mouth corners and contours, eye corners, and eyebrow centers. FAPs are based on the study of minimal facial actions and are closely related to muscle actions. Each FAP value is simply the displacement of a particular feature point from its neutral position expressed in terms of the facial animation parameter units (FAPUs). The FAPUs correspond to fractions of distances between key facial features (e.g., the distance between the eyes). For example, the facial animation engine developed at MIRALab uses MPEG-4 facial animation standard (Kshishagar et al. 2000) for animating 3D facial models in real time (see Figure 33.5). This parameterized model is capable of displaying a variety of facial expressions, including speech pronunciation with the help of 66 low-level FAPs.

Recently, the efforts in the field of phoneme extraction have resulted into software systems capable of extracting phonemes from synthetic as well as natural speech and generating lip synchronized speech animation from these phonemes, thus creating a complete talking head system. It is possible to mix emotions with speech in a natural way, thus imparting the virtual character an emotional behavior. The ongoing efforts are concentrated on imparting “emotional” autonomy to the virtual face enabling a dialogue between the real and the virtual humans with natural emotional responses. Kshirsagar and Magnenat-Thalmann (2001) use statistical analysis of the facial feature point movements. As the data are captured for fluent speech, the analysis reflects the dynamics of the facial movements related to speech production. The results of the analysis were successfully applied for a more realistic speech animation. Also, this has enabled us to easily blend between various facial expressions and speech. The use of MPEG-4 feature points for data capture and facial animation enabled us to restrict the quantity

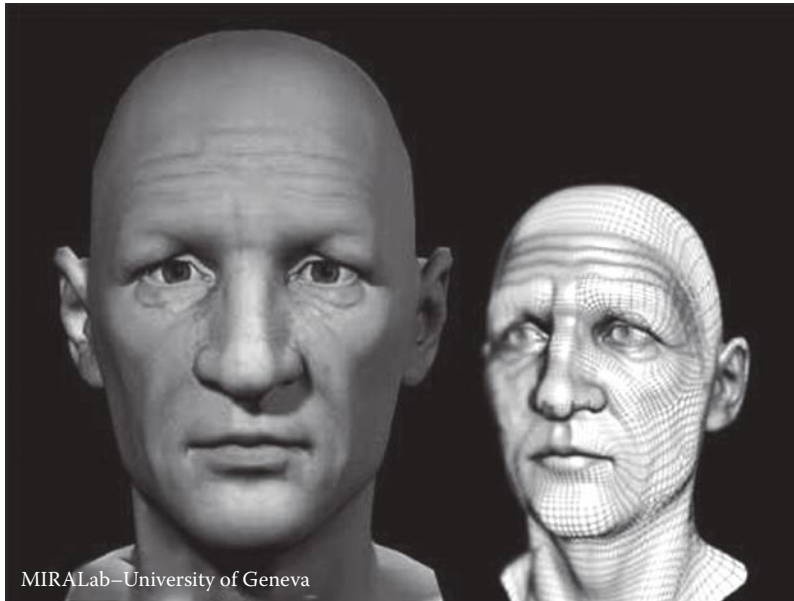

FIGURE 33.5 Facial animation and recreation of expressions of an old man. (Courtesy of MIRALab, University of Geneva, Geneva, Switzerland.)

of data being processed, at the same time offering more flexibility with respect to the facial model. We would like to further improve the effectiveness of the expressive speech using various time envelopes for the expressions that may be linked to the meaning of sentences. Kshirsagar and Magnenat-Thalmann (2002) have also developed a system incorporating a personality model for an emotional autonomous virtual human.

Although MPEG-4 has mainly been used in animating virtual humans, it also proved to be useful for animating humanoid robots. Ben Moussa et al. (2010) and Kasap (2011) present a paradigm for controlling facial expressions using MPEG-4. Through interpolation between the extremes of robot servomotor values and MPEG-4 values, they succeeded in controlling the robot with the same animation mechanisms they use for the animation of virtual humans. This made it possible to perform lip synchronization, emotion expression, and gaze behavior management on the robot in the same way it is done with virtual humans.

In order to achieve realistic facial expressions, one should also take the eye movements into consideration. As has been often expressed, the eyes are a window to the soul. They play an important role in many aspects of human interaction including emotion expression, conversation regulation, attention behavior, and instruction giving. Fukayama et al. (2002) investigated the relationship between gaze parameters (amount and mean duration of gaze at the user and the direction of the gaze when averting the user) and the impression the user gets from the agent's gaze behavior (like/dislike, activity/potency, strong/weak, cold/warm, etc.) and propose a gaze movement model that enables an embodied agent to convey different impressions to users. Another eye movement model is presented by Park Lee et al. (2002), where the eye movement was based on empirical studies of saccades and statistical models of eye-tracking data collected in their study. Based on empirical data and psychological theories, Cig et al. (2010) propose a model where the head and the eyes are moved in accordance with the mood of the embodied agent. Furthermore, another role of gaze is the conversation regulation. Having realistic gaze behavior in a conversation improves the interaction between the user and the embodied agent. Lee et al. (2007) combine different existing psychological theories and present a gaze model guided by turn-taking, discourse, and attention in a conversion. Čereković et al. (2009)

implemented a more advanced multiparty dialogue management system that incorporates gaze tracking and motion detection to recognize the user's conversational cues.

33.7 Behavioral Methods

33.7.1 Autonomous Characters

For games and virtual reality (VR), the animation of characters needs to be dynamically generated in response to the user behavior but not driven by the user. Characters should be able to act on their own; they should be ACs. Autonomy is generally the quality or state of being self-governing. Rather than acting from a script, an AC is aware of its changing virtual environment, making its own decisions in real time in a coherent and effective way. To be autonomous, an AC must be able to perceive its environment and decide what to do to reach an intended goal. The decisions are then transformed into motor control actions, which are animated so that the behavior is believable. Therefore, an AC's behavior often consists of repeating the following sequence: perception of the environment, action selection, and reaction. There are several properties that determine how ACs make their decisions: perception, adaptation and intelligence, memory, emotions, personality, and motivation.

Perception of the elements in the environment is essential for ACs, as it gives them an awareness of what is changing. An AC continuously modifies its environment, which, in turn, influences its perceptions. Therefore, sensorial information drastically influences AC's behavior. This means that one cannot build believable ACs without considering the way they perceive the world and each other. It is tempting to simulate perception by directly retrieving the location of each perceived object straight from the environment. But, to realize believable perception, ACs should have sensors that simulate the functionality of their organic counterparts, mainly for vision, audition, and tactile sensation. These sensors should be used as a basis for implementing everyday behaviors, such as visually directed locomotion, responses to sounds and utterances, and the handling of objects. What is important is the functionality of a sensor and how it filters the information flow coming from the environment. In a typical behavioral animation scene, the actor perceives the objects and the other actors in the environment, which provides information on their nature and position. This information is used by the behavioral model to decide the action to take, which results in a motion procedure. The AC perceives its environment from a small window in which the environment is rendered from its point of view. Synthetic vision was first introduced by Renault et al. (1990) where an actor navigates in a corridor avoiding obstacles by offscreen rendering of the scene from the point of view of the agent. This technique is later applied by Tu and Terzopoulos (1994) in the perception system of artificial fishes. Blumberg et al. (1996) used synthetic vision for his autonomous virtual dog in order to avoid obstacles. Noser et al. (1995) proposed a synthetic vision model based on false coloring and dynamic octrees. Peters and O'Sullivan (2002) extend the synthetic vision model in two different ways. In *distinct mode*, false coloring is applied to each distant object, and in some cases objects are grouped according to some different criteria that is called *grouped vision mode*. A different approach to synthetic vision is proposed in Bordeux et al. (1999) based on perceptual filters, which receives a perceptible entity from the scene and decides if it should pass or not. A main distinction between virtual human perception models is whether they are based on task perception or biological perception (Kim et al. 2005). Biological perception or bottom-up visual attention is an alerting mechanism to unexpected dangers as explained in Peters and O'Sullivan (2003). Task-based or top-down approaches such as Chopra-Khullar and Badler (1999) and Gillies and Dodgson (2002) consider task-related objects as the focus of attention. This may be extended to gaze attention behaviors for other ACs or even crowds (Grillon and Thalmann 2009). Despite it is rare, aural perception is also modeled and applied by some researchers like Noser and Thalmann (1995) who introduced the concept of synthetic audition. A recent example in Herrero and de Antonio (2003) framework is described to capture the position of the sound source. The concepts are related to human auditory perception such

as interaural differences, auditory acuity, and auditory. More recently, an artificial life environment (Conde and Thalmann 2006) framework equips a virtual human with the main virtual sensors, based on an original approach inspired by neuroscience in the form of a small nervous system with a simplified control architecture to optimize the management of its virtual sensors as well as the virtual perception part. The processes of filtering, selection, and simplification are carried out after obtaining the sensorial information.

Adaptation and *intelligence* define how the character is capable of reasoning about what it perceives, especially when unpredictable events happen. An AC should constantly choose the best action so that it can survive in its environment and accomplish its goals. As the environment changes, the AC should be able to react dynamically to new elements, so its beliefs and goals may evolve over time. An AC determines its next action by reasoning about what it knows to be true at specific times. Its knowledge is decomposed into its beliefs and internal states, goals, and plans, which specify a sequence of actions required to achieve a specific goal.

Adding *memory* capabilities to models of human emotions, personality, and behavior traits is a step toward a more natural interaction style. It is necessary for an AC to have a memory so that similar behaviors can be selected when predictable elements reappear. Noser et al. (1995) proposed the use of an octree as the internal representation of the environment seen by an actor because it can represent the visual memory of an actor in a 3D environment with static and dynamic objects. Kasap et al. (2009) developed a memory-based emotion model that uses the memory of past interactions to build long-term relationships between the AC and users.

The believability of an AC is made possible by the emergence of *emotions* clearly expressed at the right moment. An emotion is an emotive reaction to a perception that induces a character to assume a physical response, facial expression, or gesture, or select a specific behavior. The apparent emotions of an AC and the way it reacts are what give it the appearance of a living being with needs and desires. Without them, an actor would just look like an automaton. There is a variety of psychological researches on emotion, and they are classified into four different theoretical perspectives: Darwinian, Jamesian, cognitive, and social constructivist approaches (Cornelius 1996). In order to create computational models of emotions, we need some annotation mechanisms. Ekman (1982) defines six basic labels for emotions: fear, disgust, anger, sadness, surprise, and joy following the Darwinian approach to emotions emphasizing the universality of human emotions. Recently, cognitive appraisal models of emotion are now preferred since they better explain the overall process of how emotions occur and affect our decision-making. Appraisal means a person's assessment of the environment including not only current conditions but past events as well as future prospects (Spindel et al. 1990). The OCC model of Ortony et al. (1988) is widely used for emotion simulation of embodied agents. In the OCC model, the agent's concerns in an environment are divided into goals, standards, and preferences, and twenty-two emotion labels are defined. In addition to the four theoretical approaches mentioned earlier, there are also some studies on emotions based on neurophysiology. The first representative of this approach is Plutchik (1980) who defines eight emotions in an emotion spectrum like the color spectrum, and it is possible to produce new emotions by combining these emotions (e.g., disappointment = sadness + surprise). Other models of emotion such as activation–evaluation (Whissel 1980) define emotions according to abstract and continuous dimensions rather than discrete labels.

Personality influences the way a person perceives their environment, affects their behavior, and distinguishes one from another. Although there is no universally accepted theory of personality, five-factor model or OCEAN model (McCrae and John 1992) are most widely used ones in the simulation of computer characters. According to this model, the personality of a person can be defined according to five different traits: openness, conscientiousness, extroversion, agreeableness, and neuroticism, and they are explained in Hampson (1999). Openness means being open to experience new things, being imaginative, intelligent, and creative, whereas conscientiousness indicates responsibility, reliability, and tidiness. In other words, conscientious people think about all the outputs of their behaviors before taking action and take the responsibility for their actions. An extravert person is outgoing, sociable, assertive,

and energetic to achieve his or her goals. Agreeableness means a person is trustable, kind, and cooperative considering other people's goals and is ready to surrender his or her own goals. Finally, a neurotic person is anxious, nervous, and prone to depression and lacks emotional stability. Usually, a character is represented as a combination of these traits, possibly with emphasis on one of them. Although this static trait-based model of personality does not reflect the complexity of human behavior truly, it has been widely accepted to be used in computational models because of its simplicity.

Motivation is also a key cause of action, and we will consider basic motivations as essential to model life in the virtual world. When looking at the perspective of ACs, an AC can choose whether or not to pay attention and/or react to a given environmental stimulus according to its goals (Caamero 2000). The relation between motivations and emotions of a virtual human is simulated in de Sevin and Thalmann (2005). According to this framework, emotions influence motivations at qualitative levels such as length, perception, activation, and interruption.

33.8 Crowd Simulation

With the advent of crowd simulation (Thalmann and Musse 2007) technology, it becomes possible to create large-scale virtual environments populated by tens of thousands of virtual humans. Crowds have wide applications for both real-time simulation and non-real-time simulation. Virtual crowds are used to simulate epic battles in the movie industry; crowds are exploited to populate virtual worlds in computer games; in the area of safety training, trainees can participate in evacuation scenarios to practice controlling crowds in emergency situations like earthquakes, fires, and floods. Rendering large crowds is usually based on the instantiation of a small set of human templates. McDonnell et al. (2008) showed that introducing color variety was paramount to avoid a clone effect. Maim et al. (2009a) introduced an approach to obtain improved color variety based on segmentation maps using graphics processing unit (GPU) shader programming (deHeras et al. 2005). An accessory is a simple mesh representing any element that can be added to the original mesh of a virtual human (Maim et al. 2009b). Typical accessories include bags, glasses, hats, and mobile phones.

Crowd behavior and motion planning are two topics that have long been studied in fields such as robotics and sociology. More recently, however, and due to the technological improvements, these domains have aroused the interest of the computer graphics community as well.

The first approach studied was agent based and represents a natural way to simulate crowds as independent individuals interacting with each other. Such algorithms usually handle short-distance collision avoidance, in which navigation remains local. Reynolds (1999) proposed to use simple rules to model crowds and groups of interacting agents. Musse and Thalmann (1997, 2001) used sociological concepts in order to simulate relationships among virtual humans. Shao and Terzopoulos (2005) used perceptual, behavioral, and cognitive models to simulate individuals. Kirchner and Shadschneider (2002) used static potential fields to rule a cellular automaton. Metoyer and Hodgins (2003) proposed an avoidance algorithm based on a Bayesian decision process. Nevertheless, the main problem with agent-based algorithms is their low performance. With these methods, simulating thousands of pedestrians in real time requires the use of particular machines supporting parallelizations (Reynolds 2006). Moreover, such approaches forbid the construction of autonomous adaptable behaviors and can only manage crowds of pedestrians with local objectives. To solve the problems inherent in local navigation, some behavioral approaches have been extended with global navigation. Bayazit et al. (2003) stored global information in nodes of a probabilistic road map to handle navigation and introduced simple rules in order to manage groups. Sung et al. (2004) first introduced an architecture for developing situation-based crowd behavior, including groups. They later combined probabilistic road maps with motion graphs to find paths and animations to steer characters to a goal (Sung et al. 2005). Lau and Kuffner (2006) used pre-computed search trees of motion clips to accelerate the search for the best paths and motion sequences to reach an objective. Lamarche and Donikian (2004) used automatic topological model extraction of

FIGURE 33.6 Crowd simulation. (From Maim, J. et al., *IEEE Comput. Graphics Appl.*, 29(4), 44, 2009b.)

the environment for individual navigation. Another method, introduced by Kamphuis and Overmars (2004), allowed a group of agents to maintain a given cohesion while trying to reach a goal. Although these approaches offer appealing results, they are not fast enough to simulate thousands of pedestrians in real time. Loscos et al. (2003) presented a behavioral model based on a 2D map of the environment. Their method is suited for simulating wandering crowds but does not provide high-level control on pedestrian goals. Pettré et al. (2006, 2007) presented a novel approach to automatically extract a topology from the scene geometry and handle path planning using a navigation graph (see Figure 33.6). The main advantage of this technique is that it handles uneven and multilayered terrains. Nevertheless, it does not treat interpedestrian collision avoidance. Finally, Helbing et al. (1994, 2000) used agent-based approaches to handle motion planning but mainly focused on emergent crowd behaviors, in particular scenarios.

Another approach to motion planning is inspired by fluid dynamics. Such techniques use a grid to discretize the environment into cells. Hughes (2002, 2003) interpreted crowds as density fields to rule the motion planning of pedestrians. The resulting potential fields are dynamic, guiding pedestrians to their objective while avoiding obstacles. Chenney (2004) developed a model of flow tiles that ensures, under reasonable conditions, that agents do not require any form of collision detection at the expense of precluding any interaction between them. More recently, Treuille et al. (2006) proposed realistic motion planning for crowds. Their method produces a potential field that provides, for each pedestrian, the next suitable position in space (a waypoint) to avoid all obstacles. Compared to agent-based approaches, these techniques allow to simulate thousands of pedestrians in real time and are also able to show emergent behaviors. However, they produce less believable results, because they require assumptions that prevent treating each pedestrian with individual characteristics. For instance, only a limited number of goals can be defined and assigned to sets of pedestrians. The resulting performance depends on the size of the grid cells and the number of sets.

Hybrid approaches have been also proposed. Pelechano et al. (2007) combined psychological, physiological, and geometrical rules with physical forces to simulate dense crowds of autonomous agents. In a recent work, Yersin et al. (2008) introduced a hybrid architecture offering a scalable solution for real-time crowd motion planning. Based on a navigation graph, the environment is divided into regions

of varying interest. In regions of high interest, a potential field-based approach is exploited. In other regions, motion planning is ruled by a navigation graph and a short-term collision avoidance algorithm.

Except the topological model of the environment and path planning, collision avoidance is another challenging problem that needs to be addressed. Collision avoidance techniques should be efficient enough to prevent a large number of agents from bumping into each other in real time. Considering the case in which each agent navigates independently without explicit communication with other agents, van den Berg et al. (2008) propose a new concept the “reciprocal velocity obstacle,” which takes into account the reactive behavior of the other agents by implicitly assuming that the other agents make a similar collision avoidance reasoning. This concept can be applied to navigation of hundreds of agents in densely populated environments containing both static and moving obstacles for real-time simulation.

Ondrej et al. (2010) explored a novel vision-based approach of collision avoidance between walkers that fits the requirements of interactive crowd simulation. By simulating humans based on cognitive science results, visual stimuli are used to detect future collisions as well as the level of danger.

33.9 Cloth Animation

Weil (1986) pioneered cloth animation using an approximated model based on relaxation of the surface. Kunii and Godota (1990) used a hybrid model incorporating physical and geometrical techniques to model garment wrinkles. Aono (1990) simulated wrinkle propagation on a handkerchief using an elastic model. Terzopoulos and Fleischer (1988) applied their general elastic to a wide range of objects including cloth. Lafleur et al. (1991) and Carignan et al. (1992) have described complex interaction of clothes with synthetic actors in motion, which marked the beginning of a new era in cloth animation (Figure 33.7).

The first particle systems for cloth simulation were grid based (Breen et al. 1994, Eberhardt et al. 1996) and already featured the simulation of nonlinear behavior curves through formulations that made them quite analogous to continuum mechanics models. Their accuracy was however fairly limited for large deformations and required quite long computation times. Faster models, based on mass-spring grids, have become popular since fast implicit numerical integration methods were used (Baraff and Witkin 1998), because they allow a simple expression of the Jacobian of the particle forces while requiring only simple computations (Choi and Ko 2002, Desbrun et al. 1999, Meyer et al. 2001). Combined with advanced implicit integration methods (Eberhardt et al. 2000, Hauth and Eitzmuss 2001, Volino and Magnenat-Thalmann 2005b), these simulation schemes have become popular for real-time and interactive applications. Unfortunately, mass-spring systems are unable to model surface elasticity accurately (Wang and Deravajan 2005). Although some techniques have been developed to match their parameters with those of the simulated material, they do not allow full

FIGURE 33.7 3D garment. (Courtesy of MIRALab, University of Geneva, Geneva, Switzerland.)

discrimination among deformation modes (Bianchi et al. 2004), and they remain particularly inaccurate for anisotropic and nonlinear models. Such issues have given particle systems a reputation for inaccuracy.

On the other hand, FEMs have a good maturity for mechanical simulation. Their traditional field of application is elastic solid or shell modeling for mechanical engineering purposes, a context where linear elasticity and small deformations are the underlying assumptions. These formulations have not adapted well to very deformable objects such as cloth, and early attempts to model cloth using high-order elements (Eischen et al. 1996) led to impractically high computation times. Numerous authors have attempted to accelerate the computations required for finite elements. Preinverting the linear system matrix, used by Desbrun et al. (1999) for particle systems, may speed up the computation (Bro-Nielsen and Cotin 1996, Cotin et al. 1999) but is only practical when the mechanical system is small enough. Condensing the dynamics on the boundary of a closed volume can reduce the number of unknowns to solve at each time step (James and Pai 1999). These precomputations are possible when the force displacement relation is linear, which requires both geometrical and material linearity measurements while keeping material linearity. This is called the Saint Venant–Kirchhoff model, and it is used in volume simulation (Barbic and James 2005, Debunne et al. 2001, Hauth et al. 2003, O’Brien and Hodgins 1999, Picinbobo et al. 2003, Zhuang and Canny 2000). Recently, a new approach has been proposed, where the strain tensor is factored as the product of a pure rotation with Cauchy’s linear strain tensor aligned along the strain eigendirections (Irving et al. 2004, Muller et al. 2002, Nesme et al. 2005).

Volino et al. (2009) present a model that only addresses tensile viscoelasticity, which deals with in-plane deformations. Meanwhile, bending elasticity deals with out-of-plane deformations (surface curvature), and its main visible effect is to limit fold curvature and wrinkle size. In the context of high-accuracy simulations, this tensile model can easily be complemented by a bending model using the schemes defined by Grinspun et al. (2003) or Volino and Magnenat-Thalmann (2006).

33.10 Research Issues and Summary

Computer animation is no more just a tool to produce movies. It is now the basis for games, simulation, and VR. Moreover, real-time virtual humans are now part of virtual worlds, and people will increasingly communicate with them through broadband multimedia networks. In the future, the application of computer animation to the scientific world will become very common in scientific areas: fluid dynamics, molecular dynamics, thermodynamics, plasma physics, astrophysics, etc. Real-time complex animation systems will be developed taking advantage of VR devices and simulation methods. An integration between simulation methods and VR-based animation will lead to systems allowing the user to interact with complex time-dependent phenomena providing interactive visualization and interactive animation. The future will be intelligent virtual characters with memory and emotion and able to speak, to communicate, and to understand the situation. They will be able to dynamically react to the user and the environment. However, such future systems require real-time spontaneous animation for any situation. This is not possible today, and we are still far from this goal. But the current development is promising, and one will see more and more spectacular dynamic animations.

Further Information

Textbooks on computer

Parent, R. 2008. *Computer Animation: Algorithms and Techniques*, 2nd edn., Morgan-Kaufmann, Burlington, MA.

Kerlow, I. 2004. *The Art of 3-D Computer Animation and Effects*, John Wiley & Sons, Los Angeles, CA.

Magnenat Thalmann, N. and Thalmann, D. (eds.) 2004. *Handbook of Virtual Humans*, John Wiley & Sons, West Sussex, U.K.

Two books could be mentioned for *Crowd Simulation* and Cloth simulation:

Thalmann, D. and Musse, S.R. 2012. *Crowd Simulation*, 2nd edn., Springer, London, U.K.

Volino, P., Magnenat-Thalmann, N. 2000. *Virtual Clothing: Theory and Practice*, Springer, Berlin, Germany.

Journal dedicated to computer animation: *Computer Animation and Virtual Worlds* published by John Wiley & Sons, Chichester, U.K. (since 1990).

Although computer animation is always represented in major computer graphics conferences like SIGGRAPH, Computer Graphics International (CGI), Pacific Graphics, and Eurographics, there are only two annual conferences dedicated to computer animation:

Computer Animation and Social Agents (CASA), organized each year by the Computer Graphics Society. Proceedings are published as a Special Issue of *Computer Animation and Virtual Worlds* (John Wiley & Sons).

Symposium on Computer Animation (SCA) organized by SIGGRAPH and Eurographics.

34.1 Introduction

Logical systems have been applied to various intelligent systems as their theoretical foundations or reasoning languages such as logic programming. However, some actual systems include a lot of inconsistency such as contradictions, dilemma, and conflicts. It is required to deal with such inconsistency in the same system if we formalize the system in logic aiming at an intelligent system. Ordinal logical systems can not deal with inconsistency such as p and $\neg p$ consistently in the system. A logical system that can deal with inconsistency is known as *paraconsistent logic*. The main purpose of paraconsistent logic is to deal with inconsistency in a framework of consistent logical systems. It has been more than six decades since the first paraconsistent logical system was proposed by S. Jaskowski [8]. It was four decades later than that a family of paraconsistent logic called *annotated logic* was proposed in [3,44]. They can deal with inconsistency with many truth values called annotations that should be attached to each atomic formula, although their formula valuation is two-valued.

The paraconsistent annotated logic was developed from the viewpoint of logic programming [10], aimed at applications to computer science such as semantics for knowledge bases in [2,9,45]. Furthermore, in order to deal with inconsistency and nonmonotonic reasoning in a framework of annotated logic programming, the paraconsistent annotated logic programming was developed to treat ontological (strong) negation and the stable model semantics [7,6] in [13] and named *annotated logic program with strong negation* (ALPSN). It has been applied to some nonmonotonic systems, default logic [42], autoepistemic logic [12], and a nonmonotonic assumption based truth maintenance system (ATMS) [4] as their computational models in [14,31,32]. ALPSN can deal with not only inconsistency such as conflict but also nonmonotonic reasoning such as default reasoning. However, it seems to be more important and useful from a practical viewpoint to deal with resolving conflict in a logical way than just to express conflicts consistently. It is not so adequate for ALPSN to deal with resolving conflict or decision making based on resolving conflict in its logical framework. Defeasible logic [5] is known as one of formalizations for nonmonotonic reasoning called *defeasible reasoning* that can deal with

resolving conflict easily in a logical way [1,38,39]. However, defeasible logic cannot treat inconsistency in its syntax and its inference rules are too complicated to implement them easily. Therefore, in order to deal with defeasible reasoning in a framework of paraconsistent annotated logic programming, a new version of ALPSN called *vector annotated logic program with strong negation* (VALPSN) was also proposed and applied to resolving conflict [15–17]. It also has been shown that VALPSN provides a computational model of a defeasible logic [18]. Moreover, VALPSN has been extended to deal with deontic notions (obligation, forbiddance, and permission) [11], and the extended version of VALPSN was named *extended vector annotated logic program with strong negation* (EVALPSN) in [19,20]. EVALPSN can deal with defeasible deontic reasoning [40] and has been applied to various kinds of safety verification-based control. The basic ideas of EVALPSN safety verification are that each control system has norms such as guidelines for safe control. Such norms can be formulated in EVALPSN deontic expressions; then the safety verification for control systems can be carried out by EVALPSN defeasible deontic reasoning. Compared to conventional safety verification methods, EVALPSN safety verification has some advantages such that it can provide a formal safety verification method and a computational framework for control systems as logic programming. Considering the safety verification for process control, there are cases in which the safety verification for process order is significant. EVALPSN has been applied to railway interlocking safety verification [23], robot action control [21,24,25,34], safety verification for air traffic control [22], traffic signal control [26], discrete event control [27–29], and pipeline valve control [30,33].

This chapter is organized as follows: in Section 34.2, the paraconsistent annotated logic program EVALPSN is reviewed; in Section 34.3, the outline of EVALPSN-based safety verification system is introduced and examples of its application to pipeline valve control are also given; in Section 34.4, we conclude this chapter by describing the advantages and disadvantages of applying EVALPSN to intelligent control systems.

We assume that the readers are familiar with the basic knowledge of logic and logic program.

34.2 EVALPSN

In this section, we review a paraconsistent annotated logic program EVALPSN briefly [20]. Generally, a truth value called an *annotation* is explicitly attached to each literal in annotated logic programs [2]. For example, let p be a literal, μ an annotation, then

$$p : \mu$$

is called an *annotated literal*. The set of annotations constitutes a complete lattice. An annotation in EVALPSN has a form of

$$[(i, j), \mu]$$

called an *extended vector annotation*. The first component (i, j) is called a *vector annotation* and the set of vector annotations constitutes the complete lattice,

$$\mathcal{T}_v(n) = \{(x, y) \mid 0 \leq x \leq n, 0 \leq y \leq n, x, y, \text{ and } n \text{ are integers}\},$$

in Figure 34.1. The ordering (\preceq_v) of complete lattice $\mathcal{T}_v(n)$ is defined as

$$\text{let } (x_1, y_1), (x_2, y_2) \in \mathcal{T}_v(n),$$

$$(x_1, y_1) \preceq_v (x_2, y_2) \quad \text{iff} \quad x_1 \leq x_2 \quad \text{and} \quad y_1 \leq y_2.$$

FIGURE 34.1 Lattice $\mathcal{T}_v(2)$ and lattice \mathcal{T}_d .

For each extended vector annotated literal $p : [(i, j), \mu]$, integer i denotes the amount of positive information to support literal p and integer j denotes the negative one. The second component μ is an index of fact and deontic notions such as obligation, and the set of the second components constitutes the complete lattice,

$$\mathcal{T}_d = \{\perp, \alpha, \beta, \gamma, *1, *2, *3, \top\}.$$

The ordering (\preceq_d) of complete lattice \mathcal{T}_d is described by Hasse's diagram in Figure 34.1. The intuitive meaning of each member of complete lattice \mathcal{T}_d is as follows:

- \perp (unknown), \top (inconsistency)
- α (fact), β (obligation), γ (non-obligation),
- *1(fact and obligation), *2(obligation and non-obligation),
- *3(fact and non-obligation).

Then the complete lattice $\mathcal{T}_e(n)$ of extended vector annotations is defined as the product $\mathcal{T}_v(n) \times \mathcal{T}_d$ of complete lattices $\mathcal{T}_v(n)$ and \mathcal{T}_d . The ordering (\preceq_e) of complete lattice $\mathcal{T}_e(n)$ is defined as let $[(i_1, j_1), \mu_1]$ and $[(i_2, j_2), \mu_2] \in \mathcal{T}_e$,

$$[(i_1, j_1), \mu_1] \preceq_e [(i_2, j_2), \mu_2] \text{ iff } (i_1, j_1) \preceq_v (i_2, j_2) \text{ and } \mu_1 \preceq_d \mu_2.$$

There are two kinds of *epistemic negation* (\neg_1 and \neg_2) in EVALPSN, both of which are defined as mappings over complete lattices $\mathcal{T}_v(n)$ and \mathcal{T}_d , respectively.

Definition 34.1 (epistemic negations \neg_1 and \neg_2 in EVALPSN)

$$\begin{aligned} \neg_1([(i, j), \mu]) &= [(j, i), \mu], \quad \forall \mu \in \mathcal{T}_d, \\ \neg_2([(i, j), \perp]) &= [(i, j), \perp], \quad \neg_2([(i, j), \alpha]) = [(i, j), \alpha], \\ \neg_2([(i, j), \beta]) &= [(i, j), \gamma], \quad \neg_2([(i, j), \gamma]) = [(i, j), \beta], \\ \neg_2([(i, j), *1]) &= [(i, j), *3], \quad \neg_2([(i, j), *2]) = [(i, j), *2], \\ \neg_2([(i, j), *3]) &= [(i, j), *1], \quad \neg_2([(i, j), \top]) = [(i, j), \top]. \end{aligned}$$

If we regard epistemic negation as a syntactical operation, epistemic negations followed by literals can be eliminated by the syntactical operation. For example,

$$\neg_1(p : [(2,0),\alpha]) = p : [(0,2),\alpha] \quad \text{and} \quad \neg_2(q : [(1,0),\beta]) = p : [(1,0),\gamma].$$

There is another negation called *strong negation* (\sim) in EVALPSN, and it is treated as well as classical negation.

Definition 34.2 (strong negation \sim) (see [3])

Let F be any formula and \neg be \neg_1 or \neg_2 :

$$\sim F =_{def} F \rightarrow ((F \rightarrow F) \wedge \neg(F \rightarrow F)).$$

Definition 34.3 (well-extended vector annotated literal)

Let p be a literal.

$$p : [(i, 0), \mu] \quad \text{and} \quad p : [(0, j), \mu]$$

are called *weva* (*well-extended vector annotated*) *literals*, where $i, j \in \{1, 2, \dots, n\}$ and $\mu \in \{\alpha, \beta, \gamma\}$.

Definition 34.4 (EVALPSN)

If L_0, \dots, L_n are weva literals,

$$L_1 \wedge \dots \wedge L_i \wedge \sim L_{i+1} \wedge \dots \wedge \sim L_n \rightarrow L_0$$

is called an *EVALPSN clause*. An *EVALPSN* is a finite set of EVALPSN clauses.

Usually, a deontic operator \bigcirc is used for expressing obligation in deontic logic; we describe the relation between deontic expressions and EVALPSN literals. Let \bigcirc be a deontic operator representing obligation and p a literal and,

p is represented by $p : [(m, 0), \alpha]$ (fact),

$\bigcirc p$ is represented by $p : [(m, 0), \beta]$ (obligation),

$\bigcirc\neg p$ is represented by $p : [(0, m), \beta]$ (forbiddance),

$\neg\bigcirc\neg p$ is represented by $p : [(0, m), \gamma]$ (permission),

where m is a positive integer.

We now address the formal interpretation of EVALPSN literals. Generally, the interpretation of annotated proposition is defined as follows: let ν be the set of all propositional symbols, \mathcal{F} the set of all formulas, and \mathcal{T} the complete lattice of annotations; then, an interpretation I is a function:

$$I : \nu \longrightarrow \mathcal{T}.$$

To each interpretation I , the valuation function such that

$$v_I : \mathcal{F} \longrightarrow \{0,1\}$$

is defined as follows:

- (1) Let p be a propositional symbol and μ an annotation:

$$v_I(p : \mu) = 1 \text{ if } \mu \leq I(p), \quad v_I(p : \mu) = 0 \text{ if } \mu \not\leq I(p),$$

where the symbol \leq is the order over complete lattice \mathcal{T} .

- (2) Let A and B be any formulas, and A not an annotated atom:

$$v_I(\neg A) = 1 \text{ if } v_I(A) = 0, \quad v_I(\sim B) = 1 \text{ if } v_I(B) = 0;$$

other formulas, $A \rightarrow B$, $A \wedge B$, $A \vee B$ are evaluated as usual.

We here note that for any literal p , $v_I(p : \perp) = 1$ holds, which intuitively means that annotated literal $p : \perp$ is always satisfied, where \perp is the bottom annotation of the complete lattice of annotations.

Example 34.1 Suppose an EVALPSN

$$P = \{p : [(0,1), \alpha] \wedge \sim q : [(2,0), \beta] \rightarrow r : [(0,1), \gamma], \quad (34.1)$$

$$p : [(2,0), \alpha], \quad (34.2)$$

$$p : [(0,2), \alpha], \quad (34.3)$$

$$q : [(2,0), \gamma], \quad (34.4)$$

$$q : [(1,0), \beta], \quad (34.5)$$

where p , q , and r are literals. We show the derivation of the head literal of EVALPSN clause (34.1), $r : [(0, 1), \gamma]$ in EVALPSN P . In order to derive the head literal, we need to show that the body of EVALPSN clause (34.1) is satisfied, that is, EVALP literal $p : [(0, 1), \alpha]$ is satisfied and EVALP literal $q : [(2, 0), \beta]$ is not satisfied in EVALPSN P . If we consider EVALP clause (34.2), as

$$[(0,1), \alpha] \not\leq_e [(2,0), \alpha],$$

it does not satisfy EVALP literal $p : [(0, 1), \alpha]$; on the other hand, if we consider EVALP clause (34.3), as

$$[(0,1), \alpha] \leq_e [(0,2), \alpha],$$

it satisfies EVALP literal $p : [(0, 1), \alpha]$.

On the other hand, if we consider EVALP clause (34.4), as

$$[(2,0), \beta] \not\leq_e [(2,0), \gamma],$$

it does not satisfy EVALP literal $q : [(2, 0), \beta]$; furthermore, even if we consider another EVALP clause (34.5), as

$$[(2,0),\beta] \not\leq_e [(1,0),\beta],$$

it does not satisfy EVALP literal $q : [(2, 0), \beta]$. Therefore, the head literal $r : [(0, 1), \gamma]$ of EVALPSN clause (34.1) can be derived.

34.3 EVALPSN Safety Verification for Pipeline Control

This section introduces EVALPSN-based intelligent safety verification for a pipeline valve control with a simple brewery pipeline example.

34.3.1 Pipeline Network

The pipeline network described in Figure 34.2 is taken as an example of brewery pipeline valve control based on EVALPSN safety verification. In Figure 34.2, an arrow represents the direction of liquid flow, a home-plate pentagon does a liquid tank, and a cross does a valve. In the pipeline network, we consider three kinds of physical entities,

four tanks (T_0, T_1, T_2, T_3), two valves (V_0, V_1), and

five pipes ($Pi_0, Pi_1, Pi_2, Pi_3, Pi_4$),

and three kinds of logical entities,

four processes (Pr_0, Pr_1, Pr_2, Pr_3), two valves (V_0, V_1), and

five subprocesses ($SPr_0, SPr_1, SPr_2, SPr_3, SPr_4$),

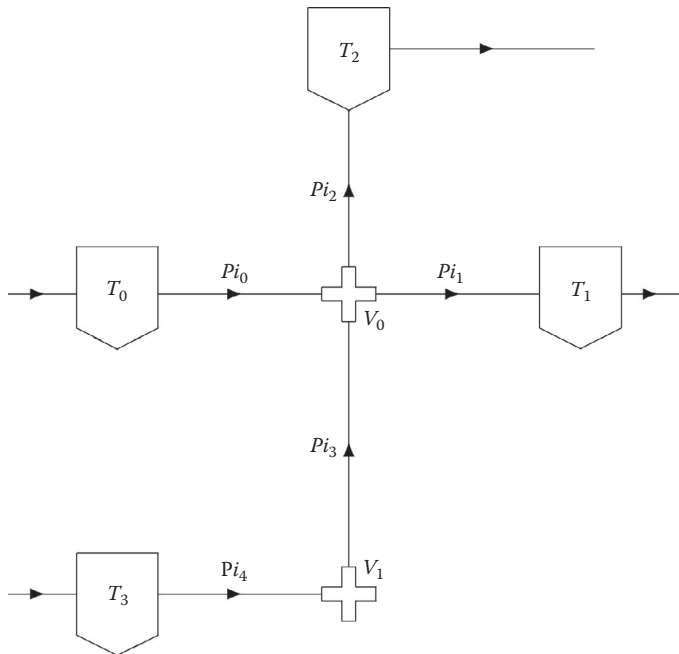

FIGURE 34.2 Pipeline example.

FIGURE 34.3 Normal and cross directions.

where the logical entities are used for EVALPSN-based safety verification. We suppose that a subprocess is defined as a logical process using a pipe, a valve is also defined to be a logically controlled entity, and a process is defined as a set of subprocesses and valves in the verification system. For example, process Pr_0 consists of subprocesses SPr_0 and SPr_1 and valve V_0 .

We assume that the valves can physically control two liquid flows in the normal and cross directions as shown in Figure 34.3. Furthermore, each logical entity is supposed to have logical states:

- Subprocesses have two logical states *locked* (l) and *free* (f), where “the subprocess is locked” means that it is logically reserved for one kind of liquid and “free” means that it can be logically reserved for any kind of liquid but unlocked.
- Valves have two logical states, *controlled mixture* (cm), representing that the valve is controlled to mix the liquid flows in normal and cross directions, and *controlled separate* (cs), representing that the valve is controlled to separate the liquid flows in normal and cross directions as shown in Figure 34.4.
- Processes have two states *set* (s) and *unset* (xs), where “the process is set” means that all subprocesses and valves in the process are locked and controlled consistently and “unset” means not set.

We also assume that there are five kinds of cleaning liquid for the pipeline network, cold water (cw), warm water (ww), hot water (hw), nitric acid (na), and caustic soda (cs). We now consider the following four processes:

Process Pr_0 a beer process,

$$T_0 \longrightarrow V_0(cs) \longrightarrow T_1$$

FIGURE 34.4 Controlled mixture and separate.

Process Pr_1 a cleaning process by nitric acid,

$$T_3 \longrightarrow V_1(\text{ cm }) \longrightarrow V_0(\text{ cs }) \longrightarrow T_2$$

Process Pr_2 a cleaning process by cold water,

$$T_3 \longrightarrow V_1(\text{ cm }) \longrightarrow V_0(\text{ cs }) \longrightarrow T_2$$

Process Pr_3 a brewery process with mixing,

In order to verify the safety for processes Pr_0 , Pr_1 , Pr_2 , and Pr_3 , the pipeline network operator issues process requests to be verified, which consists of an if-part and a then-part. The if-part of a process request describes the current logical state of the pipelines in the process to be safety verified, and the then-part of it describes permission for setting the process. For example, if a process request for verifying the safety of process Pr_1 is described as

if Subprocess SPr_0 is free, subprocess SPr_1 is free,
 valve V_0 is controlled separate physically but not locked logically.

then Process Pr_0 can be set.

We also consider the following process schedule including processes Pr_0 , Pr_1 , Pr_2 , and Pr_3 :

- PRS-0 process Pr_0 must start before any other processes
- PRS-1 process Pr_1 must start immediately before process Pr_0
- PRS-2 process Pr_2 must start immediately after process Pr_1
- PRS-3 process Pr_3 must start immediately after both processes Pr_0 and Pr_2 finished,

which are shown in the process schedule chart (Figure 34.5).

34.3.2 Pipeline Safety Property

We introduce some safety properties as the criteria of the pipeline process safety verification, SPr for subprocesses, Val for valves, and Pr for processes, which assure the safety for pipeline processes Pr_0 , Pr_1 , Pr_2 , and Pr_3 , that is, for avoiding unexpected mixtures of different kinds of liquid in the same pipeline and valve:

- SPr : It is a forbidden case that the sub process over a given pipe is simultaneously locked by different kinds of liquid.

FIGURE 34.5 Process schedule chart.

- *Val*: It is a forbidden case that valves are controlled for unexpected mixture of liquid.
- *Pr*: Whenever a process is set, all its component sub processes are locked and all its component valves are controlled consistently.

34.3.3 Predicates for Safety Verification

The EVALPSN-based safety verification is carried out by verifying whether the process request contradicts the safety properties or not in EVALPSN. Then the following three steps have to be executed:

1. The safety properties and some other control policies are translated into EVALPSN clauses, and they are stored as EVALPSN P_{sc} .
2. The if-part and then-part of the process request are translated into EVALPSN clauses as EVALPSNs P_i and P_t .
3. EVALPSN P_i is inquired from EVALPSN $\{P_{sc} \cup P_i\}$, then if *yes* is returned, the safety for the pipeline process is assured; otherwise it is not assured.

In the safety verification for pipeline processes, the following predicates are used in EVALPSN:

- $Pr(i, l)$ represents that process i for liquid l is set(s) or unset(xs), where each $i \in \{p0, p1, p2, p3\}$ is a process id corresponding to processes $Pr_0, Pr_1, Pr_2,$ and Pr_3 , and each $l \in \{b, cw, ww, hw, na, cs\}$ is a liquid id corresponding to beer, cold water, warm water, hot water, nitric acid, and caustic soda, and we have EVALP clause $Pr(i, l) : [\mu_1, \mu_2]$, where

$$\mu_1 \in \mathcal{T}_v = \{\perp_1, s, xs, \top_1\} \quad \text{and} \quad \mu_2 \in \mathcal{T}_d = \{\perp, \alpha, \beta, \gamma, *1, *2, *3, \top\}.$$

Complete lattice \mathcal{T}_v is a variant of complete lattice \mathcal{T}_v in Figure 34.6 as $n = 1$. Therefore, annotations $\perp_1, s, xs,$ and \top_1 represent vector annotations (0, 0), (1, 0), (0, 1), and (1, 1), respectively. The epistemic negation \neg_1 over \mathcal{T}_v is defined by the following mapping:

$$\begin{aligned} \neg_1([\perp_1, \mu_2]) &= [\perp_1, \mu_2], & \neg_1([s, \mu_2]) &= [xs, \mu_2], \\ \neg_1([\top_1, \mu_2]) &= [\top_1, \mu_2], & \neg_1([xs, \mu_2]) &= [s, \mu_2]. \end{aligned}$$

For example, EVALP clause $Pr(p2, b) : [s, \alpha]$ can be intuitively interpreted as “it is a fact that beer process Pr_2 is set.”

FIGURE 34.6 Complete lattice $\mathcal{T}_v(n = 1)$.

- $SPr(i, j, l)$ represents that the sub process from valve i (or tank i) to valve j (or tank j) occupied by liquid l is locked (1) or free (f). Moreover, if a sub-process is free, then the kind of liquid in the pipe does not matter, and the liquid is represented by symbol “0” (zero). Therefore, we have

$$l \in \{b, cw, ww, hw, na, cs, 0\} \text{ and } i, j \in \{v0, v1, t0, t1, t2, t3\},$$

which are valve and tank ids corresponding to valves and tanks $V_0, V_1, T_0, T_1, T_2,$ and T_3 . Then we have EVALP clause $SPr(i, j, l) : [\mu_1, \mu_2]$, where

$$\mu_1 \in \mathcal{T}_{v_2} = \{\perp_2, \perp, f, \top_2\} \quad \text{and} \quad \mu_2 \in \mathcal{T}_d = \{\perp, \alpha, \beta, \gamma, *1, *2, *3, \top\}.$$

Complete lattice \mathcal{T}_{v_2} is a variant of complete lattice \mathcal{T}_v in Figure 34.6 as $n = 1$. Therefore, annotations $\perp_2, \perp, f,$ and \top_2 represent vector annotations (0, 0), (1, 0), (0, 1), and (1, 1), respectively. The epistemic negation \neg_1 over \mathcal{T}_{v_2} is defined by the following mapping:

$$\begin{aligned} \neg_1([\perp_2, \mu_2]) &= [\perp_2, \mu_2], & \neg_1([\perp, \mu_2]) &= [f, \mu_2], \\ \neg_1([\top_2, \mu_2]) &= [\top_2, \mu_2], & \neg_1([f, \mu_2]) &= [\perp, \mu_2]. \end{aligned}$$

For example, EVALP clause $SPr(v0, t1, b) : [f, \gamma]$ can be intuitively interpreted as “the subprocess from valve $v0$ to tank $t1$ is permitted to be locked under the beer process.”

- $Val(i, l_n, l_c)$ represents that valve i occupied by two kinds of liquid $l_n, l_c \in \{b, cw, ww, hw, na, cs, 0\}$ is controlled separate (cs) or mixture (cm), where $i \in \{v0, v1\}$ is a valve id. We assume that there are two directed liquid flows in *normal* or *cross* directions of valves (Figure 34.3). Therefore, the second argument l_n represents liquid flowing in normal direction and the third argument l_c represents liquid flowing in cross direction. Generally, if a valve is released from the controlled state, liquid flow in the valve is represented by the specific symbol 0 that means “free.” We have EVALP clause $Val(i, l_n, l_c) : [\mu_1, \mu_2]$, where

$$\mu_1 \in \mathcal{T}_{v_3} = \{\perp_3, cm, cs, \top_3\} \quad \text{and} \quad \mu_2 \in \mathcal{T}_d = \{\perp, \alpha, \beta, \gamma, *1, *2, *3, \top\}.$$

Complete lattice \mathcal{T}_{v_3} is a variant of complete lattice \mathcal{T}_v in Figure 34.6 as $n = 1$. Therefore, annotations $\perp_3, cm, cs,$ and \top_3 represent vector annotations (0, 0), (1, 0), (0, 1), and (1, 1), respectively. The epistemic negation \neg_1 over \mathcal{T}_{v_3} is defined by the following mapping:

$$\begin{aligned} \neg_1([\perp_3, \mu_2]) &= [\perp_3, \mu_2], & \neg_1([cs, \mu_2]) &= [cm, \mu_2], \\ \neg_1([\top_3, \mu_2]) &= [\top_3, \mu_2], & \neg_1([cm, \mu_2]) &= [cs, \mu_2]. \end{aligned}$$

We assume that if a process finishes, all valves included in the process are controlled separate (closed). For example, EVALP clause $Val(v0, 0, 0) : [cs, \alpha]$ can be intuitively interpreted as “valve $v0$ has been released from controlled separate”; EVALP clause $Val(v0, b, cw) : [cs, \beta]$ can be intuitively interpreted as both “it is forbidden for valve $v0$ to be controlled mixture with beer b in normal direction and cold water cw in cross direction,” and “it is obligatory for valve $v0$ to be controlled separate with beer b in normal direction and cold water cw in cross direction”; and EVALP clause $Val(v0, 0, b) : [cs, \alpha]$ can be intuitively interpreted as “it is a fact that valve $v0$ is controlled separate with free flow 0 in normal direction and beer b in cross direction.”

- $Eq(l_1, l_2)$ represents that the kinds of liquids l_1 and l_2 are the same (sa) or different (di), where $l_1, l_2 \in \{b, cw, ww, hw, na, cs, 0\}$. We have EVALP clause $Eq(l_1, l_2) : [\mu_1, \mu_2]$, where

$$\mu_1 \in \mathcal{T}_{v_4} = \{\perp_4, sa, di, \top_4\} \quad \text{and} \quad \mu_2 \in \mathcal{T}_d = \{\perp, \alpha, \beta, \gamma, *1, *2, *3, \top\}.$$

Complete lattice \mathcal{T}_{v_4} is a variant of complete lattice \mathcal{T}_v in Figure 34.6 as $n = 1$. Therefore, annotations \perp_4 , sa, di, and \top_4 represent vector annotations (0, 0), (1, 0), (0, 1), and (1, 1), respectively. The epistemic negation \neg_1 is defined by the following mapping.

$$\neg_1([\perp_4, \mu_2]) = [\perp_4, \mu_2], \quad \neg_1([di, \mu_2]) = [sa, \mu_2],$$

$$\neg_1([\top_4, \mu_2]) = [\top_4, \mu_2], \quad \neg_1([sa, \mu_2]) = [di, \mu_2].$$

Now we consider process release conditions when processes have finished and define some more predicates to represent the conditions. We assume that if the terminal tank T_i of process Pr_j is filled with one kind of liquid, the finish signal $Fin(pj)$ of process Pr_j is issued.

- $Tan(ti, l)$ represents that tank T_i has been filled fully (fu) with liquid l or empty (em). Then we have EVALP clause $Tan(ti, l) : [\mu_1, \mu_2]$, where $i \in \{0, 1, 2, 3\}$ and $l \in \{b, cw, ww, hw, na, cs, 0\}$,

$$\mu_1 \in \mathcal{T}_{v_5} = \{\perp_5, fu, em, \top_5\} \quad \text{and} \quad \mu_2 \in \mathcal{T}_d = \{\perp, \alpha, \beta, \gamma, *1, *2, *3, \top\}.$$

Complete lattice \mathcal{T}_{v_5} is a variant of complete lattice \mathcal{T}_v in Figure 34.6 as $n = 1$. Therefore, annotations \perp_5 , fu, em, and \top_5 represent vector annotations (0, 0), (1, 0), (0, 1), and (1, 1), respectively. The epistemic negation \neg_1 over \mathcal{T}_{v_5} is defined by the following mapping:

$$\neg_1([\perp_5, \mu_2]) = [\perp_5, \mu_2], \quad \neg_1([fu, \mu_2]) = [em, \mu_2],$$

$$\neg_1([\top_5, \mu_2]) = [\top_5, \mu_2], \quad \neg_1([em, \mu_2]) = [fu, \mu_2].$$

Note that annotation \perp_5 can be intuitively interpreted to represent “no information in terms of liquid amount.” For example, EVALP clause $Tan(t2, 0) : [em, \alpha]$ can be interpreted as “it is a fact that tank $t2$ is empty.”

- $Str(pi)$ represents that the start signal for process Pr_i is issued (is) or not (ni).
- $Fin(pj)$ represents that the finish signal for process Pr_j has been issued (is) or not (ni). Then we have EVALP clauses $Str(pi) : [\mu_1, \mu_2]$ and $Fin(pj) : [\mu_1, \mu_2]$, where $i, j \in \{0, 1, 2, 3\}$,

$$\mu_1 \in \mathcal{T}_{v_6} = \{\perp_6, ni, is, \top_6\} \quad \text{and} \quad \mu_2 \in \mathcal{T}_d = \{\perp, \alpha, \beta, \gamma, *1, *2, *3, \top\}.$$

Complete lattice \mathcal{T}_{v_6} is a variant of complete lattice \mathcal{T}_v in Figure 34.6 as $n = 1$. Therefore, annotations \perp_6 , is, ni, and \top_6 represent vector annotations (0, 0), (1, 0), (0, 1), and (1, 1), respectively. The epistemic negation \neg_1 over \mathcal{T}_{v_6} is defined by the following mapping:

$$\neg_1([\perp_6, \mu_2]) = [\perp_6, \mu_2], \quad \neg_1([is, \mu_2]) = [ni, \mu_2],$$

$$\neg_1([\top_6, \mu_2]) = [\top_6, \mu_2], \quad \neg_1([ni, \mu_2]) = [is, \mu_2].$$

For example, EVALP clause $Fin(p3) : [\uparrow, \alpha]$ can be interpreted as “it is a fact that the finish signal for process Pr_3 has not been issued yet.”

34.3.4 Safety Property into EVALPSN

Here, we formalize all safety properties SPr , Val , and Pr in EVALPSN. Safety property SPr is intuitively interpreted as derivation rules of forbiddance. If a sub process from valve(or tank) i to valve(or tank) j is locked by one kind of liquid, it is forbidden for the subprocess to be locked by different kinds of liquid processes simultaneously. Thus, we have the following EVALPSN clauses:

$$\begin{aligned} &SPr(i, j, l_1) : [\uparrow, \alpha] \wedge \sim Eql(l_1, l_2) : [\uparrow, \alpha] \\ &\rightarrow SPr(i, j, l_2) : [\uparrow, \beta], \end{aligned} \quad (34.6)$$

where $l_1, l_2 \in \{b, cw, ww, hw, na, cs\}$. Moreover, in order to derive permission for locking subprocesses, we need the following EVALPSN clauses:

$$\sim SPr(i, j, l) : [\uparrow, \beta] \rightarrow SPr(i, j, l) : [\uparrow, \gamma], \quad (34.7)$$

where $l \in \{b, cw, ww, hw, na, cs\}$.

Safety property Val is intuitively interpreted as derivation rules of forbiddance. We have to consider two cases: one is for deriving forbiddance from changing the control state of the valve and another one is for deriving forbiddance from mixing different kinds of liquid without changing the control state of the valve.

Case 1

If a valve is controlled separate, it is forbidden for the valve to be controlled mix; conversely, if a valve is controlled mix, it is forbidden for the valve to be controlled separate. Thus, we have the following EVALPSN clauses:

$$\begin{aligned} &Val(i, l_n, l_c) : [cs, \alpha] \wedge \sim Eql(l_n, 0) : [\uparrow, \alpha] \wedge \\ &\sim Eql(l_c, 0) : [\uparrow, \alpha] \rightarrow Val(i, l_n, l_c) : [cs, \beta], \end{aligned} \quad (34.8)$$

$$\begin{aligned} &Val(i, l_n, l_c) : [cm, \alpha] \wedge \sim Eql(l_n, 0) : [\uparrow, \alpha] \wedge \\ &\sim Eql(l_c, 0) : [\uparrow, \alpha] \rightarrow Val(i, l_n, l_c) : [cm, \beta], \end{aligned} \quad (34.9)$$

where $l_n, l_c \in \{b, cw, ww, hw, na, cs, 0\}$.

Case 2

Next, we consider the other forbiddance derivation case in which different kinds of liquid are mixed even if the valve control state is not changed. We have the following EVALPSN clauses:

$$\begin{aligned} &Val(i, l_{m_1}, l_{c_1}) : [cs, \alpha] \wedge \sim Eql(l_{m_1}, l_{m_2}) : [\uparrow, \alpha] \wedge \\ &\sim Eql(l_{m_1}, 0) : [\uparrow, \alpha] \rightarrow Val(i, l_{m_2}, l_{c_2}) : [cm, \beta], \end{aligned} \quad (34.10)$$

$$\begin{aligned} &Val(i, l_{m_1}, l_{c_1}) : [cs, \alpha] \wedge \sim Eql(l_{c_1}, l_{c_2}) : [\uparrow, \alpha] \wedge \\ &\sim Eql(l_{c_1}, 0) : [\uparrow, \alpha] \rightarrow Val(i, l_{m_2}, l_{c_2}) : [cm, \beta], \end{aligned} \quad (34.11)$$

$$\begin{aligned} & Val(i, l_{n_1}, l_{c_1}) : [cm, \alpha] \wedge \sim Eq(l_{n_1}, l_{n_2}) : [sa, \alpha] \\ & \rightarrow Val(i, l_{n_2}, l_{c_2}) : [cs, \beta], \end{aligned} \quad (34.12)$$

$$\begin{aligned} & Val(i, l_{n_1}, l_{c_1}) : [cm, \alpha] \wedge \sim Eq(l_{c_1}, l_{c_2}) : [sa, \alpha] \\ & \rightarrow Val(i, l_{n_2}, l_{c_2}) : [cs, \beta], \end{aligned} \quad (34.13)$$

where $l_n, l_c \in \{b, cw, ww, hw, na, cs, 0\}$ and $l_{n_2}, l_{c_2} \in \{b, cw, ww, hw, na, cs\}$.

Note that the EVALPSN clause $\sim Eq(l_n, 0) : [sa, \alpha]$ represents that there does not exist information such that the normal direction with liquid l_n in the valve is free (not controlled). As well as the case of subprocesses, in order to derive permission for controlling valves, we need the following EVALPSN clauses:

$$\sim Val(i, l_n, l_c) : [cm, \beta] \rightarrow Val(i, l_n, l_c) : [cm, \gamma], \quad (34.14)$$

$$\sim Val(i, l_n, l_c) : [cs, \beta] \rightarrow Val(i, l_n, l_c) : [cs, \gamma], \quad (34.15)$$

where $l_n, l_c \in \{b, cw, ww, hw, na, cs, 0\}$.

Safety property Pr is intuitively interpreted as derivation rules of permission and directly translated into EVALPSN clauses as a rule: “if all the components of the process can be locked or controlled consistently, then the process can be set.” For example, if beer process Pr_0 consists of the subprocess from tank T_0 to valve V_0 , valve V_0 (beer in normal direction), and the subprocess from valve V_0 to tank T_1 , then we have the following EVALP clause to obtain permission for setting process Pr_0 :

$$\begin{aligned} & SPr(t0, v0, b) : [f, \gamma] \wedge SPr(v0, t1, b) : [f, \gamma] \wedge \\ & Val(v0, b, l) : [cm, \gamma] \wedge Tan(t0, b) : [fu, \alpha] \wedge \\ & Tan(t1, 0) : [em, \alpha] \rightarrow Pr(p0, b) : [xs, \gamma] \end{aligned} \quad (34.16)$$

where $l \in \{b, cw, ww, hw, na, cs, 0\}$. We also have the following EVALP clauses for setting other processes Pr_1 , Pr_2 , and Pr_3 :

$$\begin{aligned} & SPr(t3, v1, na) : [f, \gamma] \wedge SPr(v1, v0, na) : [f, \gamma] \wedge \\ & SPr(v0, t2, na) : [f, \gamma] \wedge Val(v0, l, na) : [cm, \gamma] \wedge \\ & Val(v1, na, 0) : [cs, \gamma] \wedge Tan(t3, na) : [fu, \alpha] \wedge \\ & Tan(t2, 0) : [em, \alpha] \rightarrow Pr(p1, na) : [xs, \gamma], \end{aligned} \quad (34.17)$$

$$\begin{aligned} & SPr(t3, v1, cw) : [f, \gamma] \wedge SPr(v1, v0, cw) : [f, \gamma] \wedge \\ & SPr(v0, t2, cw) : [f, \gamma] \wedge Val(v0, l, cw) : [cm, \gamma] \wedge \\ & Val(v1, cw, 0) : [cs, \gamma] \wedge Tan(t3, cw) : [fu, \alpha] \wedge \\ & Tan(t2, 0) : [em, \alpha] \rightarrow Pr(p2, cw) : [xs, \gamma], \end{aligned} \quad (34.18)$$

$$\begin{aligned}
& SPr(t0, v0, b) : [\underline{f}, \gamma] \wedge SPr(t3, v1, b) : [\underline{f}, \gamma] \wedge \\
& SPr(v0, t1, b) : [\underline{f}, \gamma] \wedge SPr(v0, t2, b) : [\underline{f}, \gamma] \wedge \\
& SPr(v1, v0, b) : [\underline{f}, \gamma] \wedge Val(v0, b, b) : [c\underline{s}, \gamma] \wedge \\
& Val(v1, b, 0) : [c\underline{s}, \gamma] \wedge Tan(t0, b) : [\underline{f}u, \alpha] \wedge \\
& Tan(t1, 0) : [e\underline{m}, \alpha] \wedge Tan(t3, b) : [\underline{f}u, \alpha] \wedge \\
& Tan(t2, 0) : [e\underline{m}, \alpha] \rightarrow Pr(p3, b) : [x\underline{s}, \gamma], \tag{34.19}
\end{aligned}$$

where $l \in \{b, cw, ww, hw, na, cs, 0\}$.

34.3.5 Example

Now, let us show an example of EVALPSN safety verification-based pipeline control for processes Pr_0 , Pr_1 , Pr_2 , and Pr_3 . According to the process schedule chart (Figure 1.5), we describe each stage of the EVALPSN safety verification.

Initial stage: We assume that all subprocesses and valves in the pipeline network are free (unlocked) and no process has already started. In order to verify the safety for all processes Pr_0 , Pr_1 , Pr_2 , and Pr_3 , the following fact EVALP clauses (sensed information) are input to the safety verification EVALPSN:

$$\begin{aligned}
& SPr(t0, v0, 0) : [\underline{f}, \alpha], & Val(v0, 0, 0) : [c\underline{s}, \alpha], \\
& SPr(v0, t1, 0) : [\underline{f}, \alpha], & Val(v1, 0, 0) : [c\underline{s}, \alpha], \\
& SPr(v0, t2, 0) : [\underline{f}, \alpha], \\
& SPr(v1, v0, 0) : [\underline{f}, \alpha], \\
& SPr(t3, v1, 0) : [\underline{f}, \alpha], \\
& Tan(t0, b) : [\underline{f}u, \alpha], & Tan(t1, 0) : [e\underline{m}, \alpha], \tag{34.20} \\
& Tan(t2, 0) : [e\underline{m}, \alpha], & Tan(t3, na) : [\underline{f}u, \alpha]. \tag{34.21}
\end{aligned}$$

Then, all the subprocesses and valves are permitted to be locked or controlled. However, the tank states (34.20) and (34.21) do not permit for processes Pr_2 and Pr_3 to be set. Beer process Pr_0 can be verified to be set as follows.

We have neither the forbiddance from locking subprocesses SPr_0 and SPr_1 nor forbiddance from controlling valve V_0 separate with beer in normal direction, by EVALPSN clauses (34.6), (34.9), (34.10), and (34.11) and the input fact EVALP clauses.

Then, we have permission for locking subprocesses SPr_0 and SPr_1 and controlling valve V_0 separate with beer in normal direction and any liquid in cross direction:

$$\begin{aligned}
& SPr(t0, v0, b) : [\underline{f}, \gamma], & Val(v0, b, l) : [c\underline{m}, \gamma], \\
& SPr(v0, t1, b) : [\underline{f}, \gamma],
\end{aligned}$$

where $l \in \{b, cw, ww, hw, na, cs, 0\}$, by EVALPSN clauses (34.7) and (34.14).

Moreover, we have the following EVALP clauses for the tank state:

$$\text{Tan}(t0, b) : [\text{f}\text{u}, \alpha], \quad \text{Tan}(t1, 0) : [\text{e}\text{m}, \alpha].$$

Thus, we have permission for setting beer process Pr_0 ,

$$\text{Pr}(p0, b) : [\text{x}\text{s}, \gamma],$$

by EVALPSN clause (34.16).

According to the process schedule, beer process Pr_0 has to start first, then nitric acid process Pr_1 has to be verified for safety and processed parallel to beer process Pr_0 as soon as possible. We show the safety verification for process Pr_1 at the following stage.

2nd stage: Beer process Pr_0 has already started but not finished yet, then in order to verify the safety for other processes Pr_1 , Pr_2 , and Pr_3 , the following fact EVALP clauses are input to the safety verification EVALPSN:

$$\begin{aligned} \text{SPr}(t0, v0, b) : [1, \alpha], & \quad \text{Val}(v0, b, 0) : [\text{c}\text{s}, \alpha], \\ \text{SPr}(v0, t1, b) : [1, \alpha], & \quad \text{Val}(v1, 0, 0) : [\text{c}\text{s}, \alpha], \\ \text{SPr}(v0, t2, 0) : [\text{f}, \alpha], & \\ \text{SPr}(v1, v0, 0) : [\text{f}, \alpha], & \\ \text{SPr}(t3, v1, 0) : [\text{f}, \alpha], & \\ \text{Tan}(t2, 0) : [\text{e}\text{m}, \alpha], & \quad \text{Tan}(t3, na) : [\text{f}\text{u}, \alpha]. \end{aligned}$$

The tank information permit neither cold water process Pr_2 nor beer process Pr_3 to be set. We show that only nitric acid process Pr_1 can be verified to be set as follows:

We have neither forbiddance from locking three subprocesses SPr_2 , SPr_3 , and SPr_4 , forbiddance from controlling valves V_0 separate with any liquid in normal direction, and nitric acid in cross direction nor forbiddance from controlling valve V_1 mixture(open) with nitric acid in normal direction and no liquid in cross direction, by EVALPSN clauses (34.6), (34.8), (34.9), (34.10), (34.11), and (34.12), (34.13) and the earlier fact EVALP clauses.

Therefore, we have permission for locking three subprocesses SPr_2 , SPr_3 , and SPr_4 and controlling valves V_0 and V_1 as described before,

$$\begin{aligned} \text{SPr}(v0, t2, na) : [\text{f}, \gamma], & \quad \text{Val}(v0, b, na) : [\text{c}\text{m}, \gamma], \\ \text{SPr}(v1, v0, na) : [\text{f}, \gamma], & \quad \text{Val}(v1, na, 0) : [\text{c}\text{s}, \gamma], \\ \text{SPr}(t3, v1, na) : [\text{f}, \gamma], & \end{aligned}$$

by EVALPSN clauses (34.7), (34.14) and (34.15).

Moreover, we have the following EVALP clauses for tank information:

$$\text{Tan}(t3, na) : [\text{f}\text{u}, \alpha], \quad \text{Tan}(t2, 0) : [\text{e}\text{m}, \alpha].$$

Thus, we have permission for setting nitric acid process Pr_1 ,

$$\text{Pr}(p1, na) : [\text{x}\text{s}, \gamma],$$

by EVALPSN clause (34.17).

Both beer process Pr_0 and nitric acid process Pr_1 have already started, then processes Pr_2 and Pr_3 have to be verified for safety. We show it at the following stage.

3rd stage: In order to verify the safety for cold water process Pr_2 and beer process Pr_3 , the following fact EVALP clauses are input to the safety verification EVALPSN:

$$\begin{aligned} SPr(t0, v0, b) &: [1, \alpha], & Val(v0, b, na) &: [cs, \alpha], \\ SPr(v0, t1, b) &: [1, \alpha], & Val(v1, na, 0) &: [cm, \alpha], \\ SPr(v0, t2, na) &: [1, \alpha], \\ SPr(v1, v0, na) &: [1, \alpha], \\ SPr(t3, v1, na) &: [1, \alpha]. \end{aligned}$$

Apparently, neither cold water process Pr_2 nor beer process Pr_3 is permitted to be set, since there is no tank information in the input fact EVALP clauses. We show the safety verification for process Pr_2 as an example.

We have forbiddance from locking three subprocesses SPr_2 , SPr_3 , and SPr_4 , forbiddance from controlling valve V_0 under separating with beer in normal direction and cold water in cross direction, and forbiddance from controlling valve V_1 under mixing with cold water in normal direction and no liquid in cross direction,

$$\begin{aligned} SPr(v0, t2, cw) &: [f, \beta], & Val(v0, b, cw) &: [cm, \beta], \\ SPr(v1, v0, cw) &: [f, \beta], & Val(v1, cw, 0) &: [cs, \beta], \\ SPr(t3, v1, cw) &: [f, \beta], \end{aligned}$$

by EVALPSN clauses (34.6), (34.11), and (34.12), and the input fact EVALP clauses.

The finish condition for nitric acid process Pr_1 is that tank T_2 is fully filled with nitric acid and tank T_3 is empty. If nitric acid process Pr_1 has finished and its finish conditions are satisfied, process Pr_1 is permitted to be released (unset) and has been released. It is also assumed that tank T_3 is filled with cold water and tank T_2 is empty as preparation for cold water process Pr_2 immediately after process Pr_1 finished. Then, cold water process Pr_2 has to be verified and start according to the process schedule. We show the safety verification for cold water process Pr_2 at the following stage.

4th stage: Then, since only beer process Pr_0 is being processed, the other three processes Pr_1 , Pr_2 , and Pr_3 have to be verified. In order to do that, the following fact EVALP clauses are input to the safety verification EVALPSN:

$$\begin{aligned} SPr(t0, v0, b) &: [1, \alpha], & Val(v0, b, 0) &: [cs, \alpha], \\ SPr(v0, t1, b) &: [1, \alpha], & Val(v1, 0, 0) &: [cs, \alpha], \\ SPr(v0, t2, 0) &: [f, \alpha], \\ SPr(v1, v0, 0) &: [f, \alpha], \\ SPr(t3, v1, 0) &: [f, \alpha], \\ Tan(t2, 0) &: [em, \alpha], & Tan(t3, cw) &: [fu, \alpha]. \end{aligned}$$

Since beer process Pr_0 is still being processed, neither nitric acid process Pr_1 nor beer process Pr_3 is permitted to be set, and only cold water process Pr_2 is permitted to be set as well as process Pr_1 at the 2nd stage. Therefore, we have permission for setting cold water process Pr_2 ,

$$Pr(p2, cw) : [xs, \gamma],$$

by EVALPSN clause (34.18).

Now, both beer process Pr_0 and cold water process Pr_2 are being processed. Then apparently any other process is not permitted to be set. Moreover, even if one of processes Pr_0 and Pr_2 has finished, beer process Pr_3 is not permitted to be set until both processes Pr_0 and Pr_2 finished. We show the safety verification for beer process Pr_3 at the following stages.

5th stage: If neither beer process Pr_0 nor cold water process Pr_2 has finished, we have to verify the safety for nitric acid process Pr_1 and beer process Pr_3 . The following fact EVALP clauses are input to the safety verification EVALPSN:

$$\begin{aligned} SPr(t0, v0, b) &: [1, \alpha], & Val(v0, b, cw) &: [cs, \alpha], \\ SPr(v0, t1, b) &: [1, \alpha], & Val(v1, cw, 0) &: [cm, \alpha], \\ SPr(v0, t2, cw) &: [1, \alpha], \\ SPr(v1, v0, cw) &: [1, \alpha], \\ SPr(t3, v1, cw) &: [1, \alpha]. \end{aligned}$$

Then, since all subprocesses and valves are locked and controlled, neither processes Pr_1 nor Pr_3 is permitted to be set. It is shown that beer process Pr_3 is not permitted to be set as follows:

We have forbiddance from locking three subprocesses SPr_2 , SPr_3 , and SPr_4 in process Pr_3 and controlling both valves V_0 and V_1 ,

$$\begin{aligned} SPr(v0, t2, b) &: [f, \beta], & Val(v0, b, b) &: [cs, \beta], \\ SPr(t3, v1, b) &: [f, \beta], & Val(v1, b, 0) &: [cs, \beta], \\ SPr(v1, v0, b) &: [f, \beta], \end{aligned}$$

by EVALPSN clauses (34.6), (34.8), and (34.12), and the input fact EVALP clauses.

Therefore, we cannot have permission for setting process Pr_3 .

The finish condition for cold water process Pr_2 is that tank T_2 is fully filled with cold water and tank T_3 is empty. If cold water process Pr_2 has finished and its finish condition is satisfied, process Pr_2 is permitted to be released (unset). It is also assumed that tank T_3 is filled with beer and tank T_2 is empty as preparation for beer process Pr_3 immediately after process Pr_2 finished. Then, beer process Pr_3 has to be verified and start according to the process schedule, but beer process Pr_3 cannot be permitted to be set. We show the safety verification for process Pr_3 at the following stage.

6th stage: Since only beer process Pr_0 is being processed, the other three processes Pr_1 , Pr_2 , and Pr_3 have to be verified for their safety. In order to do that, the following fact EVALP clauses are input to the safety verification EVALPSN:

$$\begin{aligned} SPr(t0, v0, b) &: [1, \alpha], & Val(v0, b, 0) &: [cs, \alpha], \\ SPr(v0, t1, b) &: [1, \alpha], & Val(v1, 0, 0) &: [cs, \alpha], \end{aligned}$$

$$SPr(v0, t2, 0) : [\underline{f}, \alpha],$$

$$SPr(v1, v0, 0) : [\underline{f}, \alpha],$$

$$SPr(t3, v1, 0) : [\underline{f}, \alpha],$$

$$Tan(t2, 0) : [\underline{em}, \alpha], \quad Tan(t3, b) : [\underline{fu}, \alpha].$$

Since beer process Pr_0 is still on being processed, beer process Pr_3 is not verified for safety due to the tank conditions and safety property Val for valve V_0 . The safety verification is carried out as follows:

We have forbiddance from controlling valve V_0 mixture,

$$Val(v0, b, b) : [cs, \beta],$$

by EVALPSN clause (34.8);

Therefore, we cannot have permission for setting the beer process Pr_3 then.

On the other hand, even if beer process Pr_0 has finished with cold water process Pr_2 being processed, beer process Pr_3 is not permitted to be set. If both processes Pr_0 and Pr_2 have finished, beer process Pr_3 is assured its safety and set. Then, process Pr_3 starts according to the process schedule. For brevity, we omit the remaining of stages.

34.4 Summary

In this chapter, we have introduced a paraconsistent annotated logic program called EVALPSN that can deal with defeasible deontic reasoning and its application to intelligent safety verification-based control with an example of pipeline valve control. EVALPSN can be applied to various kinds of safety verification and intelligent control. We summarize our chapter by showing the advantage and disadvantage of EVALPS safety verification and control.

Advantages

EVALPSN can be easily implemented in common programming languages such as Prolog or C language, moreover, if it is locally stratified [7,43], in a programmable logic controller (PLC) ladder program.

EVALPSN can be implemented as electronic circuits on micro chips [34]. Therefore, if real-time processing is required in the control system, EVALPSN should be very useful.

We have already another EVALPSN called bf(before–after)-EVALPSN, which can deal with before–after relation of processes, although we have not addressed bf-EVALPSN in this chapter. bf-EVALPSN can provide safety verification systems for process order control [35–37]. As far as we know, there seems to be no other efficient computational tool for dealing with safety verification of process order control than bf-EVALPSN. If we use both EVALPSN and bf-EVALPSN, safety verification systems for both process and its order control can be implemented under the same environment.

Disadvantages

Since basically EVALPSN itself is not a tool of logical safety verification, it includes a little complicated and redundant expressions for safety verification systems. Therefore, it might be better to develop safety verification-oriented tools or programming languages based on EVALPSN, if EVALPSN is applied to logical safety verification.

It is difficult to understand how to utilize EVALPSN fully to do practical implementation due to paraconsistent annotated logic.

35.1 Introduction

Qualitative reasoning is the area of artificial intelligence (AI) that creates representations for continuous aspects of the world, such as space, time, and quantity, which support reasoning with very little information. Typically, it has focused on scientific and engineering domains, hence its other common name, qualitative physics. It is motivated by two observations. First, people draw useful and subtle conclusions about the physical world without equations. In our daily lives, we figure out what is happening around us and how we can affect it, working with far less data, and less precise data, than would be required to use traditional, purely quantitative methods. Creating software for robots that operate in unconstrained environments and modeling human cognition require understanding how this can be done. Second, scientists and engineers appear to use qualitative reasoning when initially understanding a problem, when setting up more formal methods to solve particular problems, and when interpreting the results of quantitative simulations, calculations, or measurements. Thus, advances in qualitative reasoning should lead to the creation of more flexible software that can help engineers and scientists solve problems.

Qualitative reasoning began with de Kleer's investigation on how qualitative and quantitative knowledge interacted in solving a subset of simple textbook mechanics problems (de Kleer, 1977). After roughly a decade of initial explorations, the potential for important industrial applications led to a surge

of interest in the mid-1980s, and the area grew steadily, with rapid progress. There have been a variety of successful applications, including supervisory process control, design, failure modes and effects analysis (FMEA), and educational software.

Given its demonstrated utility in applications and its importance in understanding human cognition, work in qualitative modeling will continue to remain an important area in AI.

This chapter first surveys the state of the art in qualitative representations and in qualitative reasoning techniques. The application of these techniques to various problems is discussed subsequently.

35.2 Qualitative Representations

As is the case with many other knowledge representation issues, there is no single best qualitative representation. Instead, there exists a spectrum of choices, each with its own advantages and disadvantages for particular tasks. What all of them have in common is that they provide notations for describing and reasoning about continuous properties of the physical world. Two key issues in qualitative representation are *resolution* and *compositionality*. We discuss each in turn.

Resolution concerns the level of information detail in a representation. Resolution is an issue because one goal of qualitative reasoning is to understand how little information suffices to draw useful conclusions. Low-resolution information is available more often than precise information (“the car heading toward us is slowing down” vs. “the derivative of the car’s velocity along the line connecting us is -28 km/h/s”), but conclusions drawn with low-resolution information are often ambiguous. The role of ambiguity is important: the prediction of alternative futures (i.e., “the car will hit us” vs. “the car won’t hit us”) suggests that we may need to gather more information, analyze the matter more deeply, or take action, depending on what alternatives our qualitative reasoning uncovers. High-resolution information is often needed to draw particular conclusions (i.e., a finite element analysis of heat flow within a tablet computer design to ensure that the CPU will not cook the battery), but qualitative reasoning with low-resolution representations reveals what the interesting questions are. Qualitative representations comprise one form of tacit knowledge that people, ranging from the person on the street to scientists and engineers, use to make sense of the world.

Compositionality concerns the ability to combine representations for different aspects of a phenomenon or system to create a representation of the phenomenon or system as a whole. Compositionality is an issue because one goal of qualitative reasoning is to formalize the modeling process itself. Many of today’s AI systems are based on handcrafted knowledge bases that express information about a specific artifact or system needed to carry out a particular narrow range of tasks involving it. By contrast, a substantial component of the knowledge of scientists and engineers consists of principles and laws that are broadly applicable, both with respect to the number of systems they explain and the kinds of tasks they are relevant for. Qualitative reasoning has developed ideas and organizing techniques for knowledge bases with similar expressive and inferential power, called *domain theories*.

The remainder of this section surveys the fundamental representations used in qualitative reasoning for quantity, mathematical relationships, modeling assumptions, causality, space, and time.

35.2.1 Representing Quantity

Qualitative reasoning has explored trade-offs in representations for continuous parameters ranging in resolution from sign algebras to the hyperreals. Most of the research effort has gone into understanding the properties of low-resolution representations because the properties of high-resolution representations tend to already be well understood due to work in mathematics.

The lowest resolution representation for continuous parameters is the status abstraction, which represents a quantity by whether or not it is normal. It is a useful representation for certain diagnosis and monitoring tasks because it is the weakest representation that can express the difference between

something working and not working. The next step in resolution is the sign algebra, which represents continuous parameters as either $-$, $+$, or 0 , according to whether the sign of the underlying continuous parameter is negative, positive, or zero. The sign algebra is surprisingly powerful: because a parameter's derivatives are themselves parameters whose values can be represented as signs, some of the main results of the differential calculus (e.g., the mean value theorem) can be applied to reasoning about sign values (de Kleer and Brown, 1984). This allows sign algebras to be used for qualitative reasoning about dynamics, including expressing properties such as oscillation and stability. The sign algebra is the weakest representation that supports such reasoning.

Representing continuous values via sets of ordinal relations (also known as the *quantity space* representation) is the next step up in resolution (Forbus, 1984). For example, the temperature of a fluid might be represented in terms of its relationship between the freezing point and boiling point of the material that comprises it. Like the sign algebra, quantity spaces are expressive enough to support qualitative reasoning about dynamics. (The sign algebra can be modeled by a quantity space with only a single point of comparison, zero.) Unlike the sign algebra, which draws values from a fixed finite algebraic structure, quantity spaces provide variable resolution because new points of comparison can be added to refine values. The temperature of water in a kettle on a stove, for instance, will likely be defined in terms of its relationship with the temperature of the stove as well as its freezing and boiling points. There are two kinds of comparison points used in defining quantity spaces. *Limit points* are derived from general properties of a domain as applicable to a specific situation. Continuing with the kettle example, the particular ordinal relationships used were chosen because they determine whether or not the physical processes of freezing, boiling, and heat flow occur in that situation. The precise numerical value of limit points can change over time (e.g., the boiling point of a fluid is a function of its pressure). *Landmark values* are constant points of comparison introduced during reasoning to provide additional resolution (Kuipers, 1994). To ascertain whether an oscillating system is overdamped, underdamped, or critically damped, for instance, requires comparing successive peak values. Noting the peak value of a particular cycle as a landmark value, and comparing it to the landmarks generated for successive cycles in the behavior, provides a way of making this inference.

Intervals are a well-known variable-resolution representation for numerical values and have been heavily used in qualitative reasoning. A quantity space can be thought of as partial information about a set of intervals. If we have complete information about the ordinal relationships between limit points and landmark values, these comparisons define a set of intervals that partition a parameter's value. This natural mapping between quantity spaces and intervals has been exploited by a variety of systems that use intervals whose end points are known numerical values to refine predictions produced by purely qualitative reasoning. Fuzzy intervals have also been used in similar ways, for example, in reasoning about control systems.

Order of magnitude representations stratify values according to some notion of scale. They can be important in resolving ambiguities and in simplifying models because they enable reasoning about what phenomena and effects can safely be ignored in a given situation. For instance, heat losses from turbines are generally ignored in the early stages of power plant design, because the energy lost is very small relative to the energy being produced. Several stratification techniques have been used in the literature, including hyperreal numbers, numerical thresholds, and logarithmic scales. Three issues faced by all these formalisms are (1) the conditions under which many small effects can combine to produce a significant effect, (2) the soundness of the reasoning supported by the formalism, and (3) the efficiency of using them (Travé-Massuyès et al., 2003).

Although many qualitative representations of number use the reals as their basis, another important basis for qualitative representations of number is finite algebras. One motivation for using finite algebras is that observations are often naturally categorized into a finite set of labels (i.e., very small, small, normal, large, very large). Research on such algebras is aimed at solving problems such as how to increase the compositionality of such representations (e.g., how to propagate information across different resolution scales).

35.2.2 Representing Mathematical Relationships

Like number, a variety of qualitative representations of mathematical relationships have been developed, often by adopting and adapting systems developed in mathematics. Abstractions of the analytic functions are commonly used to provide the lower resolution and compositionality desired. For example, confluences are differential equations over the sign algebra (de Kleer and Brown, 1984). An equation such as $V = IR$ can be expressed as the confluence

$$[V] = [I] + [R]$$

where $[Q]$ denotes taking the sign of Q . Differential equations can also be expressed in this manner, for instance,

$$[F] = \partial v$$

which is a qualitative version of $F = MA$ (assuming M is always positive). Thus, any system of algebraic and differential equations with respect to time can be described as a set of confluences.

Many of the algebraic operations taken for granted in manipulating analytic functions over the reals are not valid in weak algebras (Struss, 1988). Because qualitative relationships are most often used to propagate information, this is not a serious limitation. In situations where algebraic solutions themselves are desirable, mixed representations that combine algebraic operations over the reals and move to qualitative abstractions when appropriate provide a useful approach (Williams, 1991).

Another low-resolution representation of equations uses monotonic functions over particular ranges; that is,

$$M+(\text{acceleration}, \text{force})$$

states that acceleration depends only on the force, and the function relating them is increasing monotonic (Kuipers, 1994). Compositionality is achieved using *qualitative proportionalities* (Forbus, 1984) to express partial information about functional dependency; for example,

$$\text{acceleration} \propto Q+ \text{force}$$

states that acceleration depends on force and is increasing monotonic in its dependence on force but may depend on other factors as well. Additional constraints on the function that determines force can be added by additional qualitative proportionalities; for example,

$$\text{acceleration} \propto Q- \text{mass}$$

states that acceleration also depends on mass and is decreasing monotonic in this dependence. Qualitative proportionalities must be combined via closed-world assumptions to ascertain all the effects on a quantity. Similar primitives can be defined for expressing relationships involving derivatives, to define a complete language of compositional qualitative mathematics for ordinary differential equations. As with confluences, few algebraic operations are valid for combining monotonic functions. Composition of functions of identical sign is safe; that is,

$$M + (f, g) \wedge M + (g, h) \Rightarrow M + (f, h)$$

In addition to resolution and compositionality, another issue arising in qualitative representations of mathematical relationships is causality. There are three common views on how mathematical relationships interact with the causal relationships people use in commonsense reasoning. One view is that

there is no relationship between them. The second view is that mathematical relationships should be expressed with primitives that also make causal implications. For example, qualitative proportionalities include a causal interpretation, that is, a change in force causes a change in acceleration, but not the other way around. The third view is that acausal mathematical relationships give rise to causal relationships via the particular process of using them. For example, confluences have no built-in causal direction but are used in causal reasoning by identifying the flow of information through them while reasoning with a presumed flow of causality in the physical system they model. One method for imposing causality on a set of acausal constraint equations is by computing a causal ordering (Iwasaki and Simon, 1994) that imposes directionality on a set of equations, starting from variables considered to be exogenous within the system.

Each view of causality has its merits. For tasks where causality is truly irrelevant, ignoring causality can be a reasonable approach. To create software that can span the range of human commonsense reasoning, something like a combination of the second and third views appears necessary because the appropriate notion of causality varies (Forbus and Gentner, 1986). In reasoning about chemical phenomena, for instance, changes in concentration are always caused by changes in the amounts of the constituent parts and never the other way around. In electronics, on the other hand, it is often convenient to consider voltage changes as being caused by changes in current in one part of a circuit and to consider current changes as being caused by changes in voltage in another part of the same circuit.

35.2.3 Ontology

Ontology concerns how to carve up the world, that is, what kinds of things there are and what sorts of relationships can hold between them. Ontology is central to qualitative modeling because one of its main goals is formalizing the art of building models of continuous systems. A key choice in any act of modeling is figuring out how to construe the situation or system to be modeled in terms of the available models for classes of entities and phenomena. No single ontology will suffice for the span of reasoning about continuous systems that people do. What has been developed instead is a catalog of ontologies, describing their properties and interrelationships and specifying conditions under which each is appropriate. While several ontologies are currently well understood, the catalog still contains many gaps.

An example of ontologies will make this point clearer. Consider the representation of liquids. Broadly speaking, the major distinction in reasoning about fluids is whether one individuates fluid according to a particular collection of particles or by location (Hayes, 1985). The former are called Eulerian, or piece of stuff, ontologies. The latter are called Lagrangian, or contained stuff, ontologies. The contained stuff view of liquids is used when one treats a river as a stable entity, although the particular set of molecules that comprises it is changing constantly. The piece of stuff view of liquids is used when one thinks about the changes in a fluid as it flows through a steady-state system, such as a working refrigerator. Ontologies multiply as we try to capture more aspects of human reasoning. For instance, the piece of stuff ontology can be further divided into three cases, each with its own rules of inference: (1) molecular collections, which describe the progress of an arbitrary piece of fluid that is small enough to never split apart but large enough to have extensive properties; (2) slices, which, like molecular collections, never subdivide but unlike them are large enough to interact directly with their surroundings; and (3) pieces of stuff large enough to be split into several pieces (e.g., an oil slick). Similarly, the contained stuff ontology can be further specialized according to whether or not individuation occurs simply by container (abstract-contained stuffs) or by a particular set of containing surfaces (bounded stuffs). Abstract-contained stuffs provide a low-resolution ontology appropriate for reasoning about system-level properties in complex systems (e.g., the changes over time in a lubricating oil subsystem in a propulsion plant), whereas bounded stuffs contain the geometric information needed to reason about the interactions of fluids and shape in systems such as pumps and internal combustion engines.

Cutting across the ontologies for particular physical domains are systems of organization for classes of ontologies. The most commonly used ontologies are the device ontology (de Kleer and Brown, 1984)

and the process ontology (Forbus, 1984). The device ontology is inspired by network theory and system dynamics. Like those formalisms, it construes continuous systems as networks of devices whose interactions occur solely through a fixed set of ports. Unlike those formalisms, it provides the ability to write and reason automatically with device models whose governing equations can change over time.

The process ontology is inspired by studies of human mental models and observations of practice in thermodynamics and chemical engineering. It construes continuous systems as consisting of entities whose changes are caused by processes. Process ontologies thus postulate a separate ontological category for causal mechanisms, unlike device ontologies, where causality arises solely from the interaction of the parts. Another difference between the two classes of ontologies is that in the device ontology the system of devices and connections is fixed over time, whereas in the process ontology entities and processes can come into existence and vanish over time. Each is appropriate in different contexts: for most purposes, an electronic circuit is best modeled as a network of devices, whereas a chemical plant is best modeled as a collection of interacting processes.

35.2.4 State, Time, and Behaviors

A qualitative state is a set of propositions that characterize a qualitatively distinct behavior of a system. A qualitative state describing a falling ball, for instance, would include information about what physical processes are occurring (e.g., motion downward, acceleration due to gravity) and how the parameters of the ball are changing (e.g., its position is getting lower and its downward velocity is getting larger). A qualitative state can abstractly represent an infinite number of quantitative states: although the position and velocity of the ball are different at each distinct moment during its fall, until the ball collides with the ground, the qualitative state of its motion is unchanged.

Qualitative representations can be used to partition behavior into natural units. For instance, the time over which the state of the ball falling holds is naturally thought of as an interval, ending when the ball collides with the ground. The collision itself can be described as yet another qualitative state, and the fact that falling leads to a collision with the ground can be represented via a transition between the two states. If the ball has a nonzero horizontal velocity and there is some obstacle in its direction of travel, another possible behavior is that the ball will collide with that object instead of the ground. In general, a qualitative state can have transitions to several next states, reflecting ambiguity in the qualitative representations. Returning to our ball example, and assuming that no collisions with obstacles occur, notice that the qualitative state of the ball falling occurs again once the ball has reached its maximum height after the collision. If continuous values are represented by quantity spaces and the sources of comparisons are limit points, then a finite set of qualitative states is sufficient to describe every possible behavior of a system. A collection of such qualitative states and transitions is called an *envisionment* (de Kleer, 1977). Many interesting dynamical conclusions can be drawn from an envisionment. For instance, oscillations correspond to cycles of states. Unfortunately, the fixed resolution provided by limit points is not sufficient for other dynamical conclusions, such as ascertaining whether or not the ball's oscillation is damped. If comparisons can include landmark values, such conclusions can sometimes be drawn, for example, by comparing the maximum height on one bounce to the maximum height obtained on the next bounce. The cost of introducing landmark values is that the envisionment no longer need be finite; every cycle in a corresponding fixed-resolution envisionment could give rise to an infinite number of qualitative states in an envisionment with landmarks.

A sequence of qualitative states occurring over a particular span of time is called a *behavior*. Behaviors can be described using purely qualitative knowledge, purely quantitative knowledge, or a mixture of both. If every continuous parameter is quantitative, the numerical aspects of behaviors coincide with the notion of trajectory in a state-space model. If qualitative representations of parameters are used, a single behavior can represent a family of trajectories through state space.

An idea closely related to behaviors is *histories* (Hayes, 1985). Histories can be viewed as local behaviors, that is, how a single individual or property varies through time. A behavior is equivalent to a

global history, that is, the union of all the histories for the participating individuals. The distinction is important for two reasons. First, histories are the dual of situations in the situation calculus; histories are bounded spatially and extended temporally, whereas situations are bounded temporally and extended spatially. Using histories avoids the frame problem, instead trading it for the more tractable problems of generating histories locally and determining how they interact when they intersect in space and time. The second reason is that history-based simulation algorithms can be more efficient than state-based simulation algorithms because no commitments need to be made concerning irrelevant information.

In a correct envisionment, every possible behavior of the physical system corresponds to some path through the envisionment. Because envisionments reflect only local constraints, the converse is not true; that is, an arbitrary path through an envisionment may not represent a physically possible behavior. When using an envisionment to generate hypotheses about possible behaviors, this can lead to over-generation. Paths must be tested against global constraints, such as energy conservation, to ensure their physical validity, or filtered by some other means. When using an envisionment to explain observed behaviors, this limitation is less serious, since the observed behavior, by its very nature, must be physically possible. A more serious limitation is that envisionments are often exponential in the size of the system being modeled. This means that, in practice, envisionments often are not generated explicitly and, instead, possible behaviors are searched in ways similar to those used in other areas of AI.

Many tasks require integrating qualitative states with other models of time, such as numerical models. Including precise information (e.g., algebraic expressions or floating-point numbers) about the end points of intervals in a history does not change their essential character.

35.3 Space and Shape

Qualitative representations of shape and space play an important role in spatial cognition because they provide a bridge between the perceptual and the conceptual. By discretizing continuous space, they make it amenable to symbolic reasoning. As with qualitative representations of 1D parameters, task constraints govern the choice of qualitative representation. However, problem-independent purely qualitative spatial representations suffice for fewer tasks than in the 1D case, because of the increased ambiguity in higher dimensions (Forbus et al., 1991). Consider, for example, deciding whether a protrusion can fit snugly inside a hole. If we have detailed information about their shapes, we can derive an answer. If we consider a particular set of protrusions and a particular set of holes, we can construct a qualitative representation of these particular protrusions and holes that would allow us to derive whether or not a specific pair would fit, based on their relative sizes. But if we first compute a qualitative representation for each protrusion and hole in isolation, in general the rules of inference that can be derived for this problem will be very weak. Work in qualitative spatial representations thus tends to take two approaches. The first approach is to explore what aspects do lend themselves to purely qualitative representations. The second approach is to use a quantitative representation as a starting point and compute problem-specific qualitative representations to reason with. We summarize each in turn.

An impressive catalog of qualitative spatial representations have been developed that can be used to reason about particular aspects of shape and space (Cohn and Renz, 2008). The general approach is to identify a set of relationships that provide natural decompositions of a spatial property, such as connectivity or orientation, and define calculi over these relationships to support inference. For example, the eight relationship versions of the region connection calculus (RCC) include disjoint, edge connected, partially overlapping, tangential proper part (and its inverse), non-tangential proper part (and its inverse), and equal as relationships. A transitivity table supports inference, that is, if a bird is inside a cage and a cat is outside the cage, then the bird and the cat are disjoint (and unless the connectivity changes, the bird is safe). Note that the sequence of relationships earlier also captures

some aspects of the relationships between two objects that are moving: they are apart, they touch, one enters the other, etc. Such physical interpretations have enabled such calculi to be used in reasoning about change and in interpreting visual information (Sridhar et al., 2010). The calculi vary in terms of expressiveness and efficiency: some have been shown to be NP-complete, but often tractable subsets can be found.

The use of quantitative representations to ground qualitative spatial reasoning can be viewed as a model of the ways humans use diagrams and models in spatial reasoning. For this reason such work is also known as *diagrammatic reasoning* (Glasgow et al., 1995). One form of diagram representation is the occupancy array that encodes the location of an object by cells in a (2D or 3D) grid. These representations simplify the calculation of spatial relationships between objects (e.g., whether or not one object is above another), albeit at the cost of making the object's shape implicit. Another form of diagram representation uses symbolic structures with quantitative properties, for example, numerical, algebraic, or interval (e.g., Forbus et al., 1991). These representations simplify calculations involving shape and spatial relationships, without the scaling and resolution problems that sometimes arise in array representations. However, they require a set of primitive shape elements that spans all the possible shapes of interest, and identifying such sets for particular tasks can be difficult. For instance, many intuitively natural sets of shape primitives are not closed with respect to their complement, which can make characterizing free space difficult.

Diagram representations are used for qualitative spatial reasoning in two ways. The first is as a decision procedure for spatial questions. This mimics one of the roles diagrams play in human perception. Often, these operations are combined with domain-specific reasoning procedures to produce an analog style of inference, where, for instance, the effects of perturbations on a structure are mapped into the diagram, the effect on the shapes in the diagram noted, and the results mapped back into a physical interpretation. The second way uses the diagram to construct a problem-specific qualitative vocabulary, imposing new spatial entities representing physical properties, such as the maximum height a ball can reach or regions of free space that can contain a motion. This is the *metric diagram/place vocabulary* model of qualitative spatial reasoning.

Representing and reasoning about kinematic mechanisms was one of the early successes in qualitative spatial reasoning. The possible motions of objects are represented by qualitative regions in the configuration space representing the legitimate positions of parts of mechanisms (Faltings, 1990). Whereas, in principle, a single high-dimensional configuration space could be used to represent a mechanism's possible motions (each dimension corresponding to a degree of freedom of a part of the mechanism), in practice a collection of configuration spaces, one 2D space for each pair of parts that can interact, is used. These techniques suffice to analyze a wide variety of kinematic mechanisms and can support design (Sacks and Joskowicz, 2010).

Another important class of spatial representations concerns qualitative representations of spatially distributed phenomena, such as flow structures and regions in phase space. These models use techniques from computer vision to recognize or impose qualitative structure on a continuous field of information, gleaned from numerical simulation or scientific data. This qualitative structure, combined with domain-specific models of how such structures tie to the underlying physics, enables them to interpret physical phenomena in much the same way that a scientist examining the data would (e.g., Yip, 1991; Huang and Zhao, 2000).

An important recent trend is using rich, real-world data as input for qualitative spatial reasoning. For example, several systems provide some of the naturalness of sketching by performing qualitative reasoning on spatial data input as digital ink, for tasks like mechanical design (Stahovich et al., 1998), reasoning about student's sketches in geoscience and engineering design education (Forbus et al., 2011), and communicating tactics to robot soccer teams (Gspandl et al., 2010). Qualitative representations are being used in computer vision as well, for example, as a means of combining dynamic scenes across time to interpret events (e.g., Sridhar et al., 2010).

35.3.1 Compositional Modeling, Domain Theories, and Modeling Assumptions

There is almost never a single correct model for a complex physical system. Most systems can be modeled in a variety of ways, and different tasks can require different types of models. The creation of a system model for a specific purpose is still something of an art. Qualitative reasoning has developed formalisms that combine logic and mathematics with qualitative representations to help automate the process of creating and refining models. The compositional modeling methodology (Falkenhainer and Forbus, 1991), which has become standard in qualitative reasoning, works like this: models are created from domain theories, which describe the kinds of entities and phenomena that can occur in a physical domain. A domain theory consists of a set of *model fragments*, each describing a particular aspect of the domain. Creating a model is accomplished by instantiating an appropriate subset of model fragments, given some initial specification of the system (e.g., the propositional equivalent of a blueprint) and information about the task to be performed. Reasoning about appropriateness involves the use of modeling assumptions. Modeling assumptions are the control knowledge used to reason about the validity or appropriateness of using model fragments. Modeling assumptions are used to express the relevance of model fragments. Logical constraints between modeling assumptions comprise an important component of a domain theory.

An example of a modeling assumption is assuming that a turbine is isentropic. Here is a model fragment that illustrates how this assumption is used:

```
(defEquation Isentropic-Turbine
  ((turbine ?g ?in ?out)(isentropic ?g))
  (= (spec-s ?in) (spec-s ?out)))
```

In other words, when a turbine is isentropic, the specific entropy of its inlet and outlet are equal. Other knowledge in the domain theory puts constraints on the predicate *isentropic*,

```
(for-all (?self (turbine ?self))
  (iff (= (nu-isentropic ?self) 1.0) (isentropic ?self)))
```

That is, a turbine is isentropic exactly when its isentropic thermal efficiency is 1. Although no real turbine is isentropic, assuming that turbines are isentropic simplifies early analyses when creating a new design. In later design phases, when tighter performance bounds are required, this assumption is retracted and the impact of particular values for the turbine's isentropic thermal efficiency is explored. The consequences of choosing particular modeling assumptions can be quite complex; the fragments shown here are less than one-fourth the knowledge expressing the consequences of assuming that a turbine is isentropic in a typical knowledge base.

Modeling assumptions can be classified in a variety of ways. An *ontological assumption* describes which ontology should be used in an analysis. For instance, reasoning about the pressure at the bottom of a swimming pool is most simply performed using a contained stuff representation, whereas describing the location of an oil spill is most easily performed using a piece of stuff representation. A *perspective assumption* describes which subset of phenomena operating in a system will be the subject. For example, in analyzing a steam plant, one might focus on a fluid perspective, a thermal perspective, or both at once. A *granularity assumption* describes how much detail is included in an analysis. Ignoring the implementation details of subsystems, for instance, is useful in the conceptual design of an artifact, but the same implementation details may be critical for troubleshooting that artifact. The relationships between these classes of assumptions can be complicated and domain dependent; for instance, it makes no sense to include a model of a heating coil (a choice of granularity) if the analysis does not include thermal properties (a choice of perspective).

Relationships between modeling assumptions provide global structure to domain theories. Assumptions about the nature of this global structure can significantly impact the efficiency of model formulation, as discussed in the following. In principle, any logical constraint could be imposed between modeling assumptions. In practice, two kinds of constraints are the most common. The first are implications, such as one modeling assumption requiring or forbidding another. For example,

```
(for-all (?s (system ?s))
  (implies (consider (black-box ?s))
    (for-all (?p (part-of ?p ?s)) (not (consider ?p)))))
```

says that if one is considering a subsystem as a black box, then all of its parts should be ignored. Similarly,

```
(for-all (?l (contained-stuff ?l))
  (implies (consider (pressure ?l))
    (consider (fluid-properties ?l))))
```

states that if an analysis requires considering something's pressure, then its fluid properties are relevant. The second kind of constraint between modeling assumptions is *assumption classes*. An assumption class expresses a choice required to create a coherent model under particular conditions. For example,

```
(defAssumptionClass (turbine ?self)
  (isentropic ?self) (not (isentropic ?self)))
```

states that when something is modeled as a turbine, any coherent model including it must make a choice about whether or not it is modeled as isentropic. The choice may be constrained by the data so far (e.g., different entrance and exit specific entropies), or it may be an assumption that must be made in order to complete the model. The set of choices need not be binary. For each valid assumption class, exactly one of the choices it presents must be included in the model.

35.4 Qualitative Reasoning Techniques

A variety of qualitative reasoning techniques have been developed that use the qualitative representations just outlined.

35.4.1 Model Formulation

Methods for automatically creating models for a specific task are one of the hallmark contributions of qualitative reasoning. These methods formalize knowledge and skills typically left implicit by most of traditional mathematics and engineering.

The simplest model formulation algorithm is to instantiate every possible model fragment from a domain theory, given a propositional representation of the particular scenario to be reasoned about. This algorithm is adequate when the domain theory is very focused and thus does not contain much irrelevant information. It is inadequate for broad domain theories and fails completely for domain theories that include alternative and mutually incompatible perspectives (e.g., viewing a contained liquid as a finite object vs. an infinite source of liquid). It also fails to take task constraints into account. For example, it is possible, in principle, to analyze the cooling of a cup of coffee using quantum mechanics. Even if it were possible in practice to do so, for most tasks simpler models suffice. Just how simple a model can be and remain adequate depends on the task. If I want to know if the cup of coffee will still be drinkable after an hour, a qualitative model suffices to infer that its final temperature will be that of its surroundings. If I want to know its temperature within 5% after 12 min have passed, a macroscopic quantitative model is a better choice. In other words, the goal of model formulation is to create the simplest adequate model of a system for a given task.

More sophisticated model formulation algorithms search the space of modeling assumptions, because they control which aspects of the domain theory will be instantiated. The model formulation algorithm of Falkenhainer and Forbus (1991) instantiated all potentially relevant model fragments and used an assumption-based truth maintenance system to find all legal combinations of modeling assumptions that sufficed to form a model that could answer a given query. The simplicity criterion used was to minimize the number of modeling assumptions. This algorithm is very simple and general but has two major drawbacks: (1) full instantiation can be very expensive, especially if only a small subset of the model fragments is eventually used; and (2) the number of consistent combinations of model fragments tends to be exponential for most problems. The rest of this section describes algorithms that overcome these problems.

Efficiency in model formulation can be gained by imposing additional structure on domain theories. Under at least one set of constraints, model formulation can be carried out in polynomial time (Nayak, 1994). The constraints are that (1) the domain theory can be divided into independent assumption classes and, (2) within each assumption class, the models can be organized by a (perhaps partial) simplicity ordering of a specific nature, forming a lattice of causal approximations. Nayak's algorithm computes a simplest model, in the sense of simplest within each local assumption class, but does not necessarily produce the globally simplest model.

Conditions that ensure the creation of coherent models, that is, models that include sufficient information to produce an answer of the desired form, provide powerful constraints on model formulation. For example, in generating "what-if" explanations of how a change in one parameter might affect particular other properties of the system, a model must include a complete causal chain connecting the changed parameter to the other parameters of interest. This insight can be used to treat model formulation as a best-first search for a set of model fragments providing the simplest complete causal chain (Rickel and Porter, 1994). A novel feature of this algorithm is that it also selects models at an appropriate timescale. It does this by choosing the slowest timescale phenomenon that provides a complete causal model, because this provides accurate answers that minimize extraneous detail.

As with other AI problems, knowledge can reduce search. One kind of knowledge that experienced modelers accumulate concerns the range of applicability of various modeling assumptions and strategies for how to reformulate when a given model proves inappropriate. Dynamically constructing qualitative representations from more detailed models, driven by task requirements, has been explored (Sachenbacher and Struss, 2005). Model formulation often is an iterative process. For instance, an initial qualitative model often is generated to identify the relevant phenomena, followed by the creation of a narrowly focused quantitative model to answer the questions at hand. Similarly, domain-specific error criterion can determine that a particular model's results are internally inconsistent, causing the reasoner to restart the search for a good model. One approach is to formalize model formulation as a dynamic preference constraint satisfaction problem, where more fine-grained criteria for model preference than "simplest" can be formalized and exploited (Keppens and Shen, 2004). Another promising approach is analogical model formulation, since similar models are likely to work in similar circumstances (Klenk et al., 2011).

35.4.2 Causal Reasoning

Causal reasoning explains an aspect of a situation in terms of others in such a way that the aspect being explained can be changed if so desired. For instance, a flat tire is caused by the air inside flowing out, either through the stem or through a leak. To refill the tire, we must both ensure that the stem provides a seal and that there are no leaks. Causal reasoning is thus at the heart of diagnostic reasoning as well as explanation generation.

The techniques used for causal reasoning depend on the particular notion of causality used, but they all share a common structure. First, causality involving factors within a state are identified. Second, how the properties of a state contribute to a transition (or transitions) to another state are identified, to extend the causal account over time. Because causal reasoning often involves qualitative simulation, we turn to simulation next.

35.4.3 Simulation

The new representations of quantity and mathematical relationships of qualitative reasoning expand the space of simulation techniques considerably. We start by considering varieties of purely qualitative simulation and then describe several simulation techniques that integrate qualitative and quantitative information.

Understanding *limit analysis*, the process of finding state transitions, is key to understanding qualitative simulation. Recall that a qualitative state consists of a set of propositions, some of them describing the values of continuous properties in the system. (For simplicity in this discussion, we will assume that these values are described as ordinal relations, although the same method works for sign representations and representations richer than ordinals.) Two observations are critical: (1) the phenomena that cause changes in a situation often depend on ordinal relationships between parameters of the situation, and (2) knowing just the sign of the derivatives of the parameters involved in these ordinal relationships suffices to predict how they might change over time. The effects of these changes, when calculated consistently, describe the possible transitions to other states.

An example will make this clearer. Consider again a pot of water sitting on a stove. Once the stove is turned on, heat begins to flow to the water in the pot because the stove's temperature is higher than that of the water. The causal relationship between the temperature inequality and the flow of heat means that to predict changes in the situation, we should figure out their derivatives and any other relevant ordinal relationships that might change as a result. In this qualitative state, the derivative of the water's temperature is positive, and the derivative of the stove's temperature is zero. Thus, one possible state change is that the water will reach thermal equilibrium with the stove and the flow of heat will stop. That is not the only possibility, of course. We know that boiling can occur if the temperature of the water begins to rise above its boiling temperature. That, too, is a possible transition that would end the state. Which of these transitions occurs depends on the relationship between the temperature of the stove and the boiling temperature of water.

This example illustrates several important features of limit analysis. First, surprisingly weak information (i.e., ordinal relations) suffices to draw important conclusions about broad patterns of physical behavior. Second, limit analysis with purely qualitative information is fundamentally ambiguous: it can identify what transitions might occur, but cannot by itself determine in all cases which transition will occur. Third, like other qualitative ambiguities, higher-resolution information can be brought in to resolve the ambiguities as needed. Returning to our example, any information sufficient to determine the ordinal relationship between the stove temperature and boiling suffices to resolve this ambiguity. If we are designing an electric kettle, for instance, we would use this ambiguity as a signal that we must ensure that the heating element's temperature is well above the boiling point; and if we are designing a drink warmer, its heating element should operate well below the boiling point.

Qualitative simulation algorithms vary along four dimensions: (1) their initial states, (2) what conditions they use to filter states or transitions, (3) whether or not they generate new landmarks, and (4) how much of the space of possible behaviors they explore. Envisioning is the process of generating an envisionment, that is, generating all possible behaviors. Two kinds of envisioning algorithms have been used in practice: attainable envisioners produce all states reachable from a set of initial states, and total envisioners produce a complete envisionment. Behavior generation algorithms start with a single initial state, generate landmark values, and use a variety of task-dependent constraints as filters and termination criteria (e.g., resource bounds, energy constraints).

Higher-resolution information can be integrated with qualitative simulation in several ways. One method for resolving ambiguities in behavior generation is to provide numerical envelopes to bound mathematical relationships. These envelopes can be dynamically refined to provide tighter situation-specific bounds. Such systems are called *semiquantitative* simulators (Kuipers, 1994).

A different approach to integration is to use qualitative reasoning to automatically construct a numerical simulator that has integrated explanation facilities. These *self-explanatory simulators* (Forbus and

Falkenhainer, 1990) use traditional numerical simulation techniques to generate behaviors, which are also tracked qualitatively. The concurrently evolving qualitative description of the behavior is used both in generating explanations and in ensuring that appropriate mathematical models are used when applicability thresholds are crossed. Self-explanatory simulators can be compiled in polynomial time for efficient execution, even on small computers, or created in an interpreted environment. They have been deployed mostly in education, both as a web-based medium and within classroom activities for middle school students.

35.4.4 Comparative Analysis

Comparative analysis answers a specific kind of “what-if” questions, namely, the changes that result from changing the value of a parameter in a situation. Given higher-resolution information, traditional analytic or numerical sensitivity analysis methods can be used to answer these questions; however (1) such reasoning is commonly carried out by people who have neither the data nor the expertise to carry out such analyses, and (2) purely quantitative techniques tend not to provide good explanations. Sometimes, purely qualitative information suffices to carry out such reasoning, using techniques such as exaggeration (Weld, 1990). Consider, for instance, the effect of increasing the mass of a block in a spring-block oscillator. If the mass were infinite, the block would not move at all, corresponding to an infinite period. Thus, we can conclude that increasing the mass of the block will increase the period of the oscillator.

35.4.5 Teleological Reasoning

Teleological reasoning connects the structure and behavior of a system to its goals. (By its goals, we are projecting the intent of its designer or the observer, because purposes often are ascribed to components of evolved systems.) To describe how something works entails ascribing a function to each of its parts and to explain how these functions together achieve the goals. Teleological reasoning is accomplished by a combination of abduction and recognition. Abduction is necessary because most components and behaviors can play several functional roles (de Kleer, 1984). A turbine, for instance, can be used to generate work in a power generation system and to expand a gas in a liquefaction system. Recognition is important because it explains patterns of function in a system in terms of known, commonly used abstractions. A complex power generation system with multiple stages of turbines and reheating and regeneration, for instance, still can be viewed as a Rankine cycle after the appropriate aggregation of physical processes involved in its operation (Everett, 1999).

35.4.6 Data Interpretation

There are two ways that the representations of qualitative reasoning have been used in data interpretation problems. The first is to explain a temporal sequence of measurements in terms of a sequence of qualitative states; the second is to create a qualitative model of spatially distributed numerical data, for example, phase spaces, by interpreting the results of empirical data measurements or successive numerical simulation experiments in terms of regions whose qualitative properties are constant. The underlying commonality in these problems is the use of qualitative descriptions of physical constraints to formulate compatibility constraints that prune the set of possible interpretations. We summarize each in turn.

In measurement interpretation tasks, numerical and symbolic data are partitioned into intervals, each of which can be explained by a qualitative state or sequence of qualitative states. Using precomputed envisionments or performing limit analysis online, possible transitions between states used as interpretations can be found for filtering purposes. Specifically, if a state S_1 is a possible interpretation for interval I_1 , then at least one transition from S_1 must lead to a state that is an interpretation for the next interval.

This compatibility constraint, applied in both directions, can provide substantial pruning. Additional constraints that can be applied include the likelihood of particular states occurring, the likelihood of particular transitions occurring, and estimates of durations for particular states. Algorithms have been developed that can use all these constraints to maintain a single best interpretation of a set of incoming measurements that operate in polynomial time (de Coste, 1991).

In spatial data interpretation tasks, a physical experiment (e.g., Huang and Zhao, 2000) or numerical simulation (e.g., Yip, 1991) is used to gather information about the possible behaviors of a system given a set of initial parameters. The geometric patterns these behaviors form are described using vision techniques to create a qualitative characterization of the behavior. For example, initially, simulations are performed on a coarse grid to create an initial description of the system's phase space. This initial description is then used to guide additional numerical simulation experiments, using rules that express physical properties visually.

35.4.7 Spatial Reasoning

Reasoning with purely qualitative representations uses constraint satisfaction techniques to determine possible solutions to networks of relationships. The constraints are generally expressed as transitivity tables. When metric diagrams are used, processing techniques adapted from vision and robotics research are used to extract qualitative descriptions (Bailey-Kellogg and Zhao, 2003). Some reasoning proceeds purely within these new qualitative representations, while other tasks require the coordination of qualitative and diagrammatic representations. There is now a robust flow in the other direction, that is, vision and robotics researchers adopting qualitative representations because they are more robust to compute from the data and are more appropriate for many tasks (e.g., Kuipers and Byun, 1991; Sridhar et al., 2010). For example, qualitative spatial models computed from sensors are being used by teams in RoboCup Soccer (e.g., Schiffer et al., 2006).

35.5 Applications of Qualitative Reasoning

Qualitative reasoning began as a research enterprise in the 1980s, with successful fielded applications starting to appear by the early 1990s. For example, applications in supervisory process control (LeClair et al., 1989) have been successful enough to be embedded in commercial systems. Qualitative reasoning techniques have been used in the design of complex electromechanical systems, such as photocopiers, including the automatic generation of control software. A commercial tool using qualitative reasoning for FMEA in automobile electrical circuits was adopted by a major automobile manufacturer (Price, 2000). Thus, some applications of qualitative reasoning have been in routine use for over a decade, and more applications continue to be developed, with efforts expanding to include education and scientific modeling as well as engineering. Here we briefly summarize some of these research efforts.

35.5.1 Monitoring, Control, and Diagnosis

Monitoring, control, and diagnosis, although often treated as distinct problems, are in many applications deeply intertwined. Because these tasks also have deep theoretical commonalities, they are described together here. Monitoring a system requires summarizing its behavior at a level of description that is useful for taking action. Qualitative representations correspond to descriptions naturally applied by system operators and designers and thus can help provide new opportunities for automation. An important benefit of using qualitative representations is that the concepts the software uses can be made very similar to those of people who interact with software, thus potentially improving human-computer interfaces. Qualitative representations are important for control because qualitative distinctions provide criteria that make different control actions appropriate. Diagnosis tasks impose similar requirements. It is rarely beneficial to spend the resources required to construct a very detailed quantitative model of the

way a particular part has failed when the goal is to isolate a problem. Qualitative models often provide sufficient resolution for fault isolation. Qualitative models also provide the framework for organizing fault detection (i.e., noticing that a problem has occurred) and for working around a problem, even when these tasks require quantitative information (e.g., Flad et al., 2010).

An early commercial success of qualitative reasoning was in supervisory process control, where qualitative representations are used to provide more robust control than statistical process control in curing composite parts (LeClair et al., 1989). In the early stage of curing a composite part, the temperature of the furnace needs to be kept relatively low because the part is outgassing. Keeping the furnace low during the entire curing process is inefficient, however, because lower temperatures mean longer cure times. Therefore, it is more productive to keep temperature low until outgassing stops and then increase it to finish the cure process more quickly. Statistical process control methods use a combination of analytic models and empirical tests to figure out an optimal pattern of high/low cooking times. By incorporating a qualitative description of behavior into the controller, it can detect the change in qualitative regime and control the furnace accordingly, providing both faster curing times and higher yield rates than traditional techniques.

Another use of qualitative representations is in describing control strategies used by machine operators, such as unloading cranes on docks. By recording the actions of crane operators, machine learning techniques can be used to reverse-engineer their strategies (Suc and Bratko, 2002).

In some applications a small set of fault models can be pre-enumerated. A set of models, which includes the nominal model of the system plus models representing common faults, can then be used to track the behavior of a system with a qualitative or semiquantitative simulator. Any fault model whose simulation is inconsistent with the observed behavior can thus be ruled out. Relying on a preexisting library of fault models can limit the applicability of automatic monitoring and diagnosis algorithms. One approach to overcoming this limitation is to create algorithms that require only models of normal behavior. Most consistency-based diagnosis algorithms take this approach. For example, in developing onboard diagnostics for Diesel engines, qualitative representations have been found to be useful as a robust level of description for reasoning and for abstracting away from sensor noise (e.g., Sachenbacher et al., 2000).

One limitation with consistency-based diagnosis is that the ways a system can fail are still governed by natural laws, which impose more constraint than logical consistency. This extra constraint can be exploited by using a domain theory to generate explanations that could account for the problem, via abduction. These explanations are useful because they make additional predictions that can be tested and that also can be important for reasoning about safety in operative diagnosis (e.g., if a solvent tank's level is dropping because it is leaking, then where is the solvent going?). However, in many diagnosis tasks, this limitation is not a concern.

35.5.2 Design

Engineering design activities are divided into conceptual design, the initial phase, when the overall goals, constraints, and functioning of the artifact are established, and detailed design, when the results of conceptual design are used to synthesize a constructible artifact or system. Most computer-based design tools, such as computer-aided design (CAD) systems and analysis programs, facilitate detailed design. Yet many of the most costly mistakes occur during the conceptual design phase. The ability to reason with partial information makes qualitative reasoning one of the few technologies that provides substantial leverage during the conceptual design phase (Klenk et al., 2012). Qualitative reasoning can also help automate aspects of detailed design.

One example was Mita Corporation's DC-6090 photocopier (Shimomura et al., 1995), a self-maintenance machine, in which redundant functionality is identified at design time so that the system can dynamically reconfigure itself to temporarily overcome certain faults. An envisionment including fault models, created at design time, was used as the basis for constructing the copier's control software. In operation, the copier

keeps track of which qualitative state it is in, so that it produces the best quality copy it can. More recently, fully automatic, real-time composition of control software for “plug and play” high-end printing systems has been fielded by Xerox, using planning techniques over qualitative compositional models to assemble model-based controllers as parts are added to a system in the field (Fromherz et al., 2003).

In some fields experts formulate general design rules and methods expressed in natural language. Qualitative representations can enable these rules and methods can be further formalized, so that they can be automated. In chemical engineering, for instance, several design methods for distillation plants have been formalized using qualitative representations, and designs for binary distillation plants comparable to those in the chemical engineering research literature have been generated automatically.

Automatic analysis and synthesis of kinematic mechanisms have received considerable attention. Complex fixed-axis mechanisms, such as mechanical clocks, can be simulated qualitatively, and a simplified dynamics can be added to produce convincing animations. Initial forays into conceptual design of mechanisms have been made, for example, using configuration space-based techniques to analyze higher-pair mechanisms (Sacks and Joskowicz, 2010). Qualitative representations are also useful in case-based design, because they provide a level of abstraction that simplifies adaptation (e.g., Faltings, 2001).

Qualitative reasoning also is being used to reason about the effects of failures and operating procedures. Such information can be used in FMEA. For example, potential hazards in a chemical plant design can be identified by perturbing a qualitative model of the design with various faults and using qualitative simulation to ascertain the possible indirect consequences of each fault. Commercial FMEA software using qualitative simulation for electrical system design is now being used commercially in automotive design (Price, 2000).

35.5.3 Scientific Modeling

Formalizing the art of modeling is one of the goals of qualitative reasoning, which has led to it being applied to scientific modeling in several ways. One approach is to use modeling ideas from qualitative reasoning to provide languages for organizing mathematical models in ways that support software-assisted model formulation and revision based on comparing numerical data to simulation results (e.g., Bridewell et al., 2006). Another approach is to use spatial aggregation to extract meaningful features from spatially distributed data to provide concise summarizations of structure and function (e.g., Ironi and Tentoni, 2011). Finally, in some domains traditional mathematical models are too fine grained compared to the experimental data available; hence, qualitative models can provide a more natural language for expressing theories. Two examples are ecology, for example, Bredeweg et al. (2008), where qualitative models have been used to help articulate underlying assumptions in modeling, and biology, for example, Batt et al. (2012), where hypotheses about bacterial regulatory networks are being explored via qualitative simulation with model checking. Qualitative models are also useful as an intermediate representation for eliciting and formalizing knowledge. For example, the Agroecological Knowledge Toolkit helps agricultural scientists gather and distill local ecosystem knowledge in field studies (e.g., Cerdan et al., 2012). Another example is the Calvin system (Rassbach et al., 2011), which uses qualitative representations of evidence to help geoscientists construct arguments concerning the interpretation of cosmogenic isotope data in rocks.

35.5.4 Intelligent Tutoring Systems and Learning Environments

One of the original motivations for the development of qualitative reasoning was its potential applications in intelligent tutoring systems (ITSs) and intelligent learning environments (ILEs). Qualitative representations provide a formal language for a student’s mental models (Gentner and Stevens, 1983), and thus they facilitate communication between software and student. For example, if a student modeling a block on a table leaves out the force the table exerts on the block, they can be shown a simulation where the block falls through the table, causing them to improve their model (Hirashima et al., 2009). Similarly, in learning organic chemistry, qualitative representations can provide explanations for what happens in reactions (Tang et al., 2010). For younger students, who have not had algebra or differential equations,

the science curriculum consists of learning causal mental models that are well captured by the formalisms of qualitative modeling. By using a student-friendly method of expressing models, such as concept maps, software systems have been built that help students learn conceptual models (Forbus et al., 2005; Leelawong et al., 2001), providing software support that scaffolds students in modeling (Bredeweg et al., 2010). In more advanced courses and in industrial training, qualitative reasoning provides explanations that help students make sense of the results of simulators and quantitative analysis tools, for example, to explain why a student's design violates the laws of thermodynamics when teaching about power plants.

35.5.5 Cognitive Modeling

Since qualitative reasoning was inspired by observations of how people reason about the physical world, one natural application of qualitative reasoning is cognitive simulation, that is, the construction of programs whose primary concern is accurately modeling some aspect of human reasoning and learning, as measured by comparison with psychological results. Some research has been concerned with modeling scientific discovery and conceptual change, for example, simulating the trajectories of mental models that students go through when learning intuitive notions of force (Friedman and Forbus, 2010). Several investigations suggest that qualitative representations have major role to play in understanding cognitive processes such as high-level vision. For example, Sridhar et al. (2010) describes how qualitative spatial representations can be used to help analyze video data, and Lovett et al. (2010) describes how analogical reasoning over automatically computed qualitative representations suffices to enable a computational model to outperform most adult Americans on Raven's Progressive Matrices, a visual reasoning test that correlates well with general intelligence. Qualitative order of magnitude representations play a central role in a model of moral decision-making (Dehghani et al., 2008), providing the stratification needed to model the effects of sacred values in decision-making. Commonsense reasoning appears to rely heavily on qualitative representations, although human reasoning may rely more on reasoning from experience than first-principle reasoning (Forbus and Gentner, 1997). Understanding the robustness and flexibility of human commonsense reasoning is an important scientific goal in its own right and will provide clues as to how to build better AI systems. Thus, potential use of qualitative representations by cognitive scientists may ultimately prove to be the most important application of all.

35.6 Research Issues and Summary

Qualitative reasoning is now a mature subfield with a mixture of basic and applied activities, including a number of fielded applications. Its importance is likely to continue to grow, due to the increasing number of successful applications, the continued growth in available computing power, and the rapid digitization of workflows in many human endeavors.

Although there is a substantial research base to draw upon, there are many open problems and areas that require additional research. There are still many unanswered questions about purely qualitative representations (e.g., what is the minimum information that is required to guarantee that all predicted behaviors generated from an envisionment are physically possible?), but the richest vein of research concerns the integration of qualitative knowledge with other kinds of knowledge: numerical, analytic, teleological, etc. The work on modeling to date, although a solid foundation, is still very primitive; better model formulation algorithms, well-tested conventions for structuring domain theories, and robust methods for integrating the results of multiple models are needed. Most domain modeling efforts have been driven by particular application domains and tasks, which is effective in the short run, but a more open development strategy would speed the development of integrated domain theories for a broad range of scientific and engineering knowledge. The growing importance of deep natural language understanding (Ferrucci et al., 2012) is likely to invigorate research in exploring the role of qualitative representations in natural language semantics, since they provide a natural level of description for everyday properties and events (Kuehne and Forbus, 2004; Pustejovsky and Moszkowicz, 2011).

Key Terms

- Comparative analysis:** A particular form of a “what-if” question, that is, how a physical system changes in response to the perturbation of one of its parameters.
- Compositional modeling:** A methodology for organizing domain theories so that models for specific systems and tasks can be automatically formulated and reasoned about.
- Confluence:** An equation involving sign values.
- Diagrammatic reasoning:** Spatial reasoning, with particular emphasis on how people use diagrams.
- Domain theory:** A collection of general knowledge about some area of human knowledge, including the kinds of entities involved and the types of relationships that can hold between them, and the mechanisms that cause changes (e.g., physical processes and component laws). Domain theories range from purely qualitative to purely quantitative to mixtures of both.
- Envisionment:** A description of all possible qualitative states and transitions between them for a system. Attainable envisionments describe all states reachable from a particular initial state; total envisionments describe all possible states.
- FMEA (Failure Modes and Effects Analysis):** The analysis of the consequences of the failure of one or more components for the operation of an entire system.
- Landmark:** A comparison point indicating a specific value achieved during a behavior, for example, the successive heights reached by a partially elastic bouncing ball.
- Limit point:** A comparison point indicating a fundamental physical boundary, such as the boiling point of a fluid. Limit points need not be constant over time, example, boiling points depend on pressure.
- Metric diagram:** A quantitative representation of shape and space used for spatial reasoning, the computer analog to, or model of, the combination of diagram/visual apparatus used in human spatial reasoning.
- Model fragment:** A piece of general domain knowledge that is combined with others to create models of specific systems for particular tasks.
- Modeling assumption:** A proposition expressing control knowledge about modeling, such as when a model fragment is relevant.
- Physical process:** A mechanism that can cause changes in the physical world, such as heat flow, motion, and boiling.
- Place vocabulary:** A qualitative description of space or shape that is grounded in a quantitative representation.
- Qualitative proportionality:** A qualitative relationship expressing partial information about a functional dependency between two parameters.
- Qualitative simulation:** The generation of predicted behaviors for a system based on qualitative information. Qualitative simulations typically include branching behaviors due to the low resolution of the information involved.
- Quantity space:** A set of ordinal relationships that describes the value of a continuous parameter.
- Semiquantitative simulation:** A qualitative simulation that uses quantitative information, such as numerical values or analytic bounds, to constrain its results.

Further Information

Several publically available qualitative reasoning systems that can be downloaded from the web provide an easy way to get started. Those currently being actively maintained and extended include University of Amsterdam’s Garp3, a qualitative dynamics simulator; University of Bremen’s SparQ; a qualitative spatial reasoning engine; and Northwestern University’s CogSketch, a sketch understanding system.

Papers on qualitative reasoning routinely appear in *AI, Journal of Artificial Intelligence Research (JAIR)*, and *IEEE Intelligent Systems*. Many papers first appear in the proceedings of the American

Association for Artificial Intelligence (AAAI), the International Joint Conferences on Artificial Intelligence (IJCAI), and The European Conference on Artificial Intelligence (ECAI). Every year there is an International Qualitative Reasoning Workshop, which celebrated its 25th anniversary in 2011. Its proceedings, available on the web, document the latest developments in the area.

36.1 Introduction

In essence, machine learning—more completely referred to as *statistical* machine learning—is concerned with identifying and exploiting patterns in data. This has led to another name for the same area: “pattern recognition.” Machine learning is an inherently interdisciplinary field, combining computer science with mathematics and statistics, and it has many application areas such as robotics, bioinformatics, cognitive science, speech recognition, machine vision, and medicine.

At its heart, machine learning is concerned with adaptation: modifying the parameters of a model so that the outputs more closely represent the expected results for given sets of inputs. It is this adaptation that is termed “learning” in the name of the field. Typically, the parameters of the model are adjusted through some form of optimization in order to minimize some error function. The aim of learning a model, rather than using a look-up table of possible outputs or applying predefined rules to the inputs, is to enable “generalization,” so that the machine learning algorithm can give sensible predictions on data that were not seen during training.

This chapter provides an overview of the process by which machine learning problems are approached, together with some of the more common algorithms, and then highlights a few areas of current investigation. There has been a lot of research into machine learning over recent years, so this chapter aims to focus on the common features and some differentiating factors between different algorithms before suggesting places where more complete overviews of the field can be found. A set of references for further information on particular algorithms and approaches is also provided.

Examples of the types of problems that machine learning can be usefully applied to include the following:

Predict electricity usage: Based on a set of input factors such as historical electrical usage, weather prediction, season, and what televised events are happening, predict the peak electricity usage for each day into the future. Obviously, electricity providers rely on accurate models forecasting electrical usage, so that they can provide the right amount into the grid without too much waste.

This is an example of a *regression* problem (where a dependent variable, here the electricity usage at a particular time, is predicted based on a set of input variables). It is also an example of time-series prediction, since we have a series of data probably collected at regularly spaced intervals that we wish to propagate into the future.

Predict treatment outcomes: Suppose that for some disease there is a choice of whether or not to provide a particular treatment, for example, because it is not always effective and may have unpleasant side effects. Based on the results of various tests on the patient, and data on their physiological make-up, the algorithm should try to identify those people for whom the treatment is likely to be effective.

This is an example of a *classification* problem, where the output variable identifies which of a set of classes (here just two: treat or don't treat) each input belongs to.

Classify people into different levels of risk for a loan: Using information such as age, credit card debt, and salary, place people into different classes of risk for a loan so that choices of loan limit, interest rate, and so on can be made.

This is written as a classification task, as the input variables are used to separate the individuals into a set of classes based on their loan risk. These different classes could then be used with a set of rules to decide on what loan limit should be applied. Alternatively, the problem could be treated as a regression problem, with the input data used to directly suggest an appropriate loan limit.

Robot control: Based on the positions, velocities, and accelerations of the joints of a robot arm, together with a desired trajectory, compute the electrical current that needs to be applied to the actuators. Again, this is a regression problem, since the torque required at each joint will be a continuous variable.

The four different problems have been described as either regression or classification problems, which describes the dichotomy of statistical machine learning: the desired output for the data is either a set of continuous values for regression or a class membership function. In either case, machine learning can be seen as a form of function approximation, taking a set of inputs and computing a mapping into some appropriate output space.

36.2 Overview of the “Learning from Data” Process

Machine learning algorithms learn from data. The mantra of “garbage in, garbage out” is thus nowhere more true, since algorithms given unsuitable or contradictory data will make useless predictions. However, even with appropriate data, there are still many ways in which errors can be introduced during the data preparation and training process. To assist with avoiding these errors, there is a general approach to data analysis, which can be summarized as follows:

Collect data: While algorithms are often tested, compared, and analyzed on the strength of “toy” (simple) datasets and well-known benchmarks (such as those available at the UCI Machine Learning Repository [5]), for the purposes of real data analysis, original data will need to be chosen and collected. The choice of what data to collect, and how much of it, are important considerations that significantly affect the results of any learning, just as it does any other statistical analysis. As a very basic example, suppose that we wish to predict electricity usage and do not know the weather. This will make it hard to know how much heating people will be using, making the results less accurate. However, knowing the stock market values for the current day is unlikely to help in the prediction, since these variables are presumably largely uncorrelated.

The choice of how much data to collect is also important. We will discuss the need for a variety of different sets of data shortly, but here we are just considering the number of data points required in order to generate a model. Unfortunately, the answer is a rather unhelpful “it depends”: the complexity of the underlying model, the features of the learning algorithm, and several other factors all play a role. Notwithstanding computational cost, it is better to have more data than less, and since data are rarely free (there is an inherent cost in collecting, processing, checking, and storing it), the limits on the amount of data are not generally computationally motivated.

Choose features and preprocess: This is often the “art” of machine learning, although some parts of the process can be replaced by experimentation and the requirements of the particular algorithms. In general, it requires a reasonable understanding of the dataset, the application of methods such as *dimensionality reduction* (see Section 36.4.1), and some experimentation. Many of the algorithms make assumptions about how the data will be presented, often requiring that they have been normalized to have zero mean and unit variance.

Choose model(s): There are two parts to the choice of models: the selection of particular algorithms to use and the specification of any parameters required by the model (e.g., the number of neurons in a neural network and the network topology), which often govern the complexity of the model that the algorithm can learn and the amount of training data that needs to be provided.

Train the models on the data: Generally this is relatively simple, being prescribed by the algorithms chosen.

Evaluate on independent data: The model that is trained is based on a set of data known as “training data.” These data points are samples from the space of possible data that the model is expected to predict outputs for, but they are certainly not complete, since otherwise there would be no need for any generalization, and so no need for machine learning. One possible problem with the training set is that it may not be representative of the typical data that are seen, leading to a skewed model, but there is a more serious problem that can occur during training, known as *overfitting*. In essence, the amount of training (meaning the number of times that the algorithm runs over the data and modifies its parameters) that is required for a machine learning algorithm is not usually clear. In almost all datasets, the data are not pure representations of the pattern that underlies the dataset—which is what we are trying to find—but also contain variations from an assortment of additional processes. We generally model these as a generic uncorrelated noise term and assume that the model follows a Gaussian distribution. Since the learning algorithm sees only the data points, separating the underlying model from the noise is very difficult. If the learning algorithm is trained for too long, then it will fit the data that have been presented noise and all, meaning that its prediction capabilities are compromised.

Of course, this need for more data puts extra pressure on the data collection, and one method that can be used to make the most of relatively small datasets is to replace data with computation time. The method of *k-fold cross-validation* does this by splitting the data into k folds or subsets, and then training the chosen learning algorithm on $k - 1$ of these subsets, using the missing one for testing. k different learners are trained, each with a different subset missing, and then the most accurate of the learners is selected to be used.

Use the trained model: Having generated and validated the model, it is ready to use on other data.

The most basic way in which machine learning algorithms can be separated into groups is by what data are provided for training. This is a fundamental difference: on one side is *supervised learning* (the vast majority of algorithms; see Section 36.3 for more details), where the training data consist of pairs of input data and target (desired) outputs, while on the other is *unsupervised learning*, where there is no target output provided at all (Section 36.4). Considering the aim of machine learning as either regression or classification, it should be clear that without some form of target data (showing what the correct answer is for some examples) it is impossible to provide a meaningful continuous output, and so regression is not possible. However, there are methods by which similarities between inputs can be used to cluster inputs together, providing an approach to classification that does not require target data.

Sitting in-between supervised and unsupervised learning methods are algorithms where prototype solutions are scored by some form of oracle, and the algorithm aims to maximize its reward by performing search over many possible solutions. The two main classes that fall into this category are *reinforcement learning* (see, e.g., [38]) and *evolutionary learning*, such as genetic algorithms [14,28]. These are different to the other types of machine learning in that what is learnt is not exactly a model of the underlying data generating function, but either a way to act (reinforcement learning considers the actions of an agent interacting with some environment, with the actions of the agent modifying the

environment) or the potential solution to a problem. In essence, evolutionary algorithms are stochastic search algorithms that trade off local search around current good solutions with making large-scale changes to the current solutions.

36.3 Supervised Learning

36.3.1 Nearest Neighbors

It seems clear that machine learning needs to be a bit more complicated than just a look-up table of the training data. However, it is useful to start with that simple concept and extend it a little. If the input data cover the space of possible solutions well, then identifying similar inputs to the current input and giving the same output as them seems like a reasonable idea. This is the idea of *nearest neighbor* algorithms, which require that a similarity metric is available so that neighboring inputs can be identified; generally this is the Euclidean metric in the d -dimensional input space created by treating each element of the input vector \mathbf{x} of length d as a separate dimension, so that each \mathbf{x} defines a point in the space.

Using just one neighbor can work for classification tasks but is very prone to errors from mislabelling and other effects of noise, so it is common to use k -nearest neighbors, where k needs to be chosen. For classification tasks, the output is then the majority vote of the k neighbors, while for regression tasks it can be their average value. Whichever is used, choosing an appropriate value for k is generally based on experimentation with the training data.

Figure 36.1 shows an example of a simple classification problem, where the aim is to separate the circles and crosses. The line in each figure is the *decision boundary*, which is the line when the classification changes between the two classes.

Figures like these, which generally show 2D data (for obvious reasons), hide an important consideration. As the number of dimensions in the input vector grows, so does the amount of data that is needed to cover the space. Unfortunately, a linear increase in the number of dimensions leads to an exponential increase in the number of data points required: the sampling density grows as $N^{1/d}$, so 100 samples of a 2D problem have the same coverage as 10^{10} samples of a 10D problem. This is known as the *curse of dimensionality* and it has serious consequences for machine learning, as it means that for high-dimensional spaces the data are always relatively sparse in the input space.

The k -nearest neighbor algorithm produces outputs based on the local inputs, so for accurate predictions in a particular region of input space it requires that the training data represent the data distribution well there. It is also essentially model-free, in that it does not make any assumptions about the underlying statistical distribution of the data. It does, however, assume that within each local region the data are fitted by a constant function. We will see another method that makes this assumption in Section 36.3.3.

36.3.2 Mean-Square Error

Figure 36.1 also shows a feature that is of considerable importance in machine learning: the *decision boundary*. In the figure, it identifies the delineation between crosses and circles, and once this boundary has

FIGURE 36.1 Decision boundaries for two different values of k (on the left, $k = 2$, and on the right, $k = 20$) for the k -nearest neighbor algorithm.

been identified, the separation between the two classes is complete. For k -nearest neighbors, it is typically a very wiggly line, but it doesn't have to be. If we are looking for a model-based solution to machine learning, then, by making assumptions about the number of degrees of freedom that the desired model of the data allows (and hence the complexity of the model), an alternative approach to classification can be found.

Suppose that we wish to fit a straight line between the two classes in the figure. Writing the line as $\hat{y} = \beta_1 x + \beta_0$, the two parameters that need to be found are clear. For regression, the values of \hat{y} should be predictions of the continuous output, but for classification it is less clear what values to use. However, for binary classification, coding the first class (say the circles) as zeros and the second class as ones works fine. The separation between the two classes is then the line $\hat{y} = 0.5$. The generalization of this to higher dimensions fits a hyperplane specified by d parameters, which is again a linear separator of the classes.

There are two observations to make about this linear fit. The first is that for our 2D example there are only two parameters for the line, so the problem is clearly overdetermined, since we have rather more data than that, while the second is that there is no guarantee of a perfect linear separation between the classes. For example, in Figure 36.1, there is no such line. The benefit of having lots of data is that we can fit the line that minimizes some error measure of the training data, such as the mean-square error (MSE). These error measures are known as loss functions $L(\mathbf{y}, f(\mathbf{x}))$; for MSE, it can be written as

$$L(\mathbf{y}, f(\mathbf{x})) = \sum_{i=1}^n (\mathbf{y}_i - f(\mathbf{x}_i))^2 \quad (36.1)$$

Suppose that the true function that generates the data is a function g , so that the target data $\mathbf{y} = g(\mathbf{x}) + \epsilon$ where ϵ is the noise. The expected value of the fitted MSE on an independent test set is (where $E[\cdot]$ is the statistical expectation)

$$E \left[\frac{1}{N} \sum_{i=1}^N (\mathbf{y}_i - \hat{\mathbf{y}}_i)^2 \right] \quad (36.2)$$

$$= \frac{1}{N} \sum_{i=1}^N E [\mathbf{y}_i - g(\mathbf{x}_i) + g(\mathbf{x}_i) - \hat{\mathbf{y}}_i]^2 \quad (36.3)$$

$$= \frac{1}{N} \sum_{i=1}^N E \left[(\mathbf{y}_i - g(\mathbf{x}_i))^2 \right] + E \left[(g(\mathbf{x}_i) - \hat{\mathbf{y}}_i)^2 \right] + 2E \left[(g(\mathbf{x}_i) - \hat{\mathbf{y}}_i) (\mathbf{y}_i - g(\mathbf{x}_i)) \right] \quad (36.4)$$

$$= \frac{1}{N} \sum_{i=1}^N E [\epsilon^2] + E \left[(g(\mathbf{x}_i) - \hat{\mathbf{y}}_i)^2 \right] \quad (36.5)$$

$$= \frac{1}{N} \sum_{i=1}^N E [\epsilon^2] + E \left[g(\mathbf{x}_i) - E[(\hat{\mathbf{y}}_i) + E[\hat{\mathbf{y}}_i] - \hat{\mathbf{y}}_i]^2 \right] \quad (36.6)$$

$$= \frac{1}{N} \sum_{i=1}^N E [\epsilon^2] + E \left[(g(\mathbf{x}_i) - E[\hat{\mathbf{y}}_i])^2 \right] + E \left[(E[\hat{\mathbf{y}}_i] - \hat{\mathbf{y}}_i)^2 \right] + 2E \left[(E[\hat{\mathbf{y}}_i] - \hat{\mathbf{y}}_i) (g(\mathbf{x}_i) - E[\hat{\mathbf{y}}_i]) \right] \quad (36.7)$$

$$= \frac{1}{N} \sum_{i=1}^N \text{var}(\text{noise}) + \text{bias}(\hat{\mathbf{y}}_i)^2 + \text{var}(\hat{\mathbf{y}}_i) \quad (36.8)$$

In this derivation, we have used the fact that the expectations in the last terms of (36.4) and (36.7) are zero because the noise in the test set is statistically independent of the trained model. Clearly, the variance in the noise is beyond our control. However, the same is not true of the other two terms, and

we should favor algorithms that minimize these terms. Unfortunately, a little thought shows that the two terms are in opposition: for a simple example, consider the k -nearest neighbor algorithm of the previous section again. When k is small, the neighbors will all be fairly close to the test point and so the variance in their predictions will be low (in fact, for $k = 1$, the variance will always be 0). However, the bias is high because the points are potentially very noisy. As k increases the variance also increases, since there are more data points to consider and they are further away from each other, but the overall error of the model (the bias) reduces at the same time. This is generally true for any model: the more complex the model, the lower the bias, but the higher the variance. It is known as the *bias–variance trade-off* and means that careful work is typically needed for appropriate model selection; for further details, see [13].

For classification, we can use categorical variables, and the loss function is based on an indicator function, being 0 if the data does not belong to that class, and 1 if it does. We can also compute the posterior probability of each class $P(C_i|\mathbf{x})$ and then pick the *maximum a posteriori (MAP)* estimate, which is the most probable class. While the computations here are relatively simple, using Bayes' theorem, the dependence between the different variables makes them computationally expensive. An assumption that provides a huge simplification is to treat all the variables as independent, an algorithm that goes by the name of *naïve Bayes*. It often works very well, especially in cases where the data are very high dimensional, where it makes the computations tractable.

Figure 36.2 shows three different discriminant functions that separate the (admittedly very limited) data perfectly and therefore have the same MSE value of 0. Without further data to aid in choosing one, it might seem hard to identify a suitable method of doing so, although it should be clear that the middle one is somehow “better” than the others. The concept of the *optimal separating hyperplane*, which is the hyperplane that maximizes the distance to the closest point from either of the two classes that it separates (the margin), provides a solution. This is the basis of the *support vector machine (SVM)* [40], which is one of the most commonly-used machine learning algorithms in practice, and often produces very impressive results.

Up to this stage, we have considered only linear decision boundaries, although it is clear that in general data are not linearly separable. There are two ways to deal with this issue. The first is to use a more complex model that is not limited to hyperplanes, while the second is to consider a transformation of the data into a space where they can be linearly separated. We will consider the first case in Section 36.3.4 and briefly discuss the second case here.

The left of Figure 36.3 shows an example of a simple dataset that cannot be linearly separated using the one parameter (x) provided. However, the addition of a second variable derived from the first (x^2) does allow the data to be linearly separated. Projecting the data into an appropriate set of higher dimensions can thus enable the data to be linearly separated. Methods that make use of these transformations are known as *kernel methods*; there are several potential kernels available. For further details, see [40].

FIGURE 36.2 Three different discrimination functions that all provide linear separation between the two classes of data. The identification of optimal separating hyperplanes is a fairly recent development in machine learning. (From Marsland, S., *Machine Learning: An Algorithmic Perspective*, CRC Press, Lakewood, NJ, 2009.)

FIGURE 36.3 The data in both figures are based on only one feature variable. However, in the figure on the right, the two dimensions are the variable x and x^2 . The addition of this derived variable enables the two classes to be linearly separated. (From Marsland, S., *Machine Learning: An Algorithmic Perspective*, CRC Press, Lakewood, NJ, 2009.)

36.3.3 Decision Trees

It was previously shown that the k -nearest neighbors algorithm effectively fitted a constant value around each data point. It was suggested then that there was another method that takes the same assumption further. This algorithm is the decision tree, which takes the input space and chooses one feature at a time to sequentially split the data, so that eventually the entire space is partitioned into hyper-rectangles, each of which is then represented by a constant value (such as a class membership or a constant regression output), effectively a local basis function. Figure 36.4 shows a dataset with the first two splits of it to demonstrate the process.

Decision trees are built in a greedy fashion, with the feature to be chosen at each level of the tree selected by some criteria (often based on *information gain*, which is the amount by which knowing that feature decreases the *entropy* of the remaining training set) [8].

36.3.4 Kernel Functions

If the aim of the machine learner is to construct a model of the data, then the output \hat{y} (the prediction that it makes) of the learning algorithm for input vector \mathbf{x} can be written as

$$\hat{y} = \sum_{k=1}^N w_k \phi_k(\mathbf{x}) \quad (36.9)$$

where the number (N) of functions ϕ_k represents part of the complexity of the model and the choice of functions ϕ represents the remainder. The *weights* w_k are the adjustable parameters of the model, that is,

FIGURE 36.4 Potential initial steps for a decision tree learning a dataset. Each choice performs a linear separation based on one of the feature variables. (From Marsland, S., *Machine Learning: An Algorithmic Perspective*, CRC Press, Lakewood, NJ, 2009.)

the things that have to be learned. Written in this way, the model is merely a weighted sum of separate predictors, and the learning process consists of identifying suitable weights for the chosen function model, based on minimizing the difference between the model outputs \hat{y} and the target outputs y . For example, suppose that each ϕ_k merely reproduces the k th element of the input vector. This is simply the *linear regression* model, which is well known in statistics.

36.3.4.1 Neural Networks

One common choice of function ϕ is the sigmoid (or logistic) function, commonly written as (for scalar input value z)

$$\phi(z) = \frac{1}{1 + e^{-\alpha z}} \quad (36.10)$$

where α is some predefined positive parameter. This function has three distinct phases of output: for negative values of z , it produces outputs very close to zero, while for positive values of z it produces outputs near one. Close to zero, however, it varies smoothly between the two saturation values. In the idealized version, where the sigmoid represents a step function, this can be taken as a simple model of a neuron, which accumulates charge on its surface until the potential difference between the surface and the cell body reaches a threshold, whereupon the neuron fires. Any model that is comprised of sets of these simple artificial neurons is known as a *neural network*. In the case where there are just a single set of these artificial neurons, each acting independently of the others, the model is still linear. A particular learning algorithm for this data is the Perceptron learning algorithm, where at each iteration the weights are updated by a learning rule that adapts the weights that are leading to incorrect data.

Suppose now that the functions ϕ can also contain weights within them, so $\phi(\mathbf{x}) = \sum_{k=1}^L w_{ik}x_i$, where the index i has been added to identify individual elements of input vector \mathbf{x} . This leads to a nonlinear model with two sets of weight vectors that both need to be set by the learning algorithm. The added complexity of such a model enables nonlinear functions to be learned, although at the cost of more training. One way that such networks of neurons can be visualized is as successive layers of neurons, as shown in Figure 36.5, which is an example of the *multilayer Perceptron (MLP)*. The MLP with two layers of neurons is a universal computer, capable of computing arbitrary decision boundaries [10]. The MLP is the most commonly used neural network for supervised learning. Training of the weights of the network are based on a learning rule that propagates the updates back through the network according to the error at the output [34].

FIGURE 36.5 A schematic showing a feed-forward neural network such as the MLP.

36.3.4.2 Optimization

As with many machine learning algorithms, computation of the weights and other parameters of neural networks are performed by optimization, and many of the algorithms are variations on normal algorithms for gradient descent, particularly Levenberg–Marquardt, since it is based on least squares. For further information on gradient descent algorithms and other work on numerical optimization, see a text such as [31].

One method of optimization that is unique to machine learning is the *expectation–maximization* (EM) algorithm [11], which is used in many areas of machine learning, wherever a *maximum likelihood* solution is needed based on hidden variables. In an EM algorithm, there are two steps. First, the current parameter values are used to compute the posterior distribution of the hidden variables, and then these values are used to find the expectation of the complete data log likelihood for more general parameter values. Then, in the second step, a new estimate of the parameter values is computed by maximizing the function computed in the first step. EM algorithms are guaranteed to converge to a local optimum, but not further.

36.3.4.3 Other Kernels

While the logistic function is the most common choice of function ϕ , there are alternatives. One that is commonly used in function approximation is a *radial basis function* (RBF), which, as the name implies, is any function whose value depends only on the distance of the input from the cluster center. A common radial basis is e^{-r^2} , which is effectively an unnormalized Gaussian function. RBF networks have the same computational power as feed-forward MLPs, although they are trained rather differently, positioning a set of RBFs in space and then optimizing their parameters independently.

If it is assumed that the weight vectors in Equation 36.9 come from a Gaussian distribution then we generate a simple example of a *Gaussian process*, where the prediction \hat{y} is a linear combination of Gaussian variables and therefore Gaussian itself. The covariance of the outputs is computed as a kernel function between pairs of input (training) data points \mathbf{x}_i . For the case of Equation 36.9 the kernel function is

$$k(\mathbf{x}_i, \mathbf{x}_j) = \phi(\mathbf{x}_j)^T \phi(\mathbf{x}_i) \quad (36.11)$$

The kernel defines the covariance matrix of the Gaussian process, which is iteratively updated, since the probability distribution that is being estimated at each training step N is $p(\mathbf{y}_N) = \mathcal{N}(\mathbf{y}_N | \mathbf{0}, C_N)$, where \mathbf{y}_N is the vector of training targets up to step N and C_N is the $N \times N$ covariance matrix whose elements are defined by

$$C(\mathbf{x}_i, \mathbf{x}_j) = k(\mathbf{x}_i, \mathbf{x}_j) + \sigma^2 \delta_{ji} \quad (36.12)$$

where σ is the standard deviation of the noise and $\delta_{ji} = 1$ if $j = i$ and 0 otherwise. For more general problems, the kernel needs to be chosen, and there are several common selections, including the form $e(-\|\mathbf{x}_i - \mathbf{x}_j\|)$. For more information, see [33].

36.3.5 Statistical Interpretation of Machine Learning

No matter whether or not we are predicting multinomial outputs (classification) or continuous ones (regression), the aim of machine learning is usually to use information from a set of training data \mathcal{D} to create a model $p(\mathbf{x})$. The difference between supervised and unsupervised learning is that for unsupervised learning each element of data in \mathcal{D} consists only of the input vector \mathbf{x} , while for supervised learning

each input vector is annotated with the target \mathbf{y} , so that the aim is to learn the mapping between input vector and target, that is, $p(\mathbf{x}, \mathbf{y})$. Writing this as

$$p(\mathbf{x}, \mathbf{y}) = p(\mathbf{y} | \mathbf{x}) p(\mathbf{x}) \quad (36.13)$$

it becomes clear that what we are primarily interested in is the conditional probability term on the right: given a set of input data points \mathbf{x}_i we wish to predict the most likely target value \mathbf{y}_i for each of them. In the unsupervised case, where there are no known targets, the entire distribution of interest is $p(\mathbf{x})$ and it is the estimation of this distribution that is the aim of unsupervised learning. For both supervised and unsupervised learning, the value of $p(\mathbf{x})$ is of interest, since low values of it tells us that particular data points are relatively rare. There is a type of learning known as *novelty detection* (or one-class classification) where the training data consists only of examples of what you wish to ignore (“normal” data) and the algorithm identifies inputs with low probability $p(\mathbf{x})$ as “novel.” For a summary of this type of learning, see [25].

36.3.6 Graphical Models

As the last section suggests, machine learning can be seen as the meeting point of statistics and computer science. Nowhere is this more clear than in the relatively recent development of graphical models, where graphs (in the computer science sense of a set of nodes and edges) are used to represent probabilistic models. By far the most common approach uses directed acyclic graphs, where the general formulation is known as a *Bayesian network* [20,23]. It represents the joint probability distribution of a set of variables using the nodes of the graph as the variables and the directed edges show some form of dependency between the nodes (more correctly, the absence of an edge between two nodes represents conditional independence of the second node given the first). Many other machine learning algorithms arise as special cases of the Bayesian network, not least the hidden Markov model (HMM), which was originally proposed for speech recognition but has since found many other uses [32], neural networks (including the Boltzmann machine and deep belief network [16]), and particle filters [4]. The second type of network dispenses with the directions on the edges to produce *Markov networks*, which are used in computer vision among other places, particularly the conditional random field [37].

The Bayesian network is specified by the nodes and edges, together with the conditional probability distribution of each node (conditioned on its parents in the graph). For discrete parameters, this is listed as a table, with entries for all the possible values of each of the parents, while for continuous parameters it is specified by the parameters of the chosen probability distribution. Clearly, however, it can be a relatively large collection of numbers to hold and update.

The benefit of Bayesian networks is that the conditional independence relations allow the joint distribution to be represented more compactly than would otherwise be possible. For example, in Figure 36.6, the joint probability of all the nodes in the graph is

$$P(A, B, C, D, E) = P(A) \times P(B) \times P(C | A, B) \times P(D | A) \times P(E | A, B, C, D) \quad (36.14)$$

but by using the fact that E is independent of A given its parents (B , C , and D), this can be reduced to

$$P(A, B, C, D, E) = P(A) \times P(B) \times P(C | A) \times P(D | A) \times P(E | B, C, D) \quad (36.15)$$

While this is not much of a saving in this case, it can often make a substantial difference to the complexity of the calculations in practice.

FIGURE 36.6 A possible Bayesian network, consisting of nodes representing random variables in the form of a directed acyclic graph, with the edges implying information about dependence between the variables.

One issue with Bayesian networks is that inference (i.e., computing the posterior distribution of some subset of the nodes given values for the rest) is generally computationally intractable (in fact, it is NP-hard). While several algorithms for approximating the distribution have been developed, typically based on Markov chain Monte Carlo (MCMC) sampling or mean field approximation, these are still computationally expensive.

The training of Bayesian networks is also computationally intractable, since there are a super-exponentially large number of ways to connect up the nodes into a directed acyclic graph. The problem of structure learning (identifying the edges between a set of nodes) is generally predefined based on domain knowledge, although there are algorithms based on greedy heuristics starting from an initial search point [23].

One way around these problems of computational intractability is to impose structure onto the graph, and there are examples where this leads to computationally tractable algorithms, most notably the HMM [32]. In the HMM, a schematic of which is shown in Figure 36.7, a set of unknown states are coupled using an estimate of the transition probabilities between the states, and for each state there are emission probabilities that compute how likely a set of different observations are. As the HMM forms a chain, there are efficient algorithms for both computing the probabilities based on training data and finding the most likely sequence of states for a set of observations [32].

There has been recent interest in combining Bayesian networks with first-order logic, thus obtaining a network that can encode both probabilistic and global constraints and other deterministic relationships. See [18,27] for more information.

FIGURE 36.7 A schematic of an HMM. Hidden states of the model are inferred, together with the motion between them, based on the observations that are seen.

36.3.7 Combining Learners

There have been several examples of committee algorithms, that is, algorithms that combine the outputs of several classifiers (also known as ensembles), proposed in machine learning over the last 40 years, but two relatively recent developments are by far the most successful: *boosting* and *random forests*. Both are meta-algorithms in that they combine the results of other learning algorithms to produce a more accurate output. As the name suggests, a random forest combines the outputs of many decision trees, and, in fact, decision trees are the most popular learners to boost as well. Although both are easier to describe for classification, both boosting and random forests can be extended to regression problems.

Boosting takes the output of “weak” (i.e., only just better than chance) learners and combines them by using a majority voting method, except that the output of each learner is weighted according to how accurately they work. There are many different boosting algorithms available (for a summary, see, e.g., [35]) but the original adaptive boosting algorithm is AdaBoost, and it is still one of the most commonly used.

Figure 36.8 shows the fundamental idea of boosting, which is that a subtly different dataset is used for each iteration. For the initial classifier, the data points are all weighted equally, and a classifier is trained as normal. However, once it is trained, the weights are modified so that points that were classified incorrectly receive higher weights (and those that were classified correctly lower weights), and a new classifier is trained. In this way, each classifier concentrates particularly on those points that the previous one got wrong. Once training is completed (after a set number of iterations), the outputs of the individual classifiers are combined using a function of the same weights.

Boosting often produces very impressive results. It is functionally different to other learning algorithms in that the loss function that is computed is exponential rather than based on MSE:

$$L(\mathbf{y}, f(\mathbf{x})) = \exp(-\mathbf{y}_i f(\mathbf{x}_i)) \quad (36.16)$$

This means that the algorithm is estimating the probability of getting class 1 as output as a sigmoidal function. For further details, see [35].

The other ensemble algorithm that is increasingly popular is the random forest [3,7]. It is conceptually even simpler than boosting: a collection of n bootstrap samples (i.e., samples with replacement) of the training data are made, and a decision tree is trained on each sample. In order to further reduce the potential power of each tree, at each node only some subset of the potential features is searched among, with the subset chosen at random, but with the optimal selection made from that subset. After training, the output of the classifier is the most common prediction among all of the trained trees. Random forests are often reported to be among the most accurate classification methods and work relatively efficiently on large datasets.

FIGURE 36.8 Boosting works by combining the results of several classifiers, with the classifiers being trained successively. The data are weighted differently for the next classifier to be trained, with points that have previously been classified incorrectly receiving higher weight, shown as getting larger in this figure. (From Marsland, S., *Machine Learning: An Algorithmic Perspective*, CRC Press, Lakewood, NJ, 2009.)

36.4 Unsupervised Learning

Since, by definition, unsupervised learning algorithms do not have the targets that enable problem-specific function approximations to be found, they are rather more limited in what they can achieve. In this section, we will look at algorithms for dimensionality reduction and data clustering.

36.4.1 Dimensionality Reduction

As well as being a tool in its own right, dimensionality reduction is often used as a preprocessing step, before other machine learning algorithms (particularly supervised ones) are used. Underlying the idea of dimensionality reduction is the idea that the *intrinsic dimensionality* of a data manifold is typically substantially lower than that of the original data, which has confounding factors and noise included. For example, suppose that you have a dataset of photographs of one person's face, all taken front on. The only difference is where the face appears within the image, how large it is, and the angle that the head is at. Considering each pixel as a separate element for the input vector will give massively high-dimensional data (even if the images are only 100×100 pixels, this is still a 10,000 element vector). However, the possible variation in the data can be encoded by the changes that are allowed, which is 4D (two for translation in x and y , 1 for rotation, and one for scaling). Thus, the intrinsic dimensionality of the data is 4D rather than 10,000D.

Dimensionality reduction algorithms aim to minimize the reconstruction error of the original data based on a lower-dimensional representation of it, which provides a direct function to optimize. One of the most commonly used dimensionality reduction algorithms, *principal component analysis (PCA)*, selects a linear transformation of the original basis in such a way that the first direction chosen maximizes the variance, the next takes as much as possible of the remaining variance, and so on. In this way, the last few dimensions of the data will have very little variance and can thus be safely ignored [19]. The algorithm for PCA is based on computing eigenvalues and eigenvectors of the covariance matrix of the data.

A related method to PCA is *factor analysis*, which tries to find a smaller set of uncorrelated factors (also known as latent variables) that describe the data. The underlying hypothesis is that there is some unknown set of data sources from which the data are generated, and the method aims to find those. If the sources are assumed to be statistically independent instead of uncorrelated, then the method of *independent component analysis (ICA)* [17] is recovered. This is typically explained in terms of the "cocktail party problem," where even humans can struggle to distinguish the many different speakers and isolate one against the background noise.

All of these methods produce linear basis functions. This typically makes them unsuccessful when applied to data that is nonlinear. However, the use of kernels (as in Section 36.3.4) enables variations of the standard algorithms to be used on such data [36].

36.4.2 Clustering

The second common task in unsupervised learning is to cluster similar data points together, where similar in this case generally means close together in input space according to some distance metric (usually Euclidean distance). Nearest neighbor methods provide a relatively simple way to do this, with each data point in the test data being represented by the point that it is closest to in the training data. However, this is relatively inefficient in that because the training set needs to be large to ensure that enough samples are seen to be confident that the potential test data are covered, and there will often be many samples in the training set that are close together.

Exemplar-based methods attempt to fix this problem by choosing cluster centers that best represent the training data. A simple example is the k -means algorithm, where a predetermined number of cluster centers are positioned at random in the data space and then iteratively moved by being positioned at the

mean of a set of data points until they represent the data. The two issues with this approach are that it is hard to pick k appropriately without a lot of knowledge of the dataset and the approach is very subject to local minima, getting stuck in many suboptimal solutions.

The most commonly used algorithm for unsupervised learning of clusters is the *self-organizing map* of Kohonen [22], which has been used for a vast number of different tasks [21]. In this algorithm, a regular lattice of neurons have their weight vectors refined to move successively closer to inputs that they, or their neighbors, represent well. This leads to a *feature map* with nodes that represent similar features being spaced close together in the map space through self-organization.

Further Reading

This chapter has provided a very brief skim over some of the important methods of machine learning. Many of the most important methods of machine learning have been omitted or treated very superficially for reasons of lack of space. In particular, there has been no details of algorithms nor of any research on theoretical developments of machine learning. Examples of this theory include information geometry [2], probably approximately correct (PAC) learning [39], spline fitting [41], and the Vapnik–Chervonenkis dimension [40]. In addition, there is the rich area of model selection, including consideration of various information criteria and description lengths [9].

As well as the specialist books referred to in the text, there are several general textbooks on machine learning for a variety of audiences, from undergraduate students [1,12,26,29,42], to more advanced computer scientists [6,24,30], to statisticians [15]. In addition, there are a wide range of conferences and journals covering both theory and applications.

Glossary

- Bayesian network:** A form of graphical model based on directed acyclic graphs and conditional probability tables to represent the probability distribution of the whole graph.
- Bias–variance trade-off:** The two parts of the mean-square error, which means that machine learning algorithms can produce more accurate results only at the cost of more possible variation in result, largely through overfitting.
- Boosting:** An ensemble algorithm that combines the outputs of weak learners to make more accurate predictions.
- Classification:** A type of problem in machine learning where the output variable identifies which of a set of classes the data point belongs to.
- Decision boundary:** The line between classes in a classification problem.
- Decision tree:** An algorithm that classifies data by asking questions about different elements of the input vector sequentially.
- Dimensionality reduction:** A form of machine learning, often unsupervised, that tries to find lower dimensional representations of the data manifold.
- Evolutionary learning:** A form of machine learning that mimics evolution to find better solutions via stochastic search.
- Expectation–maximization:** An optimization algorithm in machine learning to estimate hidden parameters.
- Factor analysis:** A form of unsupervised learning where a set of hidden variables are estimated to represent the data, which is assumed to be noisy.
- Gaussian process:** A supervised learning algorithm that assumes that all random variables are Gaussian distributed.
- Graphical model:** A representation of machine learning algorithms where random variables are represented as nodes and edges between nodes show some form of conditional dependence.

- Hidden Markov model:** A graphical model that predicts sequences of hidden states from sets of observations based on two sets of probabilities: transition probabilities between the states and emission probabilities from the states to the observations.
- Independent component analysis:** A method of dimensionality reduction that creates a basis where all of the basis vectors are statistically independent.
- Linearly separable data:** Data that can be separated into different classes using a hyperplane (straight line in 2D).
- Loss function:** A function that computes the cost of getting values wrong.
- k -fold cross-validation:** A method of training several versions of the same learner on different subsets of the training data and using the one that is most successful.
- k -means:** An algorithm for unsupervised learning that represents each node by the nearest cluster center.
- k -nearest neighbors:** An algorithm that predicts outputs based on the k data points from the training set that are closest to the current input.
- Kernel:** The inner product in some space of a pair of data points.
- Markov network:** A form of graphical model where the edges are undirected.
- Maximum a posteriori:** The choice of class in a classification problem as the one with the highest posterior probability from Bayes' theorem.
- Multilayer perceptron:** A generalization of the perceptron neural network to have multiple layers of neurons, which can thus fit more complex decision boundaries.
- Naïve Bayes classifier:** A classifier that works by computing the maximum a posteriori estimate under the assumption that all of the features are statistically independent.
- Neural network:** Any of a set of machine learning algorithms based on a simple model of a neuron, with weighted connections between layers of such neurons.
- Novelty detection:** A form of machine learning where data are presented only for the normal classes, and anything not seen during training is highlighted as novel.
- Optimal separating hyperplane:** The hyperplane that separates data by maximizing the distance between the classes.
- Overfitting:** One cause of poor generalization in machine learning algorithms, where the model fits both the underlying model and the noise in the training data.
- Perceptron:** A linear neural network consisting of a layer of neurons that are connected to the inputs by a set of adaptive weights.
- Principal component analysis:** A method of dimensionality reduction where the coordinate axes are linearly transformed so that the first direction has maximal variation, the next direction next most maximal, and so on.
- Radial basis function:** A function whose output depends only on the radial distance to the point. It is possible to make a machine learning algorithm that linearly combines the outputs of such functions.
- Random forest:** A supervised learning algorithm that trains a large number of decision trees on different subsets of the data and combines their outputs to get a more accurate answer than any of them individually.
- Regression:** A problem where a dependent variable is predicted based on a set of input variables.
- Reinforcement learning:** A form of machine learning where the algorithm is told how well it has performed on the data but not how to improve.
- Self-organizing map:** An algorithm for unsupervised learning where the weights of neurons are updated to better represent inputs that are close to either than neuron or its neighbors.
- Supervised learning:** A form of machine learning where each item of training data has an associated target vector showing the correct answer and the aim is to generalize from these examples to all data.

Support vector machine: A machine learning algorithm that maximizes the separation of classes in the data to fit the optimal separating hyperplane.

Unsupervised learning: A form of machine learning where no target data are provided and the algorithm needs to exploit similarities between data points.

37.1 Introduction

The statistical approach to machine learning has been immensely successful. It often forms the foundation of other AI systems: for example, natural language processing, computer vision, image processing, data mining, intelligent search engines, recommender systems, and bioinformatics all owe much to statistical machine learning. Over the years, it has become apparent that this approach is improved with weaker prior models and greater reliance on data. This has led to the emergence of “big data” and the mantra “Let the data speak for themselves.” However, the amount of data required grows exponentially as the gap widens between weaker priors and more sophisticated concepts that require greater subtlety and complexity. Statistical machine learning seems to be reaching a plateau that is well short of human-level concept learning.

Modern explanation-based learning (EBL) addresses this issue by including an additional source of information: a general symbolic inferential domain theory. This domain theory often employs first-order representations that allow much greater expressiveness than the propositional (zeroth-order) expressiveness of statistical methods such as the Bayes or Markov networks. The domain theory can be approximate; it need not be complete, correct, or consistent in the sense required by conventional logic. In EBL, the domain theory serves as *analytic evidence* to complement the empirical statistical evidence of observed examples. EBL’s domain theory requires a new semantic interpretation to allow derived expressions to be treated as evidence rather than as truths or constraints on possible worlds. Because of its reliance on a prior domain theory, EBL is not as generally applicable as conventional statistical learning. However, with even modest prior domain knowledge, EBL can learn complex concepts more accurately, more confidently, and with far fewer examples.

The domain theory encodes general understanding discovered by others about the workings of the world. Imagine a conventional “big data” approach to training medical doctors. Instead of medical texts and classroom lectures, each student would be given a long string of specific examples. Each student would follow some idiosyncratic path, perhaps recapitulating the development of medical understanding but culminating finally in inventing his or her own version of the pathogenic theory of disease, physiology, pharmacological biochemistry, and so on. For both humans and computers, this would seem a tall order and unnecessarily complicated. When general prior knowledge of the world is already

FIGURE 37.1 Machine learners: statistical (a) choosing $c \in H$ based on the empirical evidence of Z , EBL and (b) choosing $c \in H$ based on both the empirical evidence of Z and the analytic evidence of Δ .

available, machine learners, like human learners, should be able to exploit it. Humans seem to learn complex concepts best using a combination of general facts together with a few illustrative examples. Modern EBL adopts this same learning style.

Learning systems (including EBL) can be applied in many paradigms including regression, semi-supervised, unsupervised, and reinforcement learning. Due to space limitations, this chapter focuses on the area of supervised classification learning. Here, a hypothesis space H is given to the learner along with a training set Z composed of examples and their training labels. The learner's task is to choose some concept $c \in H$ that best describes the pattern underlying Z . The concept sought is the one that most accurately classifies future similarly chosen examples.

Figure 37.1 illustrates a conventional statistical learner and an EBL learner. Both choose some hypothesis from the space H to output as the learned concept c . In statistical learning, this choice is based on the empirical evidence embodied by the training set Z . In EBL, the analytic evidence of the domain theory, Δ , is also used.

Modern EBL works by adding new features. These are features that the system believes will be useful in describing the underlying pattern. With such features, the desired pattern will be simpler and easier to find. The new features must be (1) inferable from the domain theory and (2) relevant to the current learning problem. Interaction between the domain theory and the training examples is crucial: a subset of training examples is selected and used to generate explanations from the domain theory. A number of explanations are constructed for the selected subset. Each explanation conjectures why the examples in the subset might merit their teacher-assigned class labels. Each explanation draws intermediate conclusions that are, in effect, new features, latent in the examples but derivable from the domain theory. Given a new example, the value of each feature is computed by a (generally nonlinear) function of the example's raw input features as dictated by the explanation.

A new augmented hypothesis space, Θ , is formed by adding these new derived features to the original raw features. A conventional statistical learner is then applied to the remaining training examples, those not in the subset used to generate explanations. These training examples are embellished with the new derived features, and the learner chooses the best hypothesis from the augmented hypothesis space, some $\theta \in \Theta$. By deriving more appropriate, higher-order features, EBL renders the pattern underlying the examples in the training set clearer and simpler, making this learning task much easier.

As a final step, the EBL system chooses a $c \in H$ that is closest in behavior to the selected θ . In θ , the EBL system has constructed an accurate description of the desired pattern. However, the description is expressed using the vocabulary of its own derived features. This form is not acceptable as an output.

The chosen $c \in H$ may be very complex even though the selected θ is simple. Note, however, that this step does not require labeled training examples. The complexity of c arises from the vocabulary mismatch between the raw input features and the more appropriate explanation-generated features. In a sense, the explanations act as a catalyst for the learner, providing a low-complexity path to an accurate high-complexity concept in H .

It may be of interest to note that this final step was neglected in early EBL systems. The oversight gave rise to what was known as the *utility problem*, attracting a good deal of research attention [13,21,22,41]. Researchers noticed that newly learned EBL concepts, although accurate, could reduce rather than

enhance the performance of the overall system. It is now clear that the utility problem is a consequence of losing control of the hypothesis space. The hypothesis space H specifies the set of acceptable outputs, often via a set of well-formedness constraints. The hypothesis space is an essential input for any machine learner (EBL or otherwise). But no such input was given to the old EBL systems; there was no guarantee that the resulting pattern was acceptable to the system utilizing the learned concept. Because hard satisfiability problems could be embedded in these unconstrained concepts, their use could be extraordinarily expensive. This could consume processing resources that might have been expended more productively elsewhere if the concept had not been learned. Two approaches were found to the utility problem. The first empirically estimates the cost of utilizing concepts, eliminating overly expensive ones. The second limits the expressiveness of the new concepts themselves to preclude in principle the possibility of expensive patterns. This third, theoretically sound, solution to the utility problem is simply to respect the hypothesis space, H . In practice, however, it can be convenient to employ one of the first two solutions.

The key in EBL is the part played by the domain theory. Modern EBL can be seen as quite similar to conventional statistical learning once the role of the domain theory is properly understood. To see this, consider an analogy between EBL and transfer learning [47] (also multitask learning [5] and domain adaptation [25,39], although with an equivocation on the term “domain”). A learner, after solving one learning problem, will be applied to a second related problem, perhaps followed by a third and fourth. Call the space of related problems a *domain*. Because the problems are related, it is possible to exploit their underlying similarity, utilizing earlier learning experiences to streamline later learning and avoiding the need to relearn the shared structure. Transfer learning is an important area of ongoing research in its own right.

Modern EBL takes this view a step further by generalizing across learners, particularly previous human learners. Instead of one learner encountering a sequence of related learning problems, there are many learners solving many problems from the domain. In this way, far more shared information can be acquired. But now the information must be communicated explicitly. In transfer learning, a single learner builds on its own representations. But different learners cannot be relied on to understand the internal representations of others. Some communication mechanism is required. This is the role of the domain theory. With this newly posited communicative ability, a learner derives the benefit without the need to experience the plethora of previous learning problems or view for itself the myriad of training examples. Rather, it capitalizes on the accumulated knowledge accrued by many other learners. For EBL, the previous learners are humans. They not only solve problems but think about them, postulating and testing new general theories. Importantly, EBL does not attempt to invent such theories. Its goal is the much more modest task of exploiting the understanding developed by others. In so doing, it avoids the difficulty and expense of reinvention.

Thus, the EBL domain theory is seen as a communication medium used by a learner to benefit from the experiences of many other learners that have previously solved many related problems over possibly many generations. The domain theory itself is seen as a cleverly condensed, codified, general summary of the information inherent in an untold number of previous experiences and training examples. Several important properties follow from this view of a domain theory:

- The representation must be sufficiently expressive to capture abstract conceptual domain commonalities. Its function is to highlight significant abstract nonlinearities within the domain. Simple patterns (e.g., linear ones) can be easily recovered via conventional statistical analysis, so their inclusion in a domain theory is of limited value. A good domain theory focuses on subtle, nonlinear, and higher-order covariate structures. This dictates the need for some kind of quantification such as first-order representations. Propositional representations are insufficient.
- The EBL domain theory captures *utility* rather than *correctness* or *truth* as in conventional logic. Like the massive collection of training examples that it summarizes, the EBL domain theory is inherently incomplete and approximate. This dictates the need for a new semantics quite different from the popular “constraints on interpretations of possible worlds” of conventional logic. There can be no notion of a *correct* or *true* domain theory. It follows that analytic inference over the domain theory must be rooted in optimization, rather than satisfiability as used in logic.

- The purpose of the domain theory is to communicate or encode important conceptual distinctions. The better the domain theory, the better this encoding. Better coding schemes are ones that make more important items more easily accessible. Thus, a better domain theory makes its more useful distinctions easier to derive.
- In EBL, a feature's derivational complexity (i.e., the minimal inferential effort sufficient for its construction) provides information on its prior expected utility. This is taken as one definition of a domain theory for EBL:

An EBL domain theory is an inferential mechanism that supports the generation of latent features in which the inverse of derivational complexity encodes expected utility over the space of problems that defines the domain.

37.2 Underlying Principles

Due to space limitations, the principles in this section remain somewhat abstract. Illustrative examples will be given in the next section. It is convenient to consider Δ as following the syntax of first-order logic. Readers unfamiliar with the terms *first-order logic*, *quantification*, *symbolic inference*, *derivation*, *interpretation*, and *possible world semantics* may wish to consult a suitable tutorial such as [18,52]. It is not necessary to assume first-order syntax; Δ may be an ad hoc mechanism. Compared to conventional logic, there are two important generalizations and one restriction. The generalizations are as follows: (1) The initial statements (analogs of the axiom set) need not be correct or consistent. By allowing approximations, the domain expert's task of rendering his understanding of the world can be greatly simplified. (2) With little additional penalty, Δ may employ higher-order statements. This is in contrast to conventional logic where including even second-order statements result in the undecidability of most of the interesting questions (such as theoremhood).

The new restriction is that the combining rule must be *paraconsistent* [49]. This avoids explosiveness (known as ECQ for *ex contradictione quodlibet*, from a contradiction everything follows). It is easy to see, for example, that if a refutational inference system is given initial statements that are only approximate, it will likely be able to prove anything. Many contradictions will arise from interactions among approximate statements. Refutational inference can succeed simply by finding one of these contradictions, independent of the negated goal. The phenomenon is not restricted to refutational systems, and the general solution is paraconsistency.

A conventional statistical learner can be viewed as searching for c^+ , the most likely hypothesis in H given the training data Z :

$$c^+ \approx \operatorname{argmax}_{h \in H} \Pr(h|Z, H) \quad (37.1)$$

Generally, finding the true *argmax* is intractable. The symbol “ \approx ” is used in place of “=” to denote that it is sufficient for an implemented learner to find a c^+ that with high confidence is a low-loss approximation to the *argmax* expression. Note that the probability of a particular h given Z is independent of the other hypotheses in H . That is, Z is conditionally independent of H given h . Along with Bayes theorem and the fact that the parameter h does not appear in $\Pr(Z)$, it follows that

$$c^+ \approx \operatorname{argmax}_{h \in H} \Pr(Z|h) \cdot \Pr(h|H) \quad (37.2)$$

where

H is the hypothesis space

Z is a set of examples $\{x_i\}$, drawn independently from some example space X , together with the training label of each

The training labels $\{y_i\}$ are assigned by some true world concept c^* that may be stochastic and in general is not in H .

Expression 37.2 seeks to maximize the likelihood of the training data subject to the probability of h given H . This second factor, $Pr(h|H)$, does not depend on any training examples so with respect to Z it is a prior. It assigns low probability to hypotheses in H that are unlikely. Computationally, it is often treated simply as a regularizer that penalizes overly complex or overly expressive hypotheses. Its role is essential; it prevents overfitting to the training set.

Care must be taken in interpreting the probabilities. In Expression 37.1, for example, $Pr(h|Z,H)$ is *not* the probability given Z and H that h actually *might be* the target concept c^* . In interesting learning problems, c^* is never in H . The patterns embodied by the real world are infinitely subtle and complex. In machine learning, the hypothesis space is chosen to balance expressiveness on the one hand and tractability on the other. It must be sufficiently rich that some element is a good approximation of c^* . Only in simple and artificially clean domains can $c^* \in H$ be legitimately assumed.

By contrast to Expression 37.1, an EBL learner searches for c^+ :

$$c^+ \approx \operatorname{argmax}_{h \in H} Pr(h|Z,H,\Delta)$$

which includes the domain theory, Δ , as an additional source of evidence. Since Z is conditionally independent of both H and Δ given h , it follows that

$$c^+ \approx \operatorname{argmax}_{h \in H} Pr(Z|h) \cdot Pr(h|H,\Delta)$$

This is Expression 37.2 adjusted to appreciate the domain theory in the choice of $h \in H$. Rather than influencing h directly, modern EBL employs the domain theory to transform the hypothesis space H into a more effective one, Θ . The domain theory encodes useful expert-supplied distinctions. These distinctions form new features derivable from Δ . Given a subset Φ of these new features (the ones that are likely to be useful for the problem at hand), an enhanced hypothesis space is formed by allowing Φ to participate on equal footing with the original raw features used in H . Let $\Theta(\Phi)$ denote the new hypothesis space enriched with the feature set Φ . An EBL system approximates the underlying pattern by choosing some $\theta^+ \in \Theta(\Phi)$:

$$\theta^+ \approx \operatorname{argmax}_{\theta \in \Theta(\Phi)} Pr(Z|\theta) \cdot Pr(\theta|\Theta(\Phi)) \quad (37.3)$$

This is just Expression 37.2 substituting $\Theta(\Phi)$ for H ; $Pr(\theta|\Theta(\Phi))$ is the prior (or regularizer). Expression 37.3 can be realized by a conventional statistical learner once $\Theta(\Phi)$ is defined. While θ^+ may describe the underlying pattern accurately, it is expressed in the vocabulary of the derived features. These are not included in H . Thus, once θ^+ is found, the EBL system chooses some $c^+ \in H$ as an acceptable output:

$$c^+ \approx \operatorname{argmin}_{h \in H} \|h - \theta^+\| \quad (37.4)$$

All three concepts, θ^+ from Θ (Expression 37.3) and both c^+ 's from H (Expressions 37.2 and 37.4), approximate the same underlying pattern.

But θ^+ does so using Φ . With a good domain theory and the right selection of derived features, Θ employs a much richer and more focused vocabulary. The underlying pattern will be clearer and its representation simpler.

Generally, θ^+ will be syntactically the simplest. Next simplest will be c^+ from Expression 37.2 because the choice is regularized by $Pr(h|H)$. The c^+ from Expression 37.4 may be quite complex. It may be well

beyond the reach of a statistical learner based on the evidence in Z alone. In EBL, regularization has already stabilized the choice of θ^+ in Expression 37.3; direct regularization in H is less of an issue. This underlies EBL's ability to confidently learn complex concepts in an example-efficient manner.

In practice, step (37.4) may be omitted in favor of either classical "utility problem" solution outlined in the previous section. This can be more convenient than the earlier theoretically sound approach, particularly if H is a feature-neutral well-formedness rule. For example, H might employ a linear separator or a Gaussian kernel using all of the example's features without caring what the features actually are. Then θ^+ itself may be returned in place of c^+ . But in this case, each new example to be classified must first be explicitly embellished with the new derived features so that the classifier can be properly evaluated.

Let Φ^+ denote the set of derived features sought by EBL. This is the set that yields the best concept from the new hypothesis space. The choice of the feature set is regularized by the derivational complexity of the set, $Pr(\Phi|\Delta)$. The domain theory's analytic evidence for the set balances the empirical fit of Expression 37.3:

$$\Phi^+ \approx \operatorname{argmax}_{\Phi \in 2^\Delta} \left(Pr(\Phi|\Delta) \cdot \max_{\theta \in \Theta(\Phi)} [Pr(Z|\theta) \cdot Pr(\theta|\Theta(\Phi))] \right) \quad (37.5)$$

Note the approximation; it is not necessary to guarantee that an optimal feature set is found. However, even finding an approximation by directly applying Expression 37.5 would be intractable. Expression 37.5 optimizes over the power set of Δ 's derivable expressions which itself may be unboundedly large.

The key is to employ explanations. An explanation for a set of training examples is any derivation from Δ that satisfactorily labels the set of examples. In EBL, a small random subset $Z_E \subset Z$ is selected to guide explanation construction. Guiding explanation construction is similar to classical EBL: a candidate explanation that is unsatisfactory will mislabel some examples. The features of these examples in the light of Δ show the relevant ways that the explanation may be amended; see [4,10,36].

An explanation has the form of a proof tree in a logical deduction. It exposes internal structure and intermediate conclusions, although, of course, now the result is conjectured rather than entailed. Procedurally also, there is a parallel between an EBL domain theory and a theorem prover of conventional logic: (1) Δ is a deterministic inferential system consisting of an inference engine and a number of expert-supplied expressions describing world behavior (the axioms of a conventional system). (2) The inference engine, as with conventional logic, derives new expressions following a prescribed matching and combining process. (3) Also as in conventional logic, Δ can be viewed formally as a finite representation denoting a possibly infinite number of derivable structures.

In EBL, several explanations are generated that cover the subset Z_E . The derived feature set, Φ^+ , is the union of derived features from the explanations. An enhanced hypothesis space, $\Theta(\Phi^+)$, is formed that includes these new features. The remaining training examples, $Z_C \equiv Z - Z_E$, are employed conventionally to choose a hypothesis from this augmented hypothesis space:

$$\theta^+ \approx \operatorname{argmax}_{\theta \in \Theta(\Phi^+)} Pr(Z_C|\theta) \cdot Pr(\theta|\Theta(\Phi^+)) \quad (37.6)$$

How are derived features formed from an explanation? The process starts with the intermediate conclusions (subgoals) that arise in deriving the explanation from Δ . Each intermediate conclusion is a predicate, possibly with arguments. The explanation specifies how the predicate and its arguments are evaluated and the role they play in concluding the classification label. For each predicate and each argument, a new feature is defined. Each predicate and argument is itself derivable from the domain theory. Each is rooted in the example's raw features, and each concludes a property deemed by the explanation to be important in assigning the class label. For each new feature, there is a feature function that follows the dictates of the explanation. When given an example, it computes the feature's value from the example's raw input features.

Thus, explanations sidestep the intractable maximization of Expression 37.5. While features are derivable from Δ , they are not derived directly. Rather explanations are derived, guided by training examples, and the features are extracted from the explanations. Explanation construction must satisfy two requirements:

1. Efficiency demands that only a few explanations be constructed.
2. Accuracy requires that the expected quality of these explanations be high.

A new semantics for Δ is the most important advance in modern EBL and allows these requirements to be met. Unlike conventional logic, the EBL inferential system denotes a *sequence*, rather than a *set*. The ordering of the derivations is by increasing derivational complexity (defined to be the minimal inferential effort sufficient for its derivation). Thus, Δ is viewed formally as the generative denotation of a possibly infinite sequence of derivations:

$$\Delta \equiv (\xi_1, \xi_2, \xi_3 \dots \xi_{521}, \xi_{522}, \xi_{523}, \xi_{524} \dots \xi_{3,671,495}, \xi_{3,671,496} \dots) \tag{37.7}$$

This apparently small change has far-reaching consequences. Each derivation is associated with some derivational complexity. Derivations with lower complexity appear earlier in the sequence, so the inverse of derivational complexity is a measure of how easily an element of Δ can be derived. This measure induces a probability distribution over Δ with

$$Pr(\xi_1|\Delta) \geq Pr(\xi_2|\Delta) \geq Pr(\xi_3|\Delta) \geq \dots$$

Consider the full distribution, $Pr(\Xi|\Delta)$, Δ 's analytic prior over derivations. What is the nature of this distribution? By definition, Δ embodies a coding scheme that communicates the expert's conceptual understanding of the domain. It follows that $Pr(\Xi|\Delta)$ is the optimal distribution associated with the code words (derivations of Sequence 37.7). Therefore, from coding theory,

$$\log Pr(\xi_i|\Delta) = -\mathcal{D}(\xi_i)$$

where $\mathcal{D}(\xi)$ denotes the derivational complexity of ξ . Let δ be the average difference in derivational complexity between adjacent ξ_i 's over Expression 37.7. Note that δ is an intrinsic property of Δ so that $\delta = \delta(\Delta)$. Knowing nothing more about Δ , the best estimate of the derivational complexity of the i 'th ξ is

$$\mathcal{D}(\xi_i) = \delta \cdot i \text{ which (from earlier) is also } -\log Pr(\xi_i|\Delta)$$

This yields a prior probability over the ξ 's given Δ of the form

$$Pr(\xi_i|\Delta) = \gamma \cdot d^i \tag{37.8}$$

where

d is a more convenient parameter than δ : ($d \equiv e^{-\delta}$)

γ is a normalizing constant

This is precisely a geometric distribution with traditional parameter $(1 - d)$. It is a discrete distribution with exponentially decaying probabilities, each multiplied by an additional factor of $(1 - d)$. The normalizing constant γ is d , and $0 < d < 1$.

Figure 37.2 shows distributions for different Δ 's with d 's of 0.6, 0.8, and 0.9. As d approaches 1, Δ behaves more like a conventional logic. In the limit as $d \rightarrow 1$, there is no erosion of confidence in Δ 's inferences: Every derivation is firmly believed; the ordering of the sequence carries no information; and the EBL system becomes a conventional logic. It would then inherit all of logic's brittleness: the statements are axiomatic constraints on possible worlds. To work, they must be carefully engineered to avoid unintended pernicious interactions.

FIGURE 37.2 Three prior distributions over derivations for values 0.6, 0.8, and 0.9 of the domain theory property d .

Conversely, as d decreases toward 0, the EBL system behaves more like a conventional statistical learner. In the limit as $d \rightarrow 0$, each hypothesis stands on its own, and there is no benefit to shorter derivations. The domain theory provides no useful information and cannot serve as analytic evidence.

Now consider what happens as a particular EBL system begins to generate explanations for Z_E , the chosen subset of training examples. Suppose Δ has d of 0.8. Let the first successful explanation of Z_E be ξ_k (the k th derivation in Expression 37.7). The previous $k - 1$ derivations originally merited the highest probability (highest in the prior for $d = 0.8$ as shown in Figure 37.2). But since these derivations cannot explain the training subset Z_E , the explanation generator does not return them.

Finding the first explanation for Z_E at ξ_k changes the distribution considerably. Let $Pr(\Xi | \Delta, Z_E)$ denote the posterior distribution over the derivable expressions after the first explanation has been generated that covers Z_E . It follows that the first $k - 1$ derivations cannot cover Z_E , and their posterior falls to 0.

The prior and the posterior for this state of affairs are shown in Figure 37.3. At this point, only the first explanation (the k th derivation in Expression 37.7) is constructed. It is illustrated as the leftmost, tallest

FIGURE 37.3 The prior distribution over derivations for $d = 0.8$, and the posterior distribution given the first explanation is the k th derivation; the explanations that cover the subset of training examples Z_E are shown as gray bars.

vertical gray bar. The other explanations that would cover Z_E if they were constructed are also illustrated as vertical gray bars. The height of each bar indicates its posterior probability.

The posterior distribution $Pr(\Xi|\Delta, Z_E)$ is simply a shifted version of the original $Pr(\Xi|\Delta)$. The change from prior to posterior can be considerable. Clearly, the KL divergence [8] from the prior to the posterior in Figure 37.3 is large. Thus, the information contained in Z_E can be quite large even though the size of Z_E may be quite small (it may even contain just one example). But unlocking this information requires Δ and, of course, sufficient processing resources to construct the first explanation. With these, EBL greatly magnifies the information content of the training examples.

The EBL procedure satisfies the two requirements mentioned earlier: the features with high expected utility are likely to be constructed from just a few of the least expensive explanations covering Z_E . These few explanations, while similar in cost, may conjecture quite different justifications. Each contributes to the set of derived features. As will be illustrated with implementations in Section 37.3, the classifier may ultimately employ relatively few derived features.

Let $\Phi(\Delta, Z_E)$ be the features added from the first few successful explanations of Z_E . Then $\Theta(\Phi(\Delta, Z_E))$ is the resulting enhanced hypothesis space. Expression 37.6 becomes

$$\theta^+ \approx \operatorname{argmax}_{\theta \in \Theta(\Phi(\Delta, Z_E))} Pr(Z_C|\theta) \cdot Pr(\theta|\Theta(\Phi(\Delta, Z_E))) \quad (37.9)$$

Thus, the EBL procedure, following Expressions 37.4 and 37.9, is as follows:

1. Employ some of the training examples, Z_E , to construct several explanations, $\{\xi_j\}$.
2. Extract features from the explanations, $\Phi(\Delta, Z_E)$, and assemble them into an extended hypothesis space, $\Theta(\Phi(\Delta, Z_E))$.
3. Use the rest of the training examples, Z_C , to choose a concept from the enhanced space, $\theta^+ \in \Theta(\Phi(\Delta, Z_E))$.
4. Choose a concept from the original space $c^+ \in H$ closest to the enhanced concept, θ^+ .

37.3 Practice

The roots of EBL can be traced back a long way. But its formalization is still emerging. The motivation of EBL is to exploit general prior knowledge. Two early AI works served as inspirations for the development of this view. These were the MACROPS learning of the STRIPS system [15] and the notion of goal regression [58]. An important conceptual step was the explicit recognition of the role of *explanation* (i.e., building a structure justifying an unobserved feature of interest such as a class label) [9,43,53]. Seminal papers [11,42] sparked an explosion of interest in EBL.

In modern EBL, the construction of features from an explanation employs similar processing to that of classical EBL [28,44]. But in classical EBL, the acquired fully formed concept was the preserved portion of the explanation, from the “operational” predicates up to the class label conclusion. In modern EBL, there is no operability criterion; all internal conclusions are used. Furthermore, the important portions of the explanation are from the raw feature leaves up to the internal conclusions. Modern EBL explanations serve to generate features, not the fully formed concept of classical EBL. Several aspects of modern EBL are shared with earlier EBL systems. Multiple explanations were explored in [7,17]. The use of an embedded statistical learner can be seen as a generalization of the research combining EBL with neural networks [56,57].

More recently, EBL has been applied to AI and machine learning problems such as structured prediction [34,36], planning [16,32,26], natural language processing [35], vision and image processing [33,34,38,46], and as a component in larger systems such as [60].

Two implementations illustrate the important EBL principles of the previous sections. The first [33] learns to distinguish ketch from schooner sailing ships in the Pascal VOC data set [14]. It shows how

FIGURE 37.4 (a) Three ketches and (b) three schooners. The EBL-augmented representations are below the raw image representations. Dots denote the highest point and center of geometry. The inferred hull and sail labels are shown light and dark pixels respectively; water and background labels are omitted.

explanation-generated features, although quite approximate, can yield an accurate classifier. The second [59] learns to distinguish similar handwritten Chinese characters. It illustrates feature generation from the interaction of domain theory distinctions and training examples. It also illustrates the ability to grow or shrink the structural complexity of the classifier in response to the difficulty of the particular learning problem.

Both systems employ the acquired EBL feature functions as “virtual sensors.” These satisfy the analytic approach to the utility problem as in [13]. In applying the learned concept, these virtual sensors embellish the new example to be classified with derived features.

Consider the right-facing sailing ships in Figure 37.4. The top row shows ketches (Figure 37.4a) and schooners (Figure 37.4b). It is not easy to tell a ketch from a schooner. The key is that the foremast of ketches is taller while in schooners the aft mast is taller. The behavior of an EBL system is compared with two conventional statistical learners.

Figure 37.5 shows learning curves for the three systems. These are error rates on a withheld test set after training on an increasing numbers of examples. The EBL system significantly outperforms the others. The conventional statistical learners are the two top lines. The better conventional learner achieves an error rate of 30% after training on 30 examples. The EBL system is shown as a dashed line with circle markers. It achieves a 21% error rate after 5 training examples and 17% after 30. On the same test images, after being told how to distinguish ketches from schooners, humans turned in an error rate of 11%. This is shown as the bottom horizontal dotted line. The human error rate reflects the relatively poor quality of the VOC data set itself. Several images are misclassified, some are framed so that the top of the masts are beyond the top of the image, and a number of images are neither ketches nor schooners but single-mast sloops.

FIGURE 37.5 Ketch vs. schooner learning curves: two conventional learners (diamond and square), the EBL learner (circle), and human performance (horizontal dotted line).

There is no accurate concept within the scope of the conventional systems. It is easy to see why. The conventional state-of-the-art systems extract code words (clustered local patches of pixels) from the training images [37] without regard to class. Two distributions over the code words are constructed. One is the distribution imposed by ketch training images and the other by schooners. Given a new unlabeled image, code words are again extracted from it. The distribution of its code words fits one of the training distributions better than the other and the image is assigned the corresponding label.

Why is this task challenging? The ketch/schooner signal to noise ratio is very low: relatively few pixels encode the class information. Furthermore, those pixels occur in small functionally defined regions that do not correspond to any particular image location. Even worse, they exhibit only high-order systematic covariate structure. The conventional systems perform better than chance only because ketches tend to be used nearer the shore and this results in somewhat different distribution of background pixels. Statistics over code words expose this distinction quite easily. But, as can be seen, their learning rates flatten. Adding many more training examples would serve only to improve the confidence in the sea-to-shore distribution. The ketch/schooner accuracy would not improve much.

Rather than the whole image, the EBL system tries to model distributions for expected conceptual constituents of the ships. These intermediate concepts are introduced by the domain theory: water, hull, sails, and background. It also specifies ways to compute properties of regions such as height, width, and centroid and their geometric relations: above, below, left, right. The chosen EBL classifier employs several derived features: the joint model of the hull and sails, the sail center of geometry, and the highest point of the sails. The learned classifier is as follows: the ketch (schooner) has a sail center of geometry left of (right of) the highest point of the sail. The relevant derived features are shown in Figure 37.4. These include the pixels corresponding to sails (darker gray), the pixels corresponding to the hull (lighter gray), and black dots to indicate the center of geometry and the highest point of the sails. Simpler, more straightforward competitors, such as comparing the positions of the highest sail points, do not perform well. It might at first seem that modeling the hull is an unnecessary complication. But the hull turns out to be more distinctive than the sails that, without the hull, are often confused with sky and clouds.

Of particular note in Figure 37.4 is the relatively poor correspondence between the explained images (lower rows) and the original images (upper rows). This illustrates the power and robustness of combining the analytic and empirical information. One might hope for a more accurate internal representation, modeling, for example, the sails more faithfully. But accuracy has a price in terms of computational efficiency and (especially) in terms of robustness. Accurate sail identification would require a feature function that is much more subtle, derivationally much more complex, and computationally much more expensive. Conventional logic requires such an accurate representation. The brittleness inherent in conventional logic is avoided in EBL precisely because of this “good enough” modeling. Features are constructed so as to be minimally sufficient for their downstream purpose.

A second system applies EBL to the problem of distinguishing offline handwritten Chinese characters. Offline means that the input is a pixel image of the drawn glyph. This is contrasted with online processing in which captured stylus information (such as position, velocity, and acceleration) is available via a touch-sensitive pad. Offline processing is significantly more difficult.

Chinese characters are more complex than digits or Latin characters; each is composed from a few to a few dozen strokes. Because there are 10–20,000 common characters, training data are much more limited. Available databases contain a few tens to a few hundred handwritten examples of each character, compared to the tens of thousands of training images available for handwritten digits and Latin characters. These conditions challenge even the best machine learning algorithms.

A space of binary classification problems can be defined by selecting two Chinese characters to distinguish. This generates problems of widely varying difficulty. Most characters are quite different from each other, resulting in relatively easy problems. But many characters have one or more very similar counterparts. These form extremely challenging classification problems, particularly given the paucity of training

FIGURE 37.6 A printed and four handwritten examples of two similar Chinese characters.

examples and the diversity of writing styles. Figure 37.6 illustrates one such difficult classification problem. The top and bottom rows show two different characters; the left column is the printed glyph, the remaining columns show each character drawn by four different writers. It is clear that the noise induced by the different writing styles is large compared to the systematic class difference between the characters.

Research on handwritten Chinese characters has a long history [24,55]. For Chinese characters, as in most statistical classification problems, the first step in state-of-the-art processing is dimensionality reduction. One of the most effective specialized feature sets is known as WDH (for weighted directional histograms) originally from [30]. First, the image is normalized and then the thousands of pixel features are compressed into several hundred parameters encoding discretized local edge gradients.

The present experiment compares the behavior of an EBL system with a support vector machine (SVM). Chinese characters are input to the SVM as WDH features. The SVM employs a radial basis kernel that preliminary experiments indicate outperforms other standard kernels.

By contrast, the EBL system inputs characters as raw image pixels. Its underlying statistical learner is also an SVM employing a radial basis kernel, but its SVM is applied to a small chosen region rather than the entire character image. Explanation-derived features define this expected high-information region. The domain theory specifies that characters are composed of strokes and that the observable features (the raw input pixels) arise from these strokes. Strokes are modeled (quite imperfectly) as long thin rectangles. Input pixels are “explained” by these rectangular strokes. The domain theory also includes an “ideal” stroke representation for each character class (i.e., a single printed character of the class similar to that of a vector font but composed of the simple rectangular strokes) and the ability to compute WDH features of an image region.

The derived features are problem-specific configurations of strokes. These features are not mentioned explicitly in the domain theory but are constructed automatically during the learning process. Given a different learning problem (i.e., a different pair of difficult characters), quite different features will be constructed.

The features form a sequence. Each feature is evaluated from the image pixels together with the values of sequentially earlier features. The value of a feature is the set of parameters that optimize the local fit of its stroke configuration in the image. The explanation conjectures that with high confidence, each feature function in the sequence can be fit to the image sufficiently accurately to support the next feature function, and that the final target region contains sufficient discriminative evidence to classify the image.

Figure 37.7 illustrates the feature sequence applied to two test instances from a particular difficult-to-distinguish pair of Chinese characters. The first column shows handwritten instances of the two characters. The top row, left to right, shows the sequence of, in this case, five derived features. Each is an expected configuration of idealized (rectangular) strokes. Strokes from the structure common to both characters are black; class-discriminative strokes are reduced in intensity and appear gray.

The value of each feature is the result of an optimization. It is the vector of affine transformation parameters that locally optimizes the fit of the stroke configuration to the pixel image. Sequentially previous values (best fits of earlier features) are used to initialize the optimization search. The correctness of each feature evaluation is contingent on the correctness of earlier feature evaluations. Each must be initialized to within some basin of attraction around the optimal value (a small locally convex optimization region).

The rows of Figure 37.7 directly below the derived features show the application of each feature to each test image. Its value, the optimized affine parameters, is illustrated by superimposing the transformed

FIGURE 37.7 Application of the learned classifier to instances of a difficult pair showing the intermediate features applied. Left: the handwritten characters; top: the constructed intermediate features; and right: the normalized discriminative feature region given to the SVM.

feature strokes onto the original image. At each step, the feature is initialized at the location predicted by the previous feature values. Then, using the feature-to-pixel fit as a gradient, the locally optimal affine transformation parameters are found. The vector of optimized parameters is the value of the feature.

As can be seen, the first feature is the average full character rendered with rectangular strokes. In this and other features, the gray class-discriminative strokes have less effect on the optimizer because of their diminished intensity. There are no previous steps; the feature is initialized to the global expected location over the training set. The basin of attraction of the feature is large since the feature includes all of the strokes. However, it is clear that the best affine fit is poor for both images. This is due to the limited flexibility afforded by an affine transformation. The fit is far too poor to reliably test for the class-discriminative stroke, but it is sufficient to initialize the second feature, consisting of five strokes, to its basin of attraction, and so on.

Each feature fulfills a role. The roles are (1) to provide information about the target window (the fifth feature performs this role), (2) to provide improved initialization for a downstream features (this is the role of the first and third features), and (3) to expand the basin of attraction of downstream features by matching and thereby removing from later gradient computations, some pixels that empirically proved distracting to the optimizer (the second and fourth features fulfill this role).

The final target region is bounded by the four common strokes of feature five. The region is normalized to a square. The result is treated conventionally: WDH features are computed on this square region and given to the RBF SVM for final classification. The normalized region for each image is shown in the rightmost column of Figure 37.7. The identification of the discriminative window is far from perfect, but it is sufficient for a large margin classifier to detect, in this case, the predominance of horizontal WDH features. Details of the system can be found in [59].

The EBL system significantly improves performance over the state-of-the-art WDH RBF SVM. The average error rate over the ten hardest-to-distinguish pairs is improved by 20%. This is particularly significant since this EBL system is only equipped to consider a single difference. An obvious refinement would be to explain multiple differences. The conventional state-of-the-art classifier, by taking a dot product with support WDH images, integrates all differences over the entire character image. While on average the EBL system outperforms the conventional statistical classifier, one exception is illustrated in the left pair of Figure 37.8. Here the RBF SVM with WDH features achieves an error rate of 15.8%, while

FIGURE 37.8 The performance of EBL compared to the state of the art is (left) slightly worse, (center) significantly better, and (right) better than human native Chinese readers.

the EBL system makes 17.3% errors. This is likely due to the existence of multiple systematic differences between the characters; the left radical is both taller and contains an additional horizontal stroke. On the other hand, the center pair of Figure 37.8 shows a significant success of EBL. Here the state-of-the-art learner achieves an error rate of 9.0%, while the EBL system's error rate is 1.6%. The right pair is also interesting. For this pair, the EBL system outperforms human native Chinese readers tasked with distinguishing the two characters in a controlled setting. The state-of-the-art statistical system achieves an error rate of 7.8%, humans turn in an error rate of 6.4%, while the EBL system achieves 4.0% errors. This is one of the more complex characters. Native Chinese readers find the pair to be quite challenging to distinguish in isolation.

37.4 Research Issues

The EBL presented in this chapter represents a significant advance over previous formalisms (e.g., [50]). But it is only the most recent snapshot in a long evolutionary path. Much work remains to be done.

First and foremost is the question of codifying domain theories. Implications for the novel semantics of prior knowledge are far reaching and not yet fully understood. While the syntax of first-order logic is standard and familiar, it evolved to fill a very different need than EBL. Because it is widely known, first-order logic is convenient for defining and analyzing EBL but it seems not to be the representation of choice for practical implementations. Most successful modern EBL systems, including the two discussed in Section 37.3, employ ad hoc inference systems. A more appropriate general representation scheme may emerge from experience with more domains.

Another important need is in the development of a more sophisticated model of analytic uncertainty. In the current presentation, derivational complexity is the measure of confidence. The development of a more refined measure is needed. Some first steps are clear. Information on trustworthiness is encoded within an explanation's internal structure. Consider again the deficiencies of conventional logic. The root cause of logic's brittleness in AI applications is the interaction between its semantics (based on satisfiability) and the qualification problem [40]. The semantics dictates that adopting its axioms means believing just as strongly all of the implications of the axioms. Unintended conclusions arise from any imprecisions or approximations in the statement of the axioms. In conventional logic, if one believes "cars move" and also that "buried things do not move," then one is equally committed to believing that "cars cannot be buried." The qualification problem states that general (universally quantified) statements intended to describe the real world can at best be approximations. One might hope to amend the axioms in order to eliminate such approximations. But the qualification problem assures us that this is impossible. For example, "birds fly" might be rendered as

$$\forall x \text{ Bird}(x) \Rightarrow \text{Flies}(x) \quad (37.10)$$

But there are obvious exceptions such as penguins and emus. Expression 37.10 can be easily amended with the known flightless birds. Unfortunately, there are always more exceptions such as cooked Thanksgiving turkeys and birds with their flight feathers clipped. Merely adding more antecedent conditions (qualifications) fails for two reasons: (1) additional (increasingly bizarre but very clear) exceptions continue to arise (birds with their feet cast in cement) and (2) the inference system becomes paralyzed by the need to entertain and defeat a myriad of unlikely but logically necessary conditions.

Let $\{\Gamma_i\}$ be the set of initial statements of EBL's Δ . Perhaps Γ_1 is Expression 37.10, Γ_2 might be a representation of "Penguins do not fly," Γ_3 "Penguins are birds," etc. These are not acceptable in conventional logic as they admit no possible worlds (the set is self-inconsistent). But in an EBL framework, "believed" means something different. To investigate this difference, consider how representations of Δ might be converted to their "closest" logical counterparts:

$$\text{Each } \Gamma_i \text{ must be replaced with } \alpha_i \Rightarrow \Gamma_i$$

where each α_i denotes the weakest sufficient condition that guarantees the truth of the corresponding Γ_i . So α_i would represent “ x is not a penguin nor is it an emu nor...nor is it cooked nor is its feet cast in any cement block nor...” It rules out every possible exception to Expression 37.10, including all the bizarre ones. The difference with conventional logic is that in EBL these α 's are implicit; they are not represented nor are they reasoned about. Their truth conditions are subtle, depending both on their context within the explanation and on the distribution of examples that will be seen. This dynamic semantics sets EBL apart from past approaches for combining logic and statistics. See [12,19,23,29]. Perhaps the closest in spirit is [29]. Since these α_i 's are not reasoned about, their probabilities of holding may be modeled as independent of each other. So an explanation composed of the set of statements $\{\Gamma_i\}$ holds with probability

$$\prod_i Pr(\alpha_i)$$

Like Expression 37.8, this yields an exponentially decaying probability over derivations. Estimates of the $Pr(\alpha_i)$'s (although not the α_i 's themselves) may be updated as experience with Δ accrues.

Experience may also be helpful to EBL in exploring more expressive domain theories, such as those with second-order statements. First-order logic represents an attractive trade-off between expressiveness and computability for logic. But the trade-off is quite different for EBL. The undecidability of higher-order logic asserts that no effective procedure can exist that reliably determines whether or not an expression is a theorem. But some, perhaps many, such determinations may be possible. These are precisely the ones with tractable derivations. An undecidable question may not halt. But failing to halt incurs infinite derivational complexity. These are implicitly ignored by an EBL system that constructs explanations in order of Expression 37.7. Furthermore, some higher-order statements can be quite useful. For example, the statement of the qualification problem is itself a higher-order statement. Humans are not paralyzed by such statements so clearly some inferential systems tolerate them well. Additional research should investigate and characterize the utility of such statements.

Another useful direction to explore concerns explanation generation. Instead of a random subset Z_E to guide explanation generation, the system might grow Z_E one example at a time. Early explanations would likely be abandoned quite frequently. But as more examples are taken into account, the explanations grow in complexity, and their expected adequacy improves; it is more likely that important distinctions are already incorporated. Standard online stopping criteria could signal when sufficient evidence has accrued. In this way, Z_E might consume something close to the minimal number of training examples, preserving the largest possible calibration set Z_C for the new concept.

There may be insight to be gained from the parallels with planning. Conventionally, in complex learning domains, some preprocessor performs dimensionality reduction. Only then does a pattern recognizer form the concept. In EBL, this division begins to be blurred. Feature evaluation proceeds sequentially with later features dependent on the choice and values of earlier ones. The enhanced representation also emerges as classification proceeds. This is reminiscent of executing a conditional or disjunctive plan. The learner plays the role of a conditional planner. It more devises a goal-directed procedure than characterizes a probability distribution.

The primary motivation for EBL is to improve example efficiency of learning. This is a clear need. But there is another, less acknowledged but more pernicious problem that EBL may also address. This concerns the representation of input data. Computational learning systems almost universally assume the data are drawn from some example space (X), and each example is represented as a vector of values from some set of features. Sometimes this assumption is warranted. An image is completely defined by a large but finite set of pixels; a natural language sentence is precisely a particular sequence of words and punctuation. Tasks such as identifying pedestrians in an image or performing semantic role labeling on the sentence fit very well into this ubiquitous representational assumption. But these are

artificial tasks that, at best, might be subtasks for useful real-world behavior. Suppose, by contrast, we command our household robot “Get me my keys from the bedroom.” The robot enters and must deal with the bedroom. Can it be described with a finite set of features? Pick an average room and make a list of all of the “features” that in principle can be noticed. It is impossible. The room is not defined by a finite set of features. Rather, it is an object of great complexity; the closer it is examined, the more features it has. This holds for most real-world objects. Humans almost never completely represent an object. Rather, we possess a suite of sensors through which we perceive the world. We choose to look more closely at some parts of the world than others, building a sufficient representation as we go, enhancing it as necessary. Our representations must consist of only a tiny subset of the possible features. And those features must be adequate for the task at hand. Include too many features and specious patterns abound; include too few and no useful pattern can be constructed. Machine learning research has evolved to avoid tasks where this becomes problematic. Conventional feature selection methods are far from satisfactory. They generally begin by enumerating *all* of the possible features and only then choosing a smaller set or combination. SVM’s can effortlessly handle large or infinite inflated feature spaces, but like other machine learners, they are paralyzed by an unboundedly rich primal feature space. These generally result in narrow margins, a high fraction of examples becoming support vectors, and poor predictive generalization. It is clear that most of the attributes of most real-world objects must be *implicitly* ignored. A promising EBL direction might be to include a description of sensors’ behaviors in the EBL domain theory, Δ . Then the bias of low derivational complexity, preferring the simplest adequate explanations, might naturally embrace a small but adequate set of object sensing commands.

Another interesting direction is to explore a human in the learning loop. In this regard, a human teacher might collaboratively help to build or to choose explanations. Human interaction has proven to be effective in theorem proving [27], which is similar to explanation building. Alternatively, the human might select or suggest elements for Z_E . In this regard, the approach might be similar to curriculum learning [1] and benefit from similar approaches.

In addition to refinements and extensions, there are several active areas in machine learning that might be explored as complementary to EBL. Perhaps the domain theory, Δ , might itself be learned. The approaches that fall under the rubric of nonparametric Bayesian learning would be relevant. Topic models, for example, allow the learner itself to discover latent structure from examples [3]. It might be fruitful to explore how the structure discovered by these systems might be employed as an EBL domain theory. A complication is that the latent hierarchies produced by nonparametric Bayesian approaches are propositional in expressiveness rather than first order. One interesting alternative is once again to introduce a human in the loop but now using natural language interaction. A number of NLP systems have examined extracting first-order or relational rules from text, essentially parsing text into the sort of semantic knowledge representation needed by EBL. See, for example, [6,20,54].

Finally, the relevance of EBL to psychology demands further exploration. There is ample evidence that humans exploit general prior knowledge during concept learning [45]. A number of studies have shown EBL-like behavior in adults [31,48,51]. There is recent experimental evidence that infants as young as 21 months also employ an EBL-like prior knowledge bias [2], going beyond statistical regularities and exploiting prior knowledge when learning.

37.5 Summary

Modern EBL enhances conventional statistical learning with analytic evidence from a general domain theory. A good domain theory introduces distinctions deemed by experts to be useful. Analytic inference supports the nonlinear interaction of these distinctions giving rise to a potentially huge number of derivable features. The explanation process insures that only a few of these, the ones relevant to the task at hand, are elevated to the status of new features. Some of these new features, perhaps many, will be specious. But others will be effective in describing aspects of the underlying pattern. A conventional

statistical learner chooses which derived features are valuable, which to disregard, and how best to combine the good ones. The resulting pattern is then translated back into the target hypothesis space.

Both analytic inference and statistical inference possess strengths and weaknesses as models for the real world. Analytic inference (i.e., symbolic deduction) handles general quantified expressions easily and naturally. It is adept at generating well-formed complex nonlinear combinations of new beliefs from old ones. But in any interesting real-world domain, it unavoidably generates specious incorrect conclusions. All its conclusions are equally believed. Real-world correctness has no place within the formalism. On the other hand, the conclusions of statistical inference are based on observed data and thus are directly connected to the real world. Statistical inference naturally embraces uncertainty and offers formal guarantees of confidence in its conclusions. But it is not easily nor naturally extended beyond propositional representations, and it requires exponentially larger data sets to confidently discover the higher-order covariate structure required by many every-day patterns in the world.

The EBL process exploits the strengths of both analytic inference and statistical inference and uses each to circumvent the inherent weaknesses of the other. The analytic component generates explanations. But these explanations do not have to be “correct” in any sense. An explanation is used only to expose derived features. It is only required that some good features be included within the set of explanations. Each good feature helps to simplify the description of the underlying pattern; each good feature relieves the statistical learner of the need to work out potentially difficult interactions among the raw input features. Bad features, those that are unhelpful in describing the pattern, are easily dismissed or discounted by a statistical learner. By leveraging both analytic and empirical evidence, EBL may help AI to scale beyond its current capabilities.

For further information on specific topics, the reader is referred to the works cited in the text.

Key Terms

Concept or classifier: A function mapping examples to labels; a hypothesis from the hypothesis space chosen by a learner as an acceptable approximation to a target concept.

Derivation: A sequence of statements such that each statement is either an initial statement from the domain theory or the result of applying the domain theory’s inference procedure to earlier statements in the sequence.

Derived feature: A property beyond an object’s raw features that are likely to be true of the object given its raw features and the domain theory.

Domain: A set or space of related (classification learning) problems.

Domain theory: A set of statements expressing general prior knowledge or beliefs about a domain that are used to drive an inference procedure generating new beliefs from old ones. In EBL it serves as analytic evidence supporting the choice of a concept from the hypothesis space.

Example: An object that can be assigned a label (classified), often represented or individuated by a set of features.

Example space: The set of all classifiable objects.

Explanation: A derivation from the domain theory that, for one or more labeled examples, infers the label from the example’s features.

Hypothesis space: The set of all well-formed concepts that in principle could be output by a learner.

Inference: Reasoning from believed statements to new statements that a rational system should also believe. Inference may be empirical (based on observations) or analytic (based on interpreted symbols) and may reflect uncertainty in the prior beliefs.

Overfitting: The selection by a learner of a concept from the hypothesis space that captures a pattern exhibited by the training examples but not exhibited by the underlying population; a learner’s concept selection based on an insignificant amount of evidence.

Raw or input features: A set of properties that defines or individuates an example.

Target concept: The veridical function embodied by the world that generates labels for examples; generally it is not contained within the hypothesis space.

Training set: A collection of labeled examples given to a learner serving as empirical evidence supporting the choice of a concept from the hypothesis space.

38.1 Introduction

Efforts using artificial intelligence (AI) to solve problems with computers—which humans routinely handle by employing innate cognitive abilities, pattern recognition, perception, and experience— invariably must turn to considerations of search. This chapter explores search methods in AI, including both *blind* exhaustive methods and informed heuristic and optimal methods, along with some more recent findings. The search methods covered include (for nonoptimal, uninformed approaches) *state-space search*, *generate and test*, *means-ends analysis*, *problem reduction*, *AND/OR Trees*, *depth-first search (DFS)*, and *breadth-first search*. Under the umbrella of heuristic (informed) methods, we discuss *hill climbing*, *best-first search*, *bidirectional search*, and the *A* algorithm*. Tree searching algorithms for games have proved to be a rich source of study and provide empirical data about heuristic methods. Included here are the *SSS* algorithm*, the use of *iterative deepening*, and variations on the *alpha-beta minimax algorithm*, including the *MTD(f)* and *NegaScout* algorithms.

Coincident with the continuing price-performance improvement of small computers is the growing interest in reimplementing some of the heuristic techniques developed for problem-solving and planning programs, to see if they can be enhanced or replaced by other algorithmic methods. Since many of the heuristic methods are computationally intensive, the second half of the chapter focuses on parallel methods, which can exploit the benefits of parallel processing. The importance of parallel search is presented through an assortment of relatively recent algorithms including the parallel iterative deepening

algorithm (PIDA*), *principal variation splitting* (PVSplit), *parallel window search* (PWS), and the *young brothers wait concept*. In addition, dynamic tree-splitting methods have evolved for both shared-memory parallel machines and networks of distributed computers. Here the issues include load balancing, processor utilization, and communication overhead. For single-agent search problems, we consider not only work-driven dynamic parallelism but also the more recent data-driven parallelism employed in *transposition table-driven (work) scheduling* (TDS). In adversarial games, tree pruning makes work load balancing particularly difficult, and hence we also consider some recent advances in dynamic parallel methods for game-tree search, including the very recent hybrid parallel window/iterative deepening search (*HyPS*), which combines the strengths of PWS and tree-splitting algorithms such as PVSplit.

Another class of search algorithms is motivated by the desire to model natural processes. We call this class of algorithms *nature-based search*. These methods include *Monte Carlo simulation*, *simulated annealing* (SA), *genetic algorithms* (GAs) and *programming*, *Tabu search* (TS), and *ant colony optimization*.

The application of raw computing power, while an anathema to some, often provides better answers than is possible by reasoning or analogy. Thus, brute force techniques form a good basis against which to compare more sophisticated methods designed to mirror the human deductive process.

38.2 Uninformed Search Methods

38.2.1 Search Strategies

All search methods in computer science share in common three characteristics: (1) a world model or database of facts based on a choice of representation providing the current state, as well as other possible states and a goal state; (2) a set of operators that defines possible transformations of states; and (3) a control strategy that determines how transformations among states are to take place by applying operators. *Forward reasoning* is one technique for identifying states that are closer to a goal state. Working backward from a goal to the current state is called *backward reasoning*. As such, it is possible to make distinctions between bottom-up and top-down approaches to problem-solving. Bottom-up is often “goal oriented”—that is, reasoning backward from a goal state to solve intermediary subgoals. Top-down or data-driven reasoning is based on simply being able to reach a state that is defined as closer to a goal. Often the application of operators to a problem state may not lead directly to a goal state, so some *backtracking* may be necessary before a goal state can be found (Barr and Feigenbaum, 1981).

38.2.2 State-Space Search

Exhaustive search of a problem space (or search space) is often not feasible or practical because of the size of the problem space. In some instances, it is, however, necessary. More often, we are able to define a set of legal transformations of a state space (moves in a board game) from which those that are more likely to bring us closer to a goal state are selected, while others are never explored further. This technique in problem-solving is known as *split and prune*. In AI the technique that emulates this approach is called *generate and test*. Good generators are complete and will eventually produce all possible solutions while not proposing redundant ones. They are also informed; that is, they will employ additional information to constrain the solutions they propose. We note that the state space together with the allowable transitions forms a graph. In AI one typically searches the state space from a distinguished starting state and produces a search tree in which some nodes (states) may be repeated on different paths. In this context, AI literature discusses tree search (e.g., game trees) even when the underlying structure is not technically a tree since, for example, the same chess position may occur many times in the game tree and thus technically have multiple parents. In this case, each occurrence of the repeated state can be viewed as a separate node.

Means-ends analysis is another state-space technique whose purpose is to reduce the difference (distance) between a current state and a goal state. Determining “distance” between any state and a goal state can be facilitated by *difference-procedure tables*, which can effectively prescribe what the next state might be. Figure 38.1 illustrates how to use the means-ends analysis.

Repeat Describe the current state, the goal state, and the difference between the two. Use the difference between the current state and goal state, to select a promising transformation procedure. Apply the promising procedure and update the current state. Until the GOAL is reached or no more procedures are available If the GOAL is reached, announce success; Otherwise, announce failure.

FIGURE 38.1 Means–ends analysis.

FIGURE 38.2 Problem reduction and the sliding block puzzle.

The technique of *problem reduction* is another important approach in AI. That is, solve a complex or larger problem by identifying smaller manageable problems (or subgoals), which you know can be solved in fewer steps.

For example, Figure 38.2 shows the “donkey” sliding block puzzle, which has been known for over 100 years. Subject to constraints on the movement of “pieces” in the sliding block puzzle, the task is to slide the blob around the vertical bar with the goal of moving it to the other side. The blob occupies four spaces and needs two adjacent vertical or horizontal spaces in order to be able to move, while the vertical bar needs two adjacent empty vertical spaces to move left or right or one empty space above or below it to move up or down. The horizontal bars’ movements are complementary to the vertical bar. Likewise, the circles can move to any empty space around them in a horizontal or vertical line. A relatively uninformed state-space search can result in over 800 moves for this problem to be solved, with plenty of backtracking necessary. By problem reduction, resulting in the subgoal of trying to get the blob on the two rows above or below the vertical bar, it is possible to solve this puzzle in just 82 moves!

Another example of a technique for problem reduction is called *AND/OR Trees*. Here, the goal is to find a solution path to a given tree by applying the following rules:

A node is solvable if

1. It is a terminal node (a primitive problem)
2. It is a nonterminal AND node whose successors are all solvable
3. It is a nonterminal OR node and least one of its successors is solvable

Similarly, a node is unsolvable if

1. It is a nonterminal node that has no successors (a nonprimitive problem to which no operator applies)
2. It is a nonterminal AND node and at least one of its successors is unsolvable
3. It is a nonterminal OR node and all of its successors are unsolvable

FIGURE 38.3 AND/OR Tree.

In Figure 38.3, nodes B and C serve as exclusive parents to subproblems EF and GH, respectively. One way of viewing the tree is with nodes B, C, and D serving as individual, alternative subproblems. B and C represent AND nodes, and node D is a terminal node. Node B (respectively node C) requires that both E and F (respectively G and H) have solutions, as indicated by the curved arrowheads connecting them. On the other hand, node A is an OR node indicating that only one of its successors (B, C, or D) needs to have a solution. Solution paths would therefore be {A-B-E-F}, {A-C-G-H}, and {A-D}. In the special case where no AND nodes occur, we have the ordinary graph occurring in a state-space search. However, the presence of AND nodes distinguishes AND/OR Trees (or graphs) from ordinary state structures, which call for their own specialized search techniques. Typical problems tackled by AND/OR Trees include games or puzzles and other well-defined state-space goal-oriented problems, such as robot planning, movement through an obstacle course, or setting a robot the task of reorganizing blocks on a flat surface.

38.2.2.1 Breadth-First Search

One way to view search problems is to consider all possible combinations of subgoals, by treating the problem as a tree search. *Breadth-first search* always explores nodes closest to the root node first, thereby visiting all nodes at a given layer first before moving to any longer paths. It pushes uniformly into the search tree. Because of memory requirements, breadth-first search is only practical on shallow trees or those with an extremely low branching factor. It is therefore not much used in practice, except as a basis for such *best-first search* algorithms such as A* and SSS*.

38.2.2.2 Depth-First Search

DFS is one of the most basic and fundamental blind search algorithms. It is used for bushy trees (with high branching factor) where a potential solution does not lie too deep in the tree. That is, “DFS is a good idea when you are confident that all partial paths either reach dead ends or become complete paths after a reasonable number of steps.” In contrast, “DFS is a bad idea if there are long paths, particularly indefinitely long paths, that neither reach dead ends nor become complete paths” (Winston, 1992).

DFS always explores the leftmost node to the left first, that is, the one that is farthest down from the root of the tree. When a dead end (terminal node) is reached, the algorithm backtracks one level and then tries to go forward again. To prevent consideration of unacceptably long paths, a depth bound is often employed to limit the depth of search. At each node, immediate successors are generated, and a transition is made to the leftmost node, where the process continues recursively until a dead end or depth limit is reached. In Figure 38.4, DFS explores the tree in the order: I-E-b-F-B-a-G-c-H-C-a-D-A. Here the notation using lowercase letters indicates possible storage of provisional information about the subtree. For example, this could be a lower bound on the value of the tree.

FIGURE 38.4 Tree example for depth-first and breadth-first search.

```

//      The A* (DFS) algorithm expands the N.i successors of node N
//      in best first order. It uses and sets solved, a global indicator.
//      It also uses a heuristic estimate function H(N), and a
//      transition cost C(N,N.i) of moving from N to N.i
//
IDA* (N) → cost
  bound ← H(N)
  while not solved
    bound ← DFS (N, bound)
  return bound // optimal cost

DFS (N, bound) → value
  if H(N) 0 // leaf node
    solved ← true
    return 0
  new_bound ←
  for each successor N.i of N
    merit ← C(N, N.i) + H(N.i)
    if merit ≤ bound
      merit ← C(N,N.i) + DFS (N.i, bound - C(N,N.i))
      if solved
        return merit
    if merit < new_bound
      new_bound ← merit
  return new_bound

```

FIGURE 38.5 The A* DFS algorithm for use with IDA*.

Figure 38.5 enhances DFS with a form of *iterative deepening* that can be used in a single-agent search like A*. DFS expands an immediate successor of some node N in a tree. The next successor to be expanded is (N.i), the one with lowest cost function. Thus, the expected value of node N.i is the estimated cost $C(N,N.i)$ plus $H(N)$, the known value of node N. The basic idea in iterative deepening is that a DFS is started with a depth bound of 1, and this bound increases by one at each new iteration. With each increase

in depth, the algorithm must reinitiate its DFS for the prescribed bound. The idea of iterative deepening, in conjunction with a memory function to retain the best available potential solution paths from iteration to iteration, is credited to Slate and Atkin (1977) who used it in their chess program. Korf (1985) showed how efficient this method is in single-agent search, with his iterative deepening A* (IDA*) algorithm.

38.2.2.3 Bidirectional Search

To this point, all search algorithms discussed (with the exception of means–ends analysis and backtracking) have been based on forward reasoning. Searching backward from goal nodes to predecessors is relatively easy. Pohl (1971) combined forward and backward reasoning into a technique called *bidirectional search*. The idea is to replace a single search graph, which is likely to grow exponentially, with two smaller graphs—one starting from the initial state and one starting from the goal. The search terminates when the two graphs intersect. This algorithm is guaranteed to find the shortest solution path through a general state-space graph. Empirical data for randomly generated graphs show that Pohl’s algorithm expands only about 1/4 as many nodes as unidirectional search (Barr and Feigenbaum, 1981). Pohl also implemented heuristic versions of this algorithm. However, determining when and how the two searches will intersect is a complex process.

Russell and Norvig (2003) analyze the bidirectional search and come to the conclusion that it is $O(b^{d/2})$ in terms of average case time and space complexity (where b is the branching factor and d is the depth). They point out that this is significantly better than $O(b^d)$, which would be the cost of searching exhaustively in one direction. The identification of subgoal states could do much to reduce the costs. The large space requirements of the algorithm are considered its weakness.

However, Kaindl and Kainz (1997) have demonstrated that the long held belief that the algorithm is afflicted by the frontiers passing each other is wrong. They developed a new generic approach that dynamically improves heuristic values but is only applicable to bidirectional heuristic search. Their empirical results have found that the bidirectional heuristic search can be performed very efficiently, with limited memory demands. Their research has resulted in a better understanding of an algorithm whose practical usefulness has been long neglected, with the conclusion that it is better suited to certain problems than corresponding unidirectional searches. For more details, the reader should review their paper (Kaindl and Kainz, 1997). The Section 38.3 focuses on heuristic search methods.

38.3 Heuristic Search Methods

George Polya, via his wonderful book *How to Solve It* (1945), may be regarded as the “father of heuristics.” Polya’s efforts focused on problem-solving, thinking, and learning. He developed a short “heuristic dictionary” of heuristic primitives. Polya’s approach was both practical and experimental. He sought to develop commonalities in the problem-solving process through the formalization of observation and experience.

The present-day notions of heuristics are somewhat different from Polya’s (Bolc and Cytowski, 1992). Current tendencies seek formal and rigid algorithmic solutions to specific problem domains, rather than the development of general approaches that could be appropriately selected and applied to specific problems.

The goal of a heuristic search is to greatly reduce the number of nodes searched in seeking a goal. In other words, problems whose complexity grows combinatorially large may be tackled. Through knowledge, information, rules, insights, analogies, and simplification, in addition to a host of other techniques, heuristic search aims to reduce the number of objects that must be examined. Heuristics do not guarantee the achievement of a solution, although good heuristics should facilitate this. Over the years, heuristic search has been defined in many different ways:

- It is a practical strategy increasing the effectiveness of complex problem-solving (Feigenbaum and Feldman, 1963).
- It leads to a solution along the most probable path, omitting the least promising ones.
- It should enable one to avoid the examination of dead ends and to use already gathered data.

The points at which heuristic information can be applied in a search include

1. Deciding which node to expand next, instead of doing the expansions in either a strictly breadth-first or depth-first order
2. Deciding which successor or successors to generate when generating a node—instead of blindly generating all possible successors at one time
3. Deciding that certain nodes should be discarded, or pruned, from the search tree

Most modern heuristic search methods are expected to bridge the gap between the completeness of algorithms and their optimal complexity (Romanycia and Pelletier, 1985). Strategies are being modified in order to arrive at a quasi-optimal, instead of optimal, solution with a significant cost reduction (Pearl, 1984). Games, especially two-person, zero-sum games with perfect information, like chess and checkers, have proven to be a very promising domain for studying and testing heuristics.

38.3.1 Hill Climbing

Hill climbing is a DFS with a heuristic measure that orders choices as nodes are expanded. The heuristic measure is the estimated remaining distance to the goal. The effectiveness of hill climbing is completely dependent upon the accuracy of the heuristic measure.

Winston (1992) explains the potential problems affecting hill climbing. They are all related to issue of local “vision” versus global vision of the search space. The *foothills problem* is particularly subject to local maxima where global ones are sought, while the *plateau problem* occurs when the heuristic measure does not hint toward any significant gradient of proximity to a goal. The *ridge problem* illustrates just what it is called: you may get the impression that the search is taking you closer to a goal state, when in fact you are traveling along a ridge that prevents you from actually attaining your goal. SA attempts to combine hill climbing with a random walk in a way that yields both efficiency and completeness (Russell and Norvig, 2003, p. 115). The idea is to “temper” the downhill process of hill climbing in order to avoid some of the pitfalls discussed earlier by increasing the probability of “hitting” important locations to explore. It is akin to intelligent guessing. A more comprehensive discussion of SA can be found in Section 38.6.2.

38.3.2 Best-First Search

Best-first search (Figure 38.6) is a general algorithm for heuristically searching any state-space graph—a graph representation for a problem that includes initial states, intermediate states, and goal states. In this sense, a directed acyclic graph (DAG), for example, is a special case of a state-space graph. Best-first search is equally applicable to data- and goal-driven searchers and supports the use of heuristic evaluation functions. It can be used with a variety of heuristics, ranging from a state’s “goodness” to sophisticated measures based on the probability of a state leading to a goal that can be illustrated by examples of Bayesian statistical measures.

Similar to the depth-first and breadth-first search algorithms, best-first search uses lists to maintain states: OPEN to keep track of the current fringe of the search and CLOSED to record states already visited. In addition, the algorithm orders states on OPEN according to some heuristic estimate of their proximity to a goal. Thus, each iteration of the loop considers the most “promising” state on the OPEN list. According to Luger and Stubblefield (1993), best-first search improves at just the point where hill climbing fails with its short-sighted and local vision.

Here is a graph of a hypothetical search space. The problem is to find a shortest path from $d1$ to $d5$ in this directed and weighted graph (Figure 38.7), which could represent a sequence of local and express subway train stops. The “F” train starts at $d1$ and visits stops $d2$ (cost 16), $d4$ (cost 7), and $d6$ (cost 11). The “D” train starts at $d1$ and $d3$ (cost 7), $d4$ (cost 13), and $d5$ (cost 12). Other choices involve

```

Procedure Best_First_Search (Start) → pointer
  OPEN ← {Start} // Initialize
  CLOSED ← { }
  While OPEN ≠ { } Do // States Remain
    remove the leftmost state from OPEN, call it X;
    if X goal then
      return the path from Start to X
    else
      generate children of X
      for each child of X do
        CASE
        the child is not on open or CLOSED:
          assign the child a heuristic value
          add the child to OPEN
        the child is already on OPEN:
          if the child was reached by a shorter path
            then give the state on OPEN the shorter path
        the child is already on CLOSED:
          if the child was reached by a shorter path then
            remove the state from CLOSED
            add the child to OPEN
        end_CASE
      put X on closed;
      re-order states on OPEN by heuristic merit (best leftmost)
  return NULL // OPEN is empty

```

FIGURE 38.6 The best-first search algorithm. (From Luger, J. and Stubblefield, W., *Artificial Intelligence: Structures and Strategies for Complex Problem Solving*, 2nd edn., Benjamin/Cummings Publishing Company Inc., Redwood City, CA, p. 121, 1993.)

FIGURE 38.7 A state-space graph for a hypothetical subway system.

combinations of “Q,” “N,” “R,” and “A” trains with the F and/or D train. By applying the “best-first search” algorithm, we can find the shortest path from $d1$ to $d5$. Figure 38.8 shows a state tree representation of this graph.

The thick arrowed path is the shortest path $[d1, d3, d4, d5]$. The dashed edges are nodes put on the OPEN node queue, but not further explored. A trace of the execution of procedure best-first search appears in the following:

1. OPEN = $[d1]$; CLOSED = $[\]$
2. Evaluate $d1$; OPEN = $[d3, d2]$; CLOSED = $[d1]$
3. Evaluate $d3$; OPEN = $[d4, d2]$; CLOSED = $[d3, d1]$
4. Evaluate $d4$; OPEN = $[d6, d5, d7, d2]$; CLOSED = $[d4, d3, d1]$
5. Evaluate $d6$; OPEN = $[d5, d7, d2]$; CLOSED = $[d6, d4, d3, d1]$
6. Evaluate $d5$; a solution is found CLOSED = $[d5, d6, d4, d3, d1]$

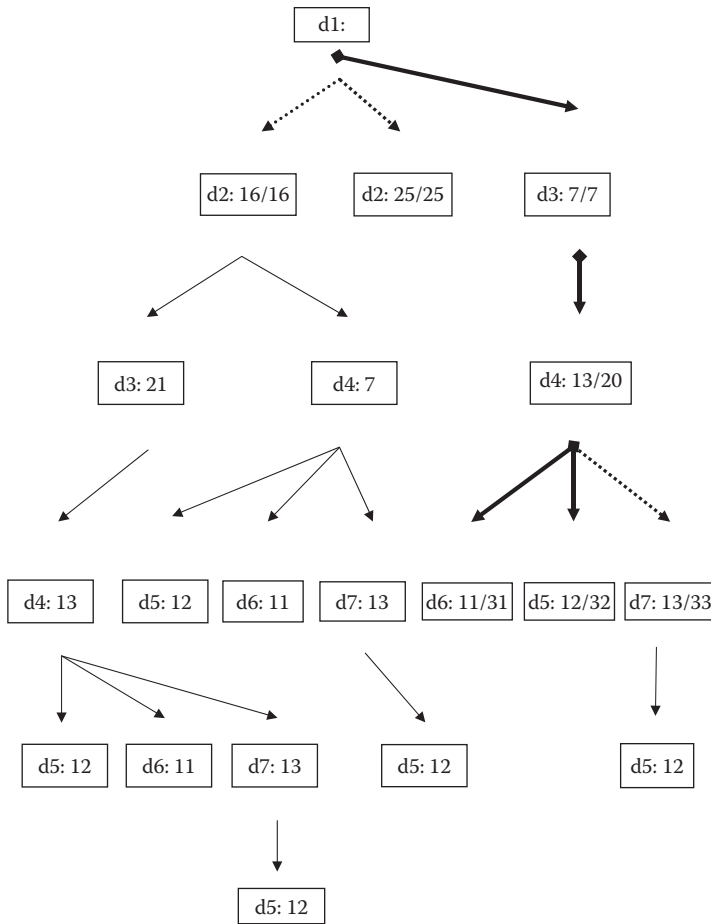

FIGURE 38.8 A search tree for the graph in Figure 38.7.

Note that nodes d6 and d5 are at the same level so we don't take d6 in our search for the shortest path. Hence, the shortest path for this graph is [d1, d3, d4, d5]. After we reach our goal state "d5," we can also find the shortest path from "d5" to "d1" by retracing the tree from d5 to d1.

When the best-first search algorithm is used, the states are sent to the OPEN list in such a way that the most promising one is expanded next. Because the search heuristic being used for measurement of distance from the goal state may prove erroneous, the alternatives to the preferred state are kept on the OPEN list. If the algorithm follows an incorrect path, it will retrieve the "next best" state and shift its focus to another part of the space. In the example earlier, children of node d2 were found to have poorer heuristic evaluations than sibling d3, and so the search shifted there. However, the children of d3 were kept on OPEN and could be returned to later, if other solutions are sought.

38.3.3 A* Algorithm

The A* algorithm, first described by Hart, Nilsson, and Raphael (1968), attempts to find the minimal cost path joining the start node and the goal in a state-space graph. The algorithm employs an ordered state-space search and an estimated heuristic cost to a goal state, f^* (known as an evaluation function), as does the best-first search (Section 38.2.2). It uniquely defines f^* , so that it can guarantee an optimal solution path. The A* algorithm falls into the *branch and bound* class of algorithms, typically employed in operations research to find the shortest path to a solution node in a graph.

The evaluation function, $f^*(n)$, estimates the quality of a solution path through node n , based on values returned from two components, $g^*(n)$ and $h^*(n)$. Here $g^*(n)$ is the minimal cost of a path from a start node to n , and $h^*(n)$ is a lower bound on the minimal cost of a solution path from node n to a goal node. As in branch and bound algorithms for trees, g^* will determine the single unique shortest path to node n . For graphs, on the other hand, g^* can err only in the direction of overestimating the minimal cost; if a shorter path is found, its value is readjusted downward. The function h^* is the carrier of *heuristic information*, and the ability to ensure that the value of $h^*(n)$ is less than $h(n)$ (i.e., $h^*(n)$ is an underestimate of the actual cost, $h(n)$, of an optimal path from n to a goal node) is essential to the optimality of the A^* algorithm. This property, whereby $h^*(n)$ is always less than $h(n)$, is known as the *admissibility condition*. If h^* is zero, then A^* reduces to the blind uniform-cost algorithm. If two otherwise similar algorithms $A1$ and $A2$ can be compared to each other with respect to their h^* function, that is, $h1^*$ and $h2^*$, then algorithm $A1$ is said to be *more informed* than $A2$ if $h1^*(n) > h2^*(n)$, whenever a node n (other than a goal node) is evaluated. The cost of computing h^* in terms of the overall computational effort involved, and algorithmic utility, determines the *heuristic power* of an algorithm. That is, an algorithm that employs an h^* that is usually accurate, but sometimes inadmissible, may be preferred over an algorithm where h^* is always minimal but hard to compute (Barr and Feigenbaum, 1981).

Thus, we can summarize that the A^* algorithm is a branch and bound algorithm augmented by the *dynamic programming principle*: the best way through a particular, intermediate node is the best way to that intermediate node from the starting place, followed by the best way from that intermediate node to the goal node. There is no need to consider any other paths to or from the intermediate node (Winston, 1992).

Stewart and White (1991) presented the multiple objective A^* algorithm (MOA*). Their research is motivated by the observation that most real-world problems have multiple, independent, and possibly conflicting objectives. MOA* explicitly addresses this problem by identifying the set of all nondominated paths from a specified start node to a given set of goal nodes in an OR graph. This work shows that MOA* is complete and is admissible, when used with a suitable set of heuristic functions.

38.4 Game-Tree Search

The standard representation used for a state-space in adversarial games is a tree. The tree is usually explored to a certain depth to determine the best move(s) by each side. Such trees can often grow exponentially, and therefore, heuristics are vital for feasible computation.

38.4.1 Alpha–Beta Algorithms

To the human player of 2-person games, the notion behind the alpha–beta algorithm is understood intuitively as the following:

- If I have determined that a move or a sequence of moves is bad for me (because of a refutation move or variation by my opponent), then I don't need to determine just how bad that move is. Instead I can spend my time exploring other alternatives earlier in the tree.
- Conversely, if I have determined that a variation or sequence of moves is bad for my opponent, then I don't determine exactly how good it is for me.

Figure 38.9 illustrates some of these ideas. Here the thick solid line represents the current solution path. This in turn has replaced a candidate solution, here shown with dotted lines. Everything to the right of the optimal solution path represents alternatives that are simply proved inferior. The path of the current solution is called the principal variation (PV) and nodes on that path are marked as PV nodes. Similarly, the alternatives to PV nodes are CUT nodes, where only a few successors are examined before a proof of inferiority is found. In time the successor to a CUT node will be an ALL node where everything must be examined to prove the cutoff at the CUT node. The number or bound value by each node represents the return to the root of the cost of the solution path.

FIGURE 38.9 The PV, CUT, and ALL nodes of a tree, showing its optimal path (bold) and value (5).

In the forty years since its inception (Knuth and Moore, 1975), the alpha-beta minimax algorithm has undergone many revisions and refinements to improve the efficiency of its pruning, and, until the invention of the MTD(f) variant, it has served as the primary search engine for two-person games. There have been many landmarks on the way, including Knuth and Moore's (1975) formulation in a negamax framework, Pearl's (1980) introduction of Scout, and the special formulation for chess with the PV search (Marsland and Campbell, 1982) and NegaScout (Reinefeld, 1983). The essence of the method is that the search seeks a path whose value falls between two bounds called alpha and beta, which form a window. With this approach, one can also incorporate an artificial narrowing of the alpha-beta window, thus encompassing the notion of "aspiration search," with a mandatory research on failure to find a value within the corrected bounds. This leads naturally to the incorporation of null window search (NWS) to improve upon Pearl's test procedure. Here the NWS procedure covers the search at a CUT node (Figure 38.9), where the cutting bound (beta) is negated and increased by 1 in the recursive call. This refinement has some advantage in the parallel search case, but otherwise NWS (Figure 38.10) is entirely equivalent to the minimal window call in NegaScout. Additional improvements include the use of iterative deepening with "transposition tables" and other move-ordering mechanisms to retain a memory of the search from iteration to iteration. A transposition table is a cache of previously generated states that are typically hashed into a table to avoid redundant work. These improvements help ensure that the better subtrees are searched sooner, leading to greater pruning efficiency (more cutoffs) in the later subtrees. Figure 38.10 encapsulates the essence of the algorithm and shows how the first variation from a set of PV nodes, as well as any superior path that emerges later, is given special treatment. Alternates to PV nodes will always be CUT nodes, where a few successors will be examined. In a minimal game tree, only one successor to a CUT node will be examined, and it will be an ALL node where everything is examined. In the general case, the situation is more complex, as Figure 38.9 shows.

```

de, alpha, beta, height) → tree_value
  if height  0
    return Evaluate(node)                // a terminal node
  next ← FirstSuccessor (node)           // a PV node
  best ← - ABS (next, -beta, -alpha, height -1)
  next ← SelectSibling (next)
  while next ≠ NULL do
    if best ≥ beta then
      return best                        // a CUT node
    alpha ← max (alpha, best)
    merit ← - NWS (next, -alpha, height -1)
    if merit > best then
      if (merit ≤ alpha) or (merit ≥ beta) then
        best ← merit
      else best ← -ABS (next, -beta, -merit, height-1)
    next ← SelectSibling (next)
  end
  return best                            // a PV node
end

NWS (node, beta, height) → bound_value
  if height  0 then
    return Evaluate(node)                // a terminal node
  next ← FirstSuccessor (node)
  estimate ← -
  while next ≠ NULL do
    merit ← - NWS (next, -beta+1, height-1)
    if merit > estimate then
      estimate ← merit
    if merit ≥ beta then
      return estimate                    // a CUT node
    next ← SelectSibling (next)
  end
  return estimate                        // an ALL node
end

```

FIGURE 38.10 Scout/PVS version of ABS in the negamax framework.

38.4.2 SSS* Algorithm

The SSS* algorithm was introduced by Stockman (1979) as a game-searching algorithm that traverses subtrees of the game tree in a best-first fashion similar to the A* algorithm. SSS* was shown to be superior to the original alpha–beta algorithm in the sense that it never looks at more nodes while occasionally examining fewer (Pearl, 1984). Roizen and Pearl (1983), the source of the following description of SSS*, state that

... the aim of SSS* is the discovery of an optimal solution tree...In accordance with the best-first split-and-prune paradigm, SSS* considers “clusters” of solution trees and splits (or refines) that cluster having the highest upper bound on the merit of its constituents. Every node in the game tree represents a cluster of solution trees defined by the set of all solution trees that share that node....the merit of a partially developed solution tree in a game is determined solely by the properties of the frontier nodes it contains, not by the cost of the paths leading to these nodes. The value of a frontier node is an upper bound on each solution tree in the cluster it represents,... SSS* establishes upper bounds on the values of partially developed solution trees by seeking the value of terminal nodes, left to right, taking the minimum value of those examined so far. These monotonically nonincreasing bounds are used to order the solution trees so that the tree of highest merit is chosen for development. The development process continues until one solution tree is fully developed, at which point that tree represents the optimal strategy and its value coincides with the minimax value of the root.

...The disadvantage of SSS* lies in the need to keep in storage a record of all contending candidate clusters, which may require large storage space, growing exponentially with search depth. (Pearl, 1984, p. 245)

Heavy space and time overheads have kept SSS* from being much more than an example of a best-first search, but current research seems destined to now relegate SSS* to a historical footnote. Recently, Plaat et al. (1995) formulated the node-efficient SSS* algorithm into the alpha-beta framework using successive NWS search invocations (supported by perfect transposition tables) to achieve a memory-enhanced test procedure that provides a best-first search. With their introduction of the MTD(f) algorithm, Plaat et al. (1995) claim that SSS* can be viewed as a special case of the time-efficient alpha-beta algorithm, instead of the earlier view that alpha-beta is a k-partition variant of SSS*. MTD(f) is an important contribution that has now been widely adopted as the standard two-person game-tree search algorithm. It is described in the succeeding text.

38.4.3 MTD(f) and NegaScout

MTD(f) is usually run in an iterative deepening fashion, and each iteration proceeds by a sequence of minimal or null window alpha-beta calls. The search works by zooming in on the minimax value, as Figure 38.11 shows.

The bounds stored in *upper bound* and *lower bound* form an interval around the true minimax value for a particular search depth d . The interval is initially set to $[-\infty, +\infty]$. Starting with the value f , returned from a previous call to MTD(f), each call to alpha-beta returns a new minimax value g , which is used to adjust the bounding interval and to serve as the pruning value for the next alpha-beta call. For example, if the initial minimax value is 50, alpha-beta will be called with the pruning values 49 and 50. If the new minimax value returned, g , is less than 50, upper bound is set to g . If the minimax value returned, g , is greater than or equal to 50, lower bound is set to g . The next call to alpha-beta will use $g - 1$ and g for the pruning values (or g and $g + 1$, if g is equal to the lower bound). This process continues until *upper bound* and *lower bound* converge to a single value, which is returned. MTD(f) will be called again with this newly returned minimax estimate and an increased depth bound until the tree has been searched to a sufficient depth.

As a result of the iterative nature of MTD(f), the use of transposition tables is essential to its efficient implementation. In tests with a number of tournament game-playing programs, MTD(f) outperformed alpha-beta search (ABS) (Scout/PVS, Figure 38.10). It generally produces trees that are 5%–15% smaller than ABS (Plaat et al., 1996). MTD(f) has been shown to examine fewer nodes than any other variants

```
int MTDf ( node_type root, int f, int d)
{
    g = f;
    upperbound = +INFINITY;
    lowerbound = -INFINITY;
    repeat
        if (g == lowerbound)
            beta = g + 1
        else
            beta = g;
    g = AlphaBetaWithMemory(root, beta - 1, beta, d);
    if (g < beta)
        then upperbound = g
        else lowerbound = g;
    until (lowerbound >= upperbound);
    return g;
}
```

FIGURE 38.11 The MTD(f) algorithm pseudo-code.

of the ABS; nevertheless, many chess program developers still prefer NegaScout (Reinefeld, 1983) to MTD(f), as it is free of dependence on transposition tables.

38.4.4 Recent Developments

Sven Koenig has developed Minimax Learning Real-Time A* (Min-Max LRTA*), a real-time heuristic search method that generalizes Korf's (1990) earlier LRTA* to nondeterministic domains. Hence, it can be applied to "robot navigation tasks in mazes, where robots know the maze but do not know their initial position and orientation (pose). These planning tasks can be modeled as planning tasks in non-deterministic domains whose states are sets of poses." Such problems can be solved quickly and efficiently with Min-Max LRTA* requiring only a small amount of memory (Koenig, 2001).

Martin Mueller (2001) introduces the use of partial order bounding (POB) rather than scalar values for the construction of an evaluation function for computer game playing. The propagation of partially ordered values through a search tree has been known to lead to many problems in practice. Instead POB compares values in the leaves of a game tree and backs up Boolean values through the tree. The effectiveness of this method was demonstrated in examples of capture races in the game of GO (Mueller, 2001).

Schaeffer et al. (2001) demonstrate that the distinctions for evaluating heuristic search should not be based on whether the application is for single-agent or two-agent search. Instead, they argue that the search enhancements applied to both single-agent and two-agent problems for creating high-performance applications are the essentials. Focus should be on generality for creating opportunities for reuse. Examples of some of the generic enhancements (as opposed to problem-specific ones) include the alpha-beta algorithm, transposition tables, and IDA*. Efforts should be made to enable more generic application of algorithms.

Hong et al. (2001) present a GA approach that can find a good next move by reserving the board evaluation of new offspring in a partial game-tree search. Experiments have proven promising in terms of speed and accuracy when applied to the game of GO.

The fast-forward (FF) planning system of Hoffman and Nebel (2001) uses a heuristic that estimates goal distances by ignoring delete lists. Facts are not assumed to be independent. It uses a new search strategy that combines hill climbing with systematic search. Powerful heuristic information is extended and used to prune the search space.

38.5 Parallel Search

The proliferation of low-cost processors and, in particular, the advent of multicore computing have stimulated interest in the use of multiple processors for parallel traversals of decision trees. The few theoretical models of parallelism do not accommodate communication and synchronization delays that inevitably impact the performance of working systems. There are several other factors to consider too, including

1. How best to employ the additional memory and I/O resources that become available with the extra processors
2. How best to distribute the work across the available processors
3. How to avoid excessive duplication of computation

Some important combinatorial problems have no difficulty with the third point because every eventual-ity must be considered, but these tend to be less interesting in an AI context.

One problem of particular interest is game-tree search, where it is necessary to compute the value of the tree while communicating an improved estimate to the other parallel searchers as it becomes available. This can lead to an "acceleration anomaly" when the tree value is found earlier than is possible with a sequential algorithm. Even so, uniprocessor algorithms can have special advantages in that they can be optimized for best pruning efficiency, while a competing parallel system may not have the right

information in time to achieve the same degree of pruning and so do more work (suffer from search overhead). Further, the very fact that pruning occurs makes it impossible to determine in advance how big any piece of work (subtree to be searched) will be, leading to a potentially serious work imbalance and heavy synchronization (waiting for more work) delays.

Although the standard basis for comparing the efficiency of parallel methods is simple,

$$\text{Speedup} = \frac{\text{Time taken by a sequential single-processor algorithm}}{\text{Time taken by a P-processor system}}$$

This is the practical definition of speedup. Many researchers use a more theoretical definition, in which P-fold speedup is the best possible. However, in practice superlinear speedup can occur for a variety of reasons. This phenomenon happens when the parallel algorithm does less total work than the sequential version. For example, each processor may work on a smaller problem and thus get improved cache performance. In search problems, the parallel version may quickly report a solution on a path that would not be searched until much later by the sequential algorithm, causing other processors to end their search before exploring nodes that the sequential algorithm would have explored.

The exponential growth of the tree size (solution space) with depth of search makes parallel search algorithms especially susceptible to anomalous speedup behavior. Clearly, acceleration anomalies are among the welcome properties, but more commonly anomalously bad performance is seen, unless the algorithm has been designed with care.

In game-playing programs of interest to AI, parallelism is primarily intended not to find the answer more quickly but to get a more reliable result (e.g., based on a deeper search). Here, the emphasis lies on scalability instead of speedup. While speedup holds the problem size constant and increases the system size to get a result sooner, scalability measures the ability to expand the size of both the problem and the system at the same time:

Thus, scale-up close to unity reflects successful parallelism:

$$\text{Scale-up} = \frac{\text{Time taken to solve a problem of size } s \text{ by a single processor}}{\text{Time taken to solve a } (P \times s) \text{ problem by an P-processor system}}$$

38.5.1 Parallel Single-Agent Search

Single-agent game-tree search is important because it is useful for several robot-planning activities, such as finding the shortest path through a maze of obstacles. It seems to be more amenable to parallelization than the techniques used in adversary games, because a large proportion of the search space must be fully seen—especially when optimal solutions are sought. This traversal can safely be done in parallel, since there are no cutoffs to be missed. Although move ordering can reduce node expansions, it does not play the same crucial role as in dual-agent game-tree search, where significant parts of the search space are often pruned away. For this reason, parallel single-agent search techniques usually achieve better speedups than their counterparts in adversary games.

Most parallel single-agent searches are based on A* or IDA*. As in the sequential case, parallel A* outperforms IDA* on a node-count basis, although parallel IDA* needs only linear storage space and runs faster. In addition, cost-effective methods exist (e.g., PWS described subsequently) that determine nonoptimal solutions with even less computing time.

38.5.1.1 Parallel A*

Given P processors, the simplest way to parallelize A* is to let each machine work on one of the currently best states on a global OPEN list (a place holder for nodes that have not yet been examined). This approach minimizes the search overhead, as confirmed in practice by Kumar et al. (1988). Their relevant

experiments were run on a shared-memory BBN Butterfly machine with 100 processors, where a search overhead of less than 5% was observed for the traveling salesperson (TSP) problem.

But elapsed time is more important than the node expansion count, because the global OPEN list is accessed both before and after each node expansion, so that memory contention becomes a serious bottleneck. It turns out that a centralized strategy for managing the OPEN list is only useful in domains where the node expansion time is large compared to the OPEN list access time. In the TSP problem, near-linear time speedups were achieved with up to about 50 processors, when a sophisticated heap data structure was used to significantly reduce the OPEN list access time (Kumar et al., 1988).

Distributed strategies using local OPEN lists reduce the memory contention problem. But again some communication must be provided to allow processors to share the most promising state descriptors, so that no computing resources are wasted in expanding inferior states. For this purpose, a global “Blackboard” table can be used to hold state descriptors of the currently best nodes. After selecting a state from its local OPEN list, each processor compares its f -value (lower bound on the solution cost) to that of the states contained in the Blackboard. If the local state is much better (or much worse) than those stored in the Blackboard, then node descriptors are sent (or received), so that all active processors are exploring states of almost equal heuristic value. With this scheme, a 69-fold speedup was achieved on an 85-processor BBN Butterfly (Kumar et al., 1988).

Although a Blackboard is not accessed as frequently as a global OPEN list, it still causes memory contention with increasing parallelism. To alleviate this problem, Huang and Davis (1989) proposed a distributed heuristic search algorithm called Parallel Iterative A* (PIA*), which works solely on local data structures. On a uniprocessor, PIA* expands the same nodes as A*, while in the multiprocessor case, it performs a parallel best-first node expansion. The search proceeds by repetitive synchronized iterations, in which processors working on inferior nodes are stopped and reassigned to better ones. To avoid unproductive waiting at the synchronization barriers, the processors are allowed to perform speculative processing. Although Huang and Davis (1989) claim that “this algorithm can achieve almost linear speedup on a large number of processors,” it has the same disadvantage as the other parallel A* variants, namely, excessive memory requirements.

38.5.1.2 Parallel IDA*

IDA* (Figure 38.5) has proved to be effective, when excessive memory requirements undermine best-first schemes. Not surprisingly it has also been a popular algorithm to parallelize. Rao et al. (1987) proposed PIDA*, an algorithm with almost linear speedup even when solving the 15-puzzle with its trivial node expansion cost. The 15-puzzle is a popular game made up of 15 tiles that slide within a 4×4 matrix. The object is to slide the tiles through the one empty spot until all tiles are aligned in some goal state. An optimal solution to a hard problem might take 66 moves. PIDA* splits the search space into disjoint parts, so that each processor performs a local cost-bounded DFS on its private portion of the state space. When a process has finished its job, it tries to get an unsearched part of the tree from other processors. When no further work can be obtained, all processors detect global termination and compute the minimum of the cost bounds, which is used as a new bound in the next iteration. Note that more than a P -fold speedup is possible when a processor finds a goal node early in the final iteration. In fact, Rao et al. (1987) report an average speedup of 9.24 with 9 processors on the 15-puzzle! Perhaps more relevant is the all-solution case where no superlinear speedup is possible. Here, an average speedup of 0.93 P with up to thirty (P) processors on a bus-based multiprocessor architecture (Sequent Balance 21000) was achieved. This suggests that only low multiprocessing overheads (locking, work transfer, termination detection, and synchronization) were experienced.

PIDA* employs a task attraction scheme like that shown in Figure 38.12 for distributing the work among the processors. When a processor becomes idle, it asks a neighbor for a piece of the search space. The donor then splits its DFS stack and transfers to the requester some nodes (subtrees) for parallel expansion. An optimal splitting strategy would depend on the regularity (uniformity of width and height) of the search tree, though short subtrees should never be given away. When the tree is regular

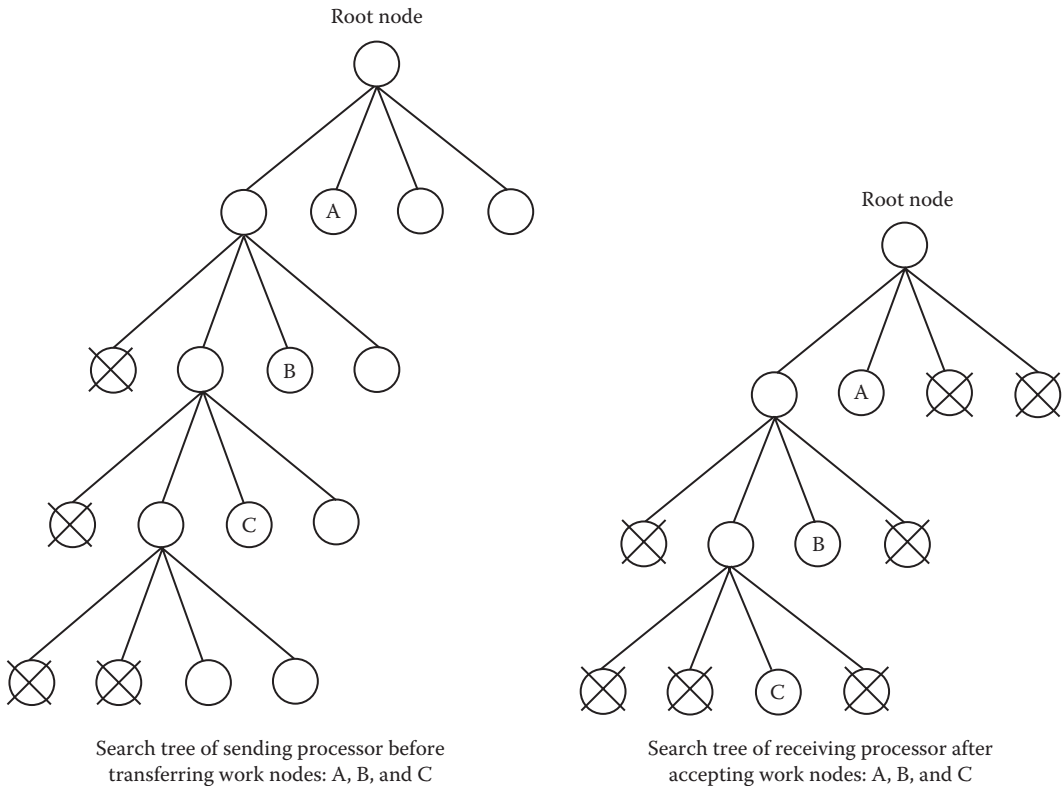

FIGURE 38.12 A work distribution scheme.

(like in the 15-puzzle), a coarse-grained work transfer strategy can be used (e.g., transferring only nodes near the root); otherwise, a slice of nodes (e.g., nodes A, B, and C in Figure 38.12) should be transferred.

38.5.1.3 Comparison with Parallel Window Search

Another parallel IDA* approach borrows from Baudet's (1978) parallel window method for searching adversary games (described later). Powley and Korf (1991) adapted this method to single-agent search, under the title PWS. Their basic idea is to simultaneously start as many iterations as there are processors. This works for a small number of processors, which either expand the tree up to their given thresholds until a solution is found (and the search is stopped) or completely expand their search space. A global administration scheme then determines the next larger search bound and node expansion starts over again.

Note that the first solution found by PWS need not necessarily be optimal. Suboptimal solutions are often found in searches of poorly ordered trees. There, a processor working with a higher cutoff bound finds a goal node in a deeper tree level, while other processors are still expanding shallower tree parts (which may contain cheaper solutions). But according to Powley and Korf (1991), PWS is not primarily meant to compete with IDA*, but it "can be used to find a nearly optimal solution quickly, improve the solution until it is optimal, and then finally guarantee optimality, depending on the amount of time available." Compared to PIDA*, the degree of parallelism is limited, and it remains unclear how to apply PWS in domains where the cost-bound increases are variable.

In summary, PWS and PIDA* complement each other. Hence, it seems natural to combine them to form a single search scheme that runs PIDA* on groups of processors administered by a global PWS algorithm. The amount of communication needed depends on the work distribution scheme. A fine-grained distribution requires more communication, while a coarse-grained work distribution generates fewer messages (but may induce unbalanced work load). Note that the choice of the work distribution

scheme also affects the frequency of good acceleration anomalies. Pertinent results have been reported by Reinefeld (1995). Using asynchronous parallel IDA* (AIDA*), near-linear speedup was obtained on a 1024 transputer-based system solving 13 instances of the 19-puzzle. Reinefeld's paper includes a discussion of the communication overheads in both ring and toroid systems, as well as a description of the work distribution scheme.

In a similar vein, Diane Cook developed a hybrid parallel window/distributed tree search (*HyPS*) (Cook, 2011) and incorporated it into the *EUREKA* system of Cook and Varnell (1998) (see succeeding text). PWS is effective when many iterations are required and reduces the redundant work of IDA*, but it fails to exploit parallelism when exploring the tree to a depth bound. Tree splitting exploits parallelism in searching the tree to a given depth in IDA* but requires excessive load balancing and performs redundant work when many iterations are required. HyPS works by dividing the available processors into clusters. Each cluster searches the same search space to a different threshold, as in PWS. Within each cluster, tree splitting is employed using operator ordering and load balancing. The algorithm adapts to different numbers of processors, and very favorable results have been reported on typical search problems that seem to indicate an improvement over existing parallel search algorithms.

Much work has also been done on parallelizing TS (discussed in Section 38.5.2) (see, e.g., Gendreau et al., 2001).

38.5.2 Adversary Games

In the area of two-person games, early simulation studies with a mandatory work first (MWF) scheme (Akl et al., 1982), and the PVSplit algorithm (Marsland and Campbell, 1982), showed that a high degree of parallelism was possible, despite the work imbalance introduced by pruning. Those papers saw that in key applications (e.g., chess), the game trees are well ordered, because of the wealth of move-ordering heuristics that have been developed (Slate and Atkin, 1977), and so the bulk of the computation occurs during the search of the first subtree. The MWF approach uses the shape of the critical tree that must be searched. Since that tree is well defined and has regular properties, it is easy to generate. In their simulation, Akl et al. (1982) consider the merits of searching the critical game tree in parallel, with the balance of the tree being generated algorithmically and searched quickly by simple tree splitting. Marsland and Campbell (1982), on the other hand, recognized that the first subtree of the critical game tree has the same properties as the whole tree, but its maximum height is one less. This so-called PV can be recursively split into parts of about equal size for parallel exploration. PVSplit, an algorithm based on this observation, was tested and analyzed by Marsland and Popowich (1985). Even so, the static processor allocation schemes like MWF and PVSplit cannot achieve high levels of parallelism, although PVSplit does very well with up to half a dozen processors. MWF in particular ignores the true shape of the average game tree, and so is at its best with shallow searches, where the pruning imbalance from the so-called deep cutoffs has less effect. Other working experience includes the first parallel chess program by Newborn, who later presented performance results (Newborn, 1988). For practical reasons Newborn only split the tree down to some prespecified common depth from the root (typically 2), where the greatest benefits from parallelism can be achieved. This use of a common depth has been taken up by Hsu (1990) in his proposal for large-scale parallelism. Depth limits are also an important part of changing search modes and in managing transposition tables.

38.5.2.1 Parallel Aspiration-Window Search

In an early paper on parallel game-tree search, Baudet (1978) suggests partitioning the range of the alpha-beta window rather than the tree. In his algorithm, all processors search the whole tree, but each with a different, nonoverlapping, alpha-beta window. The total range of values is subdivided into P smaller intervals (where P is the number of processors), so that approximately one-third of the range is covered. The advantage of this method is that the processor having the true minimax value inside its narrow window will complete more quickly than a sequential algorithm running with a full window.

Even the unsuccessful processors return a result: They determine whether the true minimax value lies below or above their assigned search window, providing important information for rescheduling idle processors until a solution is found.

Its low communication overhead and lack of synchronization needs are among the positive aspects of Baudet's approach. On the negative side, however, Baudet estimates a maximum speedup of between 5 and 6 even when using infinitely many processors. In practice, PWS can only be effectively employed on systems with two or three processors. This is because even in the best case (when the successful processor uses a minimal window), at least the critical game tree must be expanded. The critical tree has about the square root of the leaf nodes of a uniform tree of the same depth, and it represents the smallest tree that must be searched under any circumstances.

38.5.2.2 Advanced Tree-Splitting Methods

Results from fully recursive versions of PVSplit using the Parabelle chess program (Marsland and Popowich, 1985) confirmed the earlier simulations and offered some insight into a major problem: In a P-processor system, P1 processors are often idle for an inordinate amount of time, thus inducing a high synchronization overhead for large systems. Moreover, the synchronization overhead increases as more processors are added, accounting for most of the total losses, because the search overhead (number of unnecessary node expansions) becomes almost constant for the larger systems. This led to the development of variations that dynamically assign processors to the search of the PV. No table is the work of Schaeffer (1989), which uses a loosely coupled network of workstations, and Hyatt et al. (1989) independent implementation for a shared-memory computer. These dynamic splitting works have attracted growing attention through a variety of approaches. For example, the results of Feldmann et al. (1990) show a speedup of 11.8 with 16 processors (far exceeding the performance of earlier systems), and Felten and Otto (1988) measured a 101 speedup on a 256 processor hypercube. This latter achievement is noteworthy because it shows an effective way to exploit the 256 times bigger memory that was not available to the uniprocessor. The use of the extra transposition table memory to hold results of search by other processors provides a significant benefit to the hypercube system, thus identifying clearly one advantage of systems with an extensible address space.

These results show a wide variation not only of methods but also of apparent performance. Part of the improvement is accounted for by the change from a static assignment of processors to the tree search (e.g., from PVSplit) and to the dynamic processor reallocation schemes of Hyatt et al. (1989) and also Schaeffer (1989). These latter systems try to dynamically identify the ALL nodes of Figure 38.9 and search them in parallel, leaving the CUT nodes (where only a few successors might be examined) for serial expansion. In a similar vein, Ferguson and Korf (1988) proposed a "bound-and-branch" method that only assigned processors to the leftmost child of the tree-splitting nodes where no bound (subtree value) exists. Their method is equivalent to the static PVSplit algorithm and realizes a speedup of 12 with 32 processors for alpha-beta trees generated by Othello programs. This speedup result might be attributed to the smaller average branching factor of about 10 for Othello trees, compared to an average branching factor of about 35 for chess. If that uniprocessor solution is inefficient—for example, by omitting an important node-ordering mechanism like the use of transposition tables (Reinefeld and Marsland, 1994)—the speedup figure may look good. For that reason, comparisons with a standard test suite from a widely accepted game are often done and should be encouraged. Most of the working experience with parallel methods for two-person games has centered on the alpha-beta algorithm. Parallel methods for more node-count-efficient sequential methods, like SSS*, have not been successful until recently, when the potential advantages of using heuristic methods like hash tables to replace the OPEN list were exploited (Plaat et al., 1995).

38.5.2.3 Dynamic Distribution of Work

The key to successful large-scale parallelism lies in the dynamic distribution of work. There are four primary issues in dynamic search: (1) *Search overhead* measures the size of the tree searched by the parallel method with respect to the best sequential algorithm. As mentioned earlier, in some cases, superlinear

speedup can occur when the parallel algorithm actually visits fewer nodes. (2) *Synchronization overhead* problems occur when processors are idle waiting for the results from other processors, thus reducing the effective use of the parallel computing power (processor utilization). (3) *Load balancing* reflects how evenly the work has been divided among available processors and similarly affects processor utilization. (4) *Communication overhead* in a distributed memory system occurs when results must be communicated between processors via message passing.

Each of these issues must be considered in designing a dynamic parallel algorithm. The distribution of work to processors can either be accomplished in a work-driven fashion, whereby idle processors must acquire new work either from a Blackboard or by requesting work from another processor.

The young brothers wait concept (Feldmann, 1993) is a work-driven scheme in which the parallelism is best described through the help of a definition: The search for a successor $N.j$ of a node N in a game tree must not be started until after the leftmost sibling $N.1$ of $N.j$ is completely evaluated. Thus, $N.j$ can be given to another processor if and only if it has not yet been started and the search of $N.1$ is complete. Since this is also the requirement for the PVSplit algorithm, how then do the two methods differ and what are the trade-offs? There are two significant differences. The first is at start-up and the second is in the potential for parallelism. PVSplit starts much more quickly since all the processors traverse the first variation (first path from the root to the search horizon of the tree) and then split the work at the nodes on the path as the processors back up the tree to the root. Thus, all the processors are busy from the beginning, but on the other hand, this method suffers from increasingly large synchronization delays as the processors work their way back to the root of the game tree (Marsland and Popowich, 1985). Thus, good performance is possible only with relatively few processors, because the splitting is purely static. In the work of Feldmann et al. (1990), the start-up time for this system is lengthy, because initially only one processor (or a small group of processors) is used to traverse the first path. When that is complete, the right siblings of the nodes on the path can be distributed for parallel search to the waiting processors. If, for example, in the case of one thousand such processors, possibly less than one percent would initially be busy. Gradually, the idle processors are brought in to help the busy ones, but this takes time. However, and here comes the big advantage, the system is now much more dynamic in the way it distributes work, so it is less prone to serious synchronization loss. Further, although many of the nodes in the tree will be CUT nodes (which are a poor choice for parallelism because they generate high search overhead), others will be ALL nodes, where every successor must be examined and they can simply be done in parallel. Usually CUT nodes generate a cutoff quite quickly, so by being cautious about how much work is initially given away once $N.1$ has been evaluated, one can keep excellent control over the search overhead while getting full benefit from the dynamic work distribution that Feldmann's method provides.

On the other hand, transposition-driven work scheduling (TDS) for parallel single-agent and game-tree searches, proposed by Romein et al. (1999), is a data-driven technique that in many cases offers considerable improvements over work-driven scheduling on distributed memory architectures. TDS reduces the communication and memory overhead associated with the remote lookups of transposition tables partitioned among distributed memory resources. This permits lookup communication and search computation to be integrated. The use of the transposition tables in TDS, as in IDA*, prevents the repeated searching of previously expanded states.

TDS employs a distributed transposition table that works by assigning to each state a "home processor," where the transposition entry for that state is stored. A signature associated with the state indicates the number of its home processor. When a given processor expands a new state, it evaluates its signature and sends it to its home processor, without having to wait for a response, thus permitting the communication to be carried out asynchronously. In other words, the work is assigned to where the data on a particular state are stored, rather than having to lookup a remote processor's table and wait for the results to be transmitted back. Alternatively, when a processor receives a node, it performs a lookup of its local transposition table to determine whether the node has been searched before. If not, the node is stored in the transposition table and added to the local work queue. Furthermore, since each transposition table entry includes a search bound, this prevents redundant processing of the same subtree by more than one processor.

The resulting reduction in both communication and search overhead yields significant performance benefits. Speedups that surpass IDA* by a factor of more than 100 on 128 processors (Romein et al., 1999) have been reported in selected games.

Cook and Varnell (1998) report that TDS may be led into doing unnecessary work at the goal depth, however, and therefore they favor a hybrid combination of techniques that they term *adaptive parallel iterative deepening search*. They have implemented their ideas in the system called EUREKA. Their system employs machine learning to select the best technique for a given problem domain. They have recently added the HyPS algorithm (Cook, 2011) to their system, as discussed earlier.

38.5.2.4 Recent Developments

Despite advances in parallel single-agent search, significant improvement in methods for game-tree search has remained elusive. Theoretical studies have often focused on showing that linear speedup is possible on worst-order game trees. While not wrong, they make only the trivial point where exhaustive search is necessary and where pruning is impossible, and then even simple work distribution methods may yield excellent results. The true challenge, however, is to consider the case of average game trees or, even better, the strongly ordered model (where extensive pruning can occur), resulting in asymmetric trees with a significant work distribution problem and significant search overhead. The search overhead occurs when a processor examines nodes that would be pruned by the sequential algorithm, but has not yet received the relevant results from another processor.

The intrinsic difficulty of searching game trees under pruning conditions has been widely recognized. Hence, considerable research has been focused on the goal of dynamically identifying when unnecessary search is being performed, thereby freeing processing resources for redeployment. For example, Feldmann et al. (1990) used the concept of making “young brothers wait” to reduce search overhead and developed the “helpful master” scheme to eliminate the idle time of masters waiting for their slaves’ results. On the other hand, young brothers wait can still lead to significant synchronization overhead.

Generalized DFSs are fundamental to many AI problems. In this vein, Kumar and Rao (1990) have fully examined a method that is well suited to doing the early iterations of single-agent IDA* search. The unexplored parts of the trees are marked and are dynamically assigned to any idle processor. In principle, this work distribution method (illustrated in Figure 38.12) could also be used for deterministic adversary game trees. Shoham and Toledo (2001) developed a parallel, randomized best-first minimax search (RBFM). RBFM expands terminal nodes randomly chosen, with higher probabilities assigned to nodes with better values. This method seems amenable to parallelism but seems to suffer from speculative search overhead.

The invention of MTD(f) seemed to provide new hope for parallel game-tree search. Romein (2000) developed a parallel version of MTD(f) that achieved speedup over other parallel game-tree algorithms. Kishimoto and Schaeffer (2002) have developed an algorithm called TDSAB that combines MTD(f) with the transposition table-driven scheduling of TDS to achieve significant performance gains in a number of selected games. MIT’s parallel chess program Cilkchess employs a parallel version of the algorithm [supertech.csail.mit.edu/cilk/]. However, Kishimoto and Schaeffer also report that attempts at parallelizing MTD(f) can suffer from excessive synchronization overhead.

On a massively parallel system, the opportunity arises to effectively employ several techniques simultaneously when searching a game tree. A combination of a PWS search with a distributed tree search (DTS), as embodied by the HyPS algorithm of Cook (2011), is a hopeful approach. Groups of processors are assigned different thresholds or windows, thereby reducing the overhead of the duplicate work in iterative deepening search. Within each group, the threshold search of the tree can be parallelized, as in DTS, using the dynamic workload-balancing techniques discussed earlier. IBM’s Blue Gene supercomputers have been used for chess.

Many researchers feel that hardware advances will ultimately increase parallel processing power to the point where we will simply overwhelm the problem of game-tree search with brute force. They feel that this will make the need for continued improvement of parallel game-tree algorithms less critical.

Perhaps in time we will know if massive parallelism solves all our game-tree search problems. However, the results of complexity theory should assure us that unless $P = NP$, improvements in search techniques and heuristics will remain both useful and desirable.

38.6 Nature-Based Search

This section discusses search techniques that are either inspired by natural processes or derived from computational methods that have been used to simulate natural processes.

38.6.1 Monte Carlo Simulation

Earlier in this work, the speedup of a parallel algorithm was defined as

$$\text{Speedup} = \frac{\text{Time taken by a sequential single-processor algorithm}}{\text{Time taken by a P-processor algorithm}}$$

This represents an upper bound on the time savings that can be expected from parallel processing. It is evident that as larger computational tasks are confronted, parallelism alone will fail to provide the requisite computing speeds. All of the algorithms in this section rely upon probability to some extent (even TS described in 6.5 has a probabilistic version).

An early use of probability in search is with Monte Carlo simulation. This approach was widely used by John von Neumann, Stanislaw Ulam, and Nicholas Metropolis in their work on the Manhattan Project during the 1940s. These simulations use random numbers drawn from some prescribed probability distribution. This method has been used in application areas as diverse as portfolio preparation (Wu and Gertner, 2012) to Soduko (Mayorov and Whitlock, 2011). This methodology is explained thoroughly elsewhere in this book.

38.6.2 Simulated Annealing

Previously, we discussed hill climbing, a heuristic search that relies upon our insights into a problem to help make large search trees less daunting. The price we pay is that sometimes hill climbing settles at a local optimum. SA is a probabilistic search that allows counterintuitive moves with some prescribed probability. SA gets its name from the physical process of annealing wherein a metal is heated until it liquefies and then is slowly cooled until it resolidifies. Molecules in annealed metals are rearranged and metals that undergo this process are stronger and more pliable.

A successful search algorithm relies upon two strategies: *exploitation* and *exploration*. The intuition behind exploitation is that opportune points in the search space are likely to lie close to one another. Meanwhile, exploration encourages movement to a different portion of the search space, which may yield a superior return. Hill climbing searches rely heavily on exploitation as small incremental jumps are pursued as long as the objective function continues to improve. SA seeks to balance these two seemingly opposed strategies. It does so by employing a temperature parameter T , which is set to a high initial value. As the simulation progresses, T is lowered according to a *cooling schedule*. An SA search will jump from two points in the search space, x_{old} to x_{new} , whenever the objective function $F()$ is improved at x_{new} , that is, whenever $f(x_{new}) \geq f(x_{old})$ (assuming that optimum in this context means maximum). An SA differs from hill climbing, however, in that backward jumps are permitted with a probability P , which is proportional to

$$e^{-[f(x_{old})-f(x_{new})/T]} \quad (38.1)$$

FIGURE 38.13 A search in which SA is likely to outperform hill climbing.

In Figure 38.13, if a hill climbing search were to begin at x_0 , exploitation would lead it to the local optimum $f(x^*)$. An SA search would likely fare better as a counterintuitive jump from x_3 to x_4 is possible, thereby enabling convergence to the global optimum of $f(x_{best})$. Inspection of Equation 38.1 apprises us that backward jumps in an SA search are more likely when the temperature parameter T is higher. Hence, the early stages of SA favor exploration, whereas later in a search when T is lower, exploitation becomes more probable. We close our discussion by commenting that SA does not guarantee a global optimum. The likelihood of successful termination may be obtained in two ways:

1. Run the simulation longer.
2. Restart the search several times commencing the simulation each time at a different locations in the state space.

S. Kirkpatrick, C.D. Galatt, and M.P. Vecchi discovered SA in 1983 (Kirkpatrick et al., 1983).

This methodology was discovered independently in 1985 by V. Cerny (1985).

The SA search is based upon the Metropolis–Hastings algorithm (1953). SA has been effective in the solution of optimization problems.

38.6.3 Genetic Algorithms

GAs are an uninformed search as no prior knowledge is presumed about the problem domain. GA is similar to the algorithms described in Section 38.5 in that they use parallelism. In GA, a problem’s solution is encoded by a string. We consider a trivial problem to help explain the methodology. We wish to learn the two-input NOR function (see Table 38.1).

Observe that the NOR function is the complement of the two-input (inclusive) OR function. The NOR of X_1 and X_2 , written $X_1 \downarrow X_2$, equals 1 only when both X_1 and X_2 are equal to zero. We begin with a

TABLE 38.1 2-Input NOR Function

X_1	X_2	$X_1 \downarrow X_2$
0	0	1
0	1	0
1	0	0
1	1	0

String	Fitness
$s_1 = 1100$	3
$s_2 = 0101$	1
$s_3 = 0000$	3
$s_4 = 0111$	0

FIGURE 38.14 The initial population for our example. The fitness of each string is also given.

String	Fitness	Proportion of Fitness Possessed
s_1	3	$f_1/\Sigma f_i = 3/5 = 0.6$
s_2	1	$f_2/\Sigma f_i = 1/5 = 0.2$
s_3	1	$f_3/\Sigma f_i = 1/5 = 0.2$
s_4	0	$f_4/\Sigma f_i = 0/5 = 0$
		Total fitness of the population = 5 Maximum fitness = 3

FIGURE 38.15 The total and maximum fitness for population P_0 , together with the proportion of fitness possessed by each string.

String	Mate	Crossover Point	After Crossover	After Mutation
$s_1 = 1100$	s_2	$k = 3$	1101	1101
$s_2 = 0101$	s_1	$k = 3$	0100	010 <u>1</u>
$s_3 = 1100$	s_4	$k = 2$	1000	1000
$s_4 = 0000$	s_3	$k = 2$	0100	0100

FIGURE 38.16 Selection of mates.

population of strings—population size is arbitrarily set to four. The strings in this initial population (P_0) are formed by using a random number generator (*rng*). GA is an iterative procedure. A *fitness function* is used to obtain better solutions. The fitness of a string (s_i) is a measure of how well a string solves the given problem. We have a choice of representation. We can write the entries in Table 38.1 in row major order, that is, the first row 001 followed by row 010, yielding a string of length 12. Alternately, we can encode solutions via binary strings of length four; the i th bit of a string represents the result of NORing the two inputs in row i . We choose the latter representation in this example.

For example, suppose our *rng* yields the string $s_1 = 1100$. It is natural to assign a fitness, $f(s_1) = 3$, as s_1 correctly represents the NOR of three of the entries in Table 38.1, that is, rows one, three, and four; however, the second bit of $s_1 = 1$, whereas the NOR of 0 with 1 equals 0 and not 1. Assume that our *rng* yields the four strings $s_1 = 1100$, $s_2 = 0101$, $s_3 = 0000$, and $s_4 = 0111$. These four strings are depicted in Figure 38.14 along with their fitness measures.

We use three so-called *genetic operators* to obtain the next population (or generation) from the current population. Initially we obtain P_1 and so on. We continue this process until a solution is found in some population, or else the algorithm fails to converge to a solution in the allotted computation time. Three popular genetic operators are *selection*, *crossover* (also recombination), and *mutation*. With selection (more accurately, roulette wheel selection), a string is selected to help form the next population with a probability proportional to the percentage of the population’s total fitness that it possesses (see Figure 38.15).

Selection is performed in which two copies of s_1 and one copy each of s_2 and s_3 are chosen. Not surprisingly, string s_4 has not been selected. Next, pairs of strings are randomly chosen to mate with one another (see Figure 38.16). To avoid confusion, strings have been relabeled.

a	b
Parent ₁ = 1010000	Offspring ₁ = 1011111
Parent ₂ = 0011111	Offspring ₂ = 0010000

FIGURE 38.17 (a) Two parent strings are depicted. Crossover point $k = 4$ is randomly generated. (b) Offspring after crossover.

String	Fitness
$s_1 = 1101$	2
$s_2 = 0101$	1
$s_3 = 1000$	4
$s_4 = 0100$	2
Total fitness = 9 Maximum fitness = 4	

FIGURE 38.18 Population P_1 shown with fitness measures.

Crossover is next applied. We use a form of crossover in which two parent strings are used to form two offspring (see Figure 38.17). Other forms of crossover exist (Holland, 1975). A crossover point k is randomly selected for a pair of parent strings. In Figure 38.16, $k = 4$. Two offspring are shown in Figure 38.16b. Offspring₁ is identical to parent₁ before the crossover point (bits 1–3) and identical to parent₂ after the crossover point (bits 4–7). Similarly, offspring₂ is identical to parent₂ before the crossover point and identical to parent₁ after. The results of crossover are shown in the third and fourth columns of Figure 38.16.

Finally, mutation is applied to form the new population of strings. A bit in a string is inverted with a small probability of perhaps $p = 0.001$. In our toy example, we let this probability $p = 0.1$. Observe that the rightmost bit of the second string has been inverted, that is, 0100 has become 0101. The new population (P_1) is shown in Figure 38.18, with updated fitness measures. Once again, to avoid confusion, strings have been relabeled. Both the total and the maximum fitness of this population have increased. Furthermore, string s_3 solves this problem.

Recapitulating, GAs are blind, parallel, iterative, and probabilistic. GAs have been successful in many search applications—ranging from portfolio planning and stock market prediction to scheduling satellite orbits and airport landings (Williams et al., 2001). They have also met success in game playing (Chellapilla and Fogel, 2002).

GA was discovered by John Holland in the late 1960s at the University of Michigan (Holland, 1975). He cites the work of Charles Darwin as providing his inspiration. Darwin’s theory of evolution attempts to explain how natural selection enables species of flora and fauna to better adapt to conditions on this planet (Darwin, 1859, 1994, 2001). Goldberg (1989) likens the process of GA search to the process of brainstorming at a business meeting. Additional examples of GA search may be found in Lucci and Kopec (2013). The mathematics that justifies the success of GA may be found in Goldberg (1989) and Holland (1992).

38.6.4 Genetic Programming

GAs are a parallel search wherein a population of strings guided by a fitness function and genetic operators iteratively modifies strings until a solution to a problem is hopefully discovered. With *genetic programming* (GP), the goal is to design a program whose output is the solution to a given problem. GP is also a parallel algorithm; however, we cannot simply begin with a population of strings as each string must encode a properly constructed program. Traditionally, GP has worked well with LISP and other functional languages, which are based on lists; however, imperative languages such as C++ and Java are currently being used in what is known as linear GP (Brameier and Banzhaf, 2006).

FIGURE 38.19 The list (x ('y)) represents the tree shown and computes the function $x \cdot y'$.

FIGURE 38.20 Crossover in a genetic program. (a) Fracture points (\rightarrow) are selected in two parents. (b) Offspring shown after crossover.

Programs in LISP may be represented as lists. For example, the function $f(x,y)$ can be represented as $(f x y)$; the function f is followed by its two arguments, x and y . Programs in LISP can consist of functions and terminals. Functions for a problem in Boolean logic might consist of $\{+,.,'\}$, that is, the OR function, AND function, and negation. The list $(.x ('y))$ computes $x \cdot y'$ as depicted in Figure 38.19.

Three operators that are used in GP are crossover, *inversion*, and mutation. The first step in application of these operators is to identify a fracture point in the list where changes can occur. The beginning of a sublist or at a terminal is permissible fracture points. To perform crossover,

1. Select two programs from the present population
2. Randomly choose two sublists, one from each parent
3. Exchange these sublists in their offspring (see Figure 38.20)

Inversion can be accomplished by

1. Randomly selecting an individual from the present population
2. Randomly choosing two fracture points from the selected individual
3. Exchanging the specified subtrees (see Figure 38.21)

The third operator cited is mutation:

1. Choose an individual program from the present population.
2. Randomly replace a function symbol with some often function symbol OR—replace any terminal symbol with another.

An example of mutation is shown in Figure 38.22.

FIGURE 38.21 With inversion, a single parent produces one offspring. (a) Two fracture points (\leftarrow ; \rightarrow) selected in a program. (b) After inversion, we have a new program.

FIGURE 38.22 An individual parent is modified in mutation to produce a single offspring. (a) An individual parent before mutation with its selected node shown. (b) After mutation, Boolean OR in the right subtree has been changed to ANDing.

FIGURE 38.23 Four random programs with fitness shown.

With mutation, you need to perform type checking. For example, if Boolean operations are being performed, then 0 and 1 are the only operands permitted.

It is widely held that Koza discovered GP. He advises strategies for the creation of a random population. The interested reader is referred to Koza et al. (2000, 2003) for more details. To provide some insight to this methodology, we revisit our example from the previous section. There, we were using GA to search for a string that mirrored the functionality of the two-input NOR function (see Table 38.1). With a GP we seek to discover a program that when presented with two Boolean values, x_1 and x_2 , produces $x_1 \downarrow x_2$ as output. In this toy example, we shall assume that our initial population of programs consists of four trees as shown in Figure 38.23. In realistic applications, an initial population may consist of thousands of programs.

The fitness of each program is also shown in this figure. As a fitness measure, we have used the number of rows of the NOR table that each program correctly computes. For example, when $x_1 = 0$ and $x_2 = 1$, program 1 produces an output of 0, which correctly reflects the second row of Table 38.1; however, for the other three truth assignments for x_1 and x_2 , program 1 produces an output that differs from the NOR table.

Suppose that crossover is performed between programs 2 and 4 as shown in Figure 38.23 at the selected fracture points. The left offspring in Figure 38.24b is seen to have a fitness of 4 and hence correctly computes the two-input NOR function. We admit that the initial population in Figure 38.22 was

FIGURE 38.24 A fortuitous example of crossover. (a) Programs 2 and 4 with selected fracture points (\rightarrow ; \leftarrow) shown. (b) Two offspring after crossover.

not chosen randomly, and the choice of which genetic operator in Figure 38.23 (as well as the selection of population members and fracture points) also was performed with some forethought. It should be apparent, however, that permitted a larger population and allowed ample iterations, a GP would successfully solve this problem. In fact, GPs have obtained remarkable results in a number of areas—ranging from antenna design (Koza et al., 2000) to robotics (Messom and Walker, 2002). A list of new inventions discovered by GP is listed in Koza (2005).

38.6.5 Tabu Search

The previous four searches owe their discovery to some extent to natural processes. SA relies upon the metaphor provided by the annealing of metals. The evolutionary approaches of GA and GP borrow generously from Darwin's theory of natural evolution. Finally, ant colony optimization reflects the intelligence by colonies of ants. *Tabu* (also called *Taboo*) search (TS) stresses the importance of memory. To balance both exploitation and exploration, TS maintains two types of lists. A *recency Tabu list* (RTL) monitors the moves made that transfer one state of the search into another; these moves cannot be repeated until some period of time (the Tabu tenure that is set by the programmers) has elapsed. The RTL encourages exploration. TS also uses lists to control so-called aspiration criteria.

One such criterion—*aspiration by default*—will select the oldest move whenever there is a “deadlock” and all moves Tabu. Another aspiration criterion—*aspiration by direction*—favors moves that have led to superior past values of the objective function. Exploitation is fostered by this heuristic. Finally, there is an aspiration criterion that favors exploration—*aspiration by influence*—in which moves that lead to unexplored regions of the state space are favored.

TS was developed by Fred Glover in the 1970s (1997). TS has been successfully applied to problems in optimization. This methodology has also been applied to pattern classification, VLSI design, and numerous other problem domains (Emmert et. al., 2004, Glover, 1995, Tung and Chou, 2004).

38.6.6 Ant Colony Optimization

Ant colonies provide the metaphor for our next search paradigm. It is well known by entomologists that ant colonies possess remarkable intelligence. Their intellectual prowess is an example of emergent behavior, behavior at one level (often unexpected) that derives from a lower level. At the microscopic

FIGURE 38.25 Ants foraging, depositing, and dispersing from a discovered food source. (a) Ants are moving randomly. (b) Food source discovered. Ants return to nest carrying food and depositing pheromones. (c) Ants follow the pheromone trail from the nest to food source, some still move randomly.

level, however, concepts of temperature and pressure are meaningless as gas molecules have only a location and a kinetic energy level.

The emergent behavior of interest to us here is the intelligence possessed by ant colonies. In the present search, ants are viewed as agents—entities that are capable of sensing the environment, communicating with one another, and responding to the conundrums posed by their environment. M. Dorigo was the first to apply *ant colony optimization* to solve combinatorial problems (Dorigo, 1992).

Ant foraging will prove useful to us in what follows. If you were to introduce a source of food in proximity to an ant colony, ant foragers will undoubtedly form a trail that would enable their brethren to locate and retrieve this nourishment (see Figure 38.25).

In Figure 38.25a, forager ants have discovered the food source. These explorers will communicate their discovery to other ants by a process known as *stigmergy*—this is a form of indirect communication between ants. On the way back to their nest, explorer ants deposit pheromones on their trail (Figure 38.24b); these are chemicals that ants produce. There are two advantages to this form of communication:

1. One ant need not know the location of the other ants that it is communicating with.
2. The communication signal will not perish even if the sender does.

The pheromone trail will encourage exploitation by other ants in the colony.

Consult Figure 38.25c and you observe that not every ant is following the recently discovered trail. The seemingly random behavior of these foragers encourages exploration, that is, they are searching for alternate food sources that are vital for the colony's long-term survival.

We began this section by claiming that ant colony behavior was applicable to combinatorial optimization. The process of trail formation and following is used by some ant species to identify a shortest path between their colony and some food source. This facility for optimization was apparent from experiments conducted by Deneubourg and colleagues (1991).

Figure 38.26 contains a source of food that is separated from an ant colony by two paths of different lengths. In Figure 38.26a there is a barricade separating the ants from the two paths.

FIGURE 38.26 Ants separated from their colony. (a) Ants blocked by door. (b) Door raised and ants travel arbitrarily to food source, returning to nest to deposit pheromones. (c) More ants at nest follow the left (shorter) path to food source.

In Figure 38.26b the barricade is removed and we observe that ants are as likely to choose either path. The situation after some time has elapsed is shown in Figure 38.26c; ants are favoring the shorter path.

The longer path is not entirely devoid of ant traffic as this is a form of exploration. We mentioned earlier that trails are formed by pheromone deposits from explorer ants. As time passes, this chemical will evaporate. The return trip from the food sources to the ant colony will require more time along the longer path, and hence, more of the pheromone deposited there will have an opportunity to evaporate. Due to this pheromone evaporation, the shorter route will contain more pheromone than the longer one. Carrying food back to the colony will require numerous trips, visited by many ants in these additional journeys.

Choosing a shorter path enables ants to utilize less energy in food collection enabling them to finish faster. Ants thereby avoid competition from nearby colonies and are also less likely to encounter predators.

Dorigo et al. used artificial ants and artificial pheromone trails to solve instances of the TSP problem (Dorigo and Stutzle, 2004).

38.7 Most Recent Developments

The advent of the World Wide Web (WWW) in 1993 naturally led to interest in search techniques for the Internet, especially when intelligence can be applied. Search engines are computer programs that can automatically contact other network resources on the Internet, searching for specific information or key words, and report the results of their search. Intelligent agents are computer programs that help the users to conduct routine tasks, to search and retrieve information, to support decision-making, and to act as domain experts. They do more than just “search and match.” There are intelligent agents for consumers that search and filter information. Intelligent agents have been developed for product and vendor finding, for negotiation, and for learning. They can help determine what to buy to satisfy a specific need by looking for specific products’ information and then critically evaluating them. Some examples are Firefly, which uses a *collaborative filtering* process that can be described as “word of mouth” to build

the profile. It asks a consumer to rate a number of products and then matches his or her ratings with the ratings of other consumers with similar tastes, recommends products that have not yet been rated by the consumer, etc. Intelligent agents for finding products and vendors enabling discovery of bargains.

One example is Jango from NetBot/Excite. It originates requests from the user's site (rather than Jango's). Vendors have no way of determining whether the request is from a real customer or from the agent. Jango provides product reviews. Kasbah, from MIT Lab, is for users who want to sell or buy a product. It assigns the task to an agent who is then sent out to proactively seek buyers or sellers. Intelligent agents for consumers can act as negotiation agents, helping to determine the price and other terms of transactions. Kasbah has multiple agents. Users create agents for the purpose of selling and buying goods. It can exemplify three strategies: anxious, cool headed, and frugal. Tete-a-tete is an intelligent agent for considering a number of different parameters: price, warranty, delivery time, service contracts, return policy, loan options, and other value-added services. Upon request, it can even be argumentative. Finally, there are learning agents capable of learning individuals' preferences and making suitable suggestions based upon these preferences. Memory Agent from IBM and Learn Sesame from Open Sesame use learning theory for monitoring customers' interactions. It learns customers' interests, preferences, and behavior and delivers customized service to them accordingly (Deitel et al., 2001). Expect many interesting developments in this arena combining some of the theoretical findings we have presented with practical situations, to achieve exciting results.

Key Terms

- A* algorithm:** A best-first procedure that uses an admissible heuristic estimating function to guide the search process to an optimal solution.
- Admissibility condition:** The necessity that the heuristic measure never overestimates the cost of the remaining search path, thus ensuring that an optimal solution will be found.
- Alpha-beta:** The conventional name for the bounds on a depth-first minimax procedure that are used to prune away redundant subtrees in two-person games.
- AND/OR Tree:** A tree that enables the expression of the decomposition of a problem into subproblems; hence, alternate solutions to subproblems through the use of AND/OR node labeling schemes can be found.
- Ant colony optimization:** An algorithm based on the behavior of natural ant colonies.
- Aspiration criteria:** Conditions in a TS that encourage both exploitation and exploration. For example, aspiration by influence favors moves that lead to unexplored region of the search space. This condition fosters exploration.
- Backtracking:** A component process of many search techniques whereby recovery from unfruitful paths is sought by backing up to a juncture where new paths can be explored.
- Best-first search:** A heuristic search technique that finds the most promising node to explore next by maintaining and exploring an ordered OPEN node list.
- Bidirectional search:** A search algorithm that replaces a single search graph, which is likely to grow exponentially, with two smaller graphs—one starting from the initial state and one starting from the goal state.
- Blind search:** A characterization of all search techniques that are heuristically uninformed. Included among these would normally be state-space search, means-ends analysis, generate and test, DFS, and breadth-first search.
- Branch and bound algorithm:** A potentially optimal search technique that keeps track of all partial paths contending for further consideration, always extending the shortest path one level.
- Breadth-first search:** An uninformed search technique that proceeds level by level visiting all the nodes at each level (closest to the root node) before proceeding to the next level.
- Cooling schedule:** Simulating annealing uses a temperature parameter (T). Early in the search, T is high, thus encouraging exploration. As the search continues, T is lowered according to some schedule.

- Crossover:** A genetic operator that is used in both GA and GP searches. Crossover is used to generate new populations in these searches.
- Data-driven parallelism:** A load-balancing scheme in which work is assigned to processors based on the characteristics of the data.
- Depth-first search:** A search technique that first visits each node as deeply and to the left as possible.
- Exploitation:** A strategy in search algorithms that encourages staying in regions with good objective functions.
- Exploration:** A search algorithm strategy that encourages movement to unexplored regions of a search space.
- Fitness function:** A measure of goodness that is assigned to a potential solution to a given problem.
- Fracture point:** A location in a tree that identifies where a genetic operator is to be applied (used in GP).
- Generate and test:** A search technique that proposes possible solutions and then tests them for their feasibility.
- Genetic algorithm:** A blind search that is based on Darwin's theory of evolution. It is a blind search that is both parallel and probabilistic.
- Genetic operators:** Operators that are used in both GAs and GP to help form a new population.
- Genetic programming:** A parallel search in which a program is found that solves a given problem. Operators based upon Darwinian evolution drive this search.
- Heuristic search:** An informed method of searching a state space with the purpose of reducing its size and finding one or more suitable goal states.
- HyPS:** A hybrid search that combines PWS with DTS.
- Inversion:** One of the genetic operators used in GP. Inversion will randomly exchange two subtrees in a potential solution program.
- Iterative deepening:** A successive refinement technique that progressively searches a longer and longer tree until an acceptable solution path is found.
- Mandatory work first:** A static two-pass process that first traverses the minimal game tree and uses the provisional value found to improve the pruning during the second pass over the remaining tree.
- Means-ends analysis:** An AI technique that tries to reduce the "difference" between a current state and a goal state.
- Monte Carlo simulation:** An early search that employs random numbers to model uncertainty.
- MTD(f) algorithm:** A minimal window minimax search recognized as the most efficient alpha-beta variant.
- Mutation:** A genetic operator that is used in both GA and GP searches. Mutation fosters genetic diversity in a population.
- Parallel window aspiration search:** A method where a multitude of processors search the same tree but each with different (nonoverlapping) alpha-beta bounds.
- PVSplit:** A static parallel search method that takes all the *processors down the first variation to some limiting depth and then splits the* subtrees among the processors as they back up to the root of the tree.
- Recency Tabu list:** A list maintained in a TS to foster exploration.
- Selection:** A strategy used in both GA and GP searches. Selection helps to choose those potential solutions that will help to form the next population in a search.
- Simulated annealing:** A stochastic algorithm that returns optimal solutions when given an appropriate "cooling schedule."
- SSS*:** A best-first search procedure for two-person games.
- Stigmergy:** A form of indirect communication used by ants in a colony and ant agents in an ant colony-based search. Ants deposit pheromone on a trail, and this chemical can be detected by other ants.

Tabu search: A search that encourages exploration by forbidding the same moves to be made again until some prescribed time has elapsed. Criteria are also present to encourage exploitation.

Transposition table-driven scheduling (TDS): A data-driven load-balancing scheme for parallel search that assigns a state to a processor based on the characteristics or signature of the given state.

Work-driven parallelism: A load-balancing scheme in which idle processors explicitly request work from other processors

Young brothers wait concept: A dynamic variation of PVSplit in which idle processors wait until the first path of leftmost subtree has been searched before giving work to an idle processor.

Acknowledgments

The authors thank Islam M. Guemey for help with research, Erdal Kose for the best-first example, and David Kopec for technical assistance and assistance with artwork, as well as Andrew Convissar for help with figures in Section 38.6.

Further Information

The most regularly and consistently cited source of information for this article is the Journal of Artificial Intelligence. There are numerous other journals including *AAAI Magazine*, *CACM*, *IEEE Expert*, *ICGA Journal*, and the *International Journal of Computer Human Studies*, which frequently publish articles related to this subject area. Also prominent has been the *Machine Intelligence Series* of Volumes edited by Donald Michie with various others. An excellent reference source is the 3-volume Handbook of Artificial Intelligence by Barr and Feigenbaum (1981).

In addition, there are numerous national and international and national conferences on AI with published proceedings, headed by the *International Joint Conference on AI (IJCAI)*. Classic books on AI methodology include Feigenbaum and Feldman's (1963) *Computers and Thought* and Nils Nilsson's (1971) *Problem-Solving Methods in Artificial Intelligence*. There are a number of popular and thorough textbooks on AI. Two relevant books on the subject of search in are *Heuristics* (Pearl, 1984) and the more recent *Search Methods for* (Bolc and Cytowski). AI texts that have considerable focus on search techniques are George Luger's *Artificial Intelligence* (6th edn., 2008), Russell and Norvig's *Artificial Intelligence: a modern approach* (3rd edn., 2010), and most recently Lucci and Kopec's *Artificial Intelligence in the 21st century* (2013).

39.1 Introduction

Planning and scheduling are two closely related terms that are frequently interchanged in practical life. In the industrial environment, planning often means long-term scheduling, for example, allocating contract work to departments for the next several months, while scheduling means detailed scheduling, for example, allocating jobs or operations to machines with a minute precision. Hence, it may seem surprising that planning and scheduling are actually two different research areas that originated in different fields and that exploit different problem-solving techniques.

The term *planning* refers to a process of creating an organized set of actions, a *plan*, that can be executed to achieve a desired goal from a given initial situation (state), while the term *scheduling* usually refers to a process of assigning a set of actions to resources over time, the output is called a *schedule*. In complex problems, we typically start with planning, that is, we decide what to do—which actions need to be executed to achieve the goal. After that, we continue with scheduling, that is, we decide how to do it—how to allocate the actions to scarce resources and time to obtain a schedule. Finally, we execute the schedule, which involves monitoring of actions and revoking the planning and scheduling stages when necessary. This chapter covers techniques for planning and scheduling and omits the details of plan/schedule execution.

Planning is an important aspect of rational behavior and it is a fundamental topic of artificial intelligence since its beginning. Planning capabilities are necessary for autonomous controlling of vehicles of many types including space ships (Muscettola et al., 1998) and submarines (McGann et al., 2008), but we can also find planning problems in areas such as manufacturing, games, or even printing machines (Ruml et al., 2005). Planning techniques are frequently domain independent, which means that the planning system gets a formal description of a planning domain in addition to a particular problem instance as its inputs. The planning domains can be as diverse as forming towers from blocks (useful for planning in container terminals), finding paths for robots to transport goods (useful for automated warehouses), and solving puzzles (useful for modeling non-player characters in computer games).

Scheduling has been studied since the 1950s when researchers were faced with problems of efficient management of operations in workshops (Leung, 2004). It became one of the fundamental topics of

operations research. Nowadays, scheduling is important in every manufacturing facility to allocate operations to machines and workers as well as, for example, in computing environments to allocate tasks to processors and memory. The research in the area of scheduling focuses mainly on solving specific classes of scheduling problems and on establishing their computational complexity rather than on providing a general scheduling technique applicable to every scheduling problem. The result is that we have a large number of scheduling algorithms for a number of specific classes of problems (Brücker, 2001). This makes scheduling very different from the approach of planning where the focus is on solving general planning problems rather than on developing ad hoc techniques for particular planning domains. In this chapter, we formulate planning and scheduling precisely, we describe the core approaches for solving planning and scheduling problems, and we show how these approaches can be integrated. We also highlight the practical importance of this technology and we overview existing challenges and possible future developments.

39.2 Underlying Principles

As we have already mentioned, despite the close relationship between planning and scheduling, these areas are studied in different fields and use different methodologies. Planning is a typical artificial intelligence topic where it is motivated by general problem solving. Scheduling traditionally belongs to operations research, combinatorial optimization, and computational complexity. It is motivated by everyday industrial requirements for efficient production. These origins are also reflected in approaches used for problem solving. The planning techniques are frequently built around a search algorithm and they cover a broad range of problems, while the scheduling techniques are usually ad hoc algorithms dedicated to a particular class of scheduling problems. Nevertheless, as the real-life problems naturally involve planning and scheduling components, the novel planning techniques are adopting some typical scheduling approaches, such as time and resource allocation, while some scheduling techniques include planning decisions, such as selection of actions to be scheduled. In the following sections, we will describe planning and scheduling approaches separately and we will also show how each approach is related to the other.

39.2.1 Automated Planning

A classical planning task is formulated as the problem of finding a sequence of actions, called a *plan*, that transfer the world from some initial state to a desired state. This task may seem like a path-finding problem in a graph, where nodes describe the world states and arcs are annotated by actions changing the state, which is indeed an abstract view of planning. However, the state space in planning is usually so huge that it is impossible even to store the whole state space (the graph) in a computer memory. Hence, a more compact representation of the state space and the transitions between the states is necessary.

To focus on the core aspects of the planning task, we make several assumptions about the world states and how the actions are changing them. Typically, we assume that the world state is *fully observable*, that is, we know precisely the state of the world where we are. A complementary assumption is a *partially observable* world meaning that we only know a possible set of states where we can be (e.g., we do not know whether the doors that we approached are locked or not and hence we need to assume both states where the doors are locked and unlocked). Another typical assumption is that the world is *deterministic*, that is, the next state is fully determined by the current state and the action that has been applied to the state. In *nondeterministic* worlds, the state after performing an action is not fully known (e.g., after grasping some block, we may hold it or the block may still be on the table, if the grasp is not strong enough and the block fell down). The third major assumption is that the world is *static* meaning that only the planned actions are changing the world states. In *dynamic* worlds, the states may change due to other reasons, for example, nature or other agents may cause such changes. Finally, we assume the actions to be instantaneous so we only deal with action sequencing and we omit time reasoning

beyond *causal relations* (actions cause changes of the world state that allow application of other actions). There exist planning systems that can deal with more general assumptions such as durative and parallel actions with uncertain effects and partially known states that may be changed by other entities (Ghallab et al., 2004).

39.2.1.1 Planning Task

As we already mentioned, the state space in planning is usually huge. To overcome this problem when representing the world states, the planning community is frequently using the representation of *world states* as finite sets of predicates. Assume that a predicate describes some particular feature of the world state, for example, `hold(blockA)` says that we hold some object called `blockA`, and `free(blockB)` says that object `blockB` is free and can be picked up. So each predicate consists of its name describing some feature and some arguments describing the objects. We assume that no functional symbols are used in the predicates. The world state is represented using a set of predicates that are true in that state. In other words, if the predicate is not present in the set representing a given state, then this predicate is not true in that state (a closed world assumption). Assuming a finite number of predicate names and constants representing the objects, we may get only a finite though possibly a huge number of states. In practice, the objects can be grouped to describe a type of the object and the attributes in predicates can be typed to restrict which constants (objects) can be used as a meaningful attribute.

Actions represent a mechanism to describe the change of the world state. We need to describe the states where an action is applicable to and how the action changes the world state. Each *action* in classical planning is specified using a triple $(\text{Prec}, \text{PosEff}, \text{NegEff})$, where Prec is a set of predicates that must hold for the action to be applicable (*preconditions*), PosEff is a set of predicates that will hold after performing the action (*positive effects*), and NegEff is a set of predicates that will not hold after performing the action (*negative effects*). For example, action `grasp(blockA, blockB)`, describing that we grasp `blockA` laying on `blockB`, can be specified as the triple $(\{\text{free}(\text{blockA}), \text{on}(\text{blockA}, \text{blockB}), \text{empty_hand}\}; \{\text{hold}(\text{blockA}), \text{free}(\text{blockB})\}; \{\text{free}(\text{blockA}), \text{on}(\text{blockA}, \text{blockB}), \text{empty_hand}\})$. In general, we say that action A is applicable to state S if $\text{Prec}(A) \subseteq S$. The result of applying action A to state S is a new state $\text{succ}(S) = (S \setminus \text{NegEff}(A)) \cup \text{PosEff}(A)$. Notice that the action is influencing only a part of the world state. The description of the state after performing the action naturally includes the *frame axiom*—the predicates that are not modified by the action stay valid in the state. In practice, rather than specifying each possible action, we may group similar actions to a so-called *operator*. For example, instead of all possible grasping actions, we can use a single operator `grasp(X, Y)`, where X and Y are variables, saying that any object X can be grasped from any object Y when some particular conditions are satisfied: $(\{\text{free}(X), \text{on}(X, Y), \text{empty_hand}\}, \{\text{hold}(X), \text{free}(Y)\}, \{\text{free}(X), \text{on}(X, Y), \text{empty_hand}\})$. An action is obtained from the operator by substituting particular constants for the variables (this is called *grounding*). Again, it is possible to use typing to restrict which constants can be used in which attributes of the operator.

The description of predicate names and operators defines a so-called *planning domain*. For example, we can describe an abstract world where we are moving blocks to build towers of blocks (the famous block world domain). A particular *planning problem* is specified by a list of objects (constants), which we are working with, a full specification of the initial state (typically, this specification defines also the objects), and a goal condition. The goal condition is typically a set of predicates that must hold in the goal state. If G is a goal condition, then any state S such that $G \subseteq S$ is a *goal state*. The planning task is formulated as the problem of finding a sequence of actions that transfer the world (defined via the `succ` function) from the initial state to some goal state. Notice in particular that the size of the plan (the number of actions) is unknown in advance and that some actions may appear several times in the plan.

The most widely used modeling language to specify planning domains and planning problems is *Planning Domain Definition Language* (PDDL) that was proposed for the International Planning Competition (Koenig, 2012). This language is following the classical logical representation described earlier.

There also exist alternative approaches to the earlier logical formalism. A straightforward extension is based on *multivalued state variables* rather than predicates (Bäckström and Nebel, 1995). In the logical representation, we use a predicate $\text{on}(\text{blockA}, \text{blockB})$ to specify that blockA is on blockB, but we can also use a function $\text{on}(\text{blockA})$ whose value is the name of the object on which the blockA rests or the constant *nothing*. Function $\text{on}(\text{blockA})$ is an example of a state variable whose value can change in time by the application of actions. Actions in the multivalued state variable representation are described by the conditions on the values of the state variables and by the assignment of the state variables as the effects. Again, we can use an abstraction to operators so the operator $\text{grasp}(X, Y)$ has the precondition $\{\text{on}(X) = Y, \text{free}(X) = \text{yes}, \text{hand} = \text{empty}\}$ and the effect $\{\text{on}(X) \leftarrow \text{nothing}, \text{free}(X) \leftarrow \text{no}, \text{free}(Y) \leftarrow \text{yes}, \text{hand} \leftarrow \text{blockA}\}$. Notice that we are no more distinguishing the positive and negative effects as the assignment defines explicitly the values of certain state variables and these values “overwrite” the original values.

When using the multivalued state variables, we can see the planning task as finding a synchronized evolution of values of these state variables that starts with given values and reaches some specified values of certain state variables. Briefly speaking, we can describe the possible evolutions of a given state variable to form a so-called *timeline*. Finite state automata can be used to compactly represent these evolutions by specifying which values can follow a given value and how actions are changing these values (Barták, 2011). Then we need to specify how the timelines are synchronized. We described the synchronization of state variables via actions in the previous paragraph, but we can omit the actions and describe the synchronization explicitly. For example, a particular change of value of certain state variable requires a change of value of another state variable. This is a more engineering view for describing system dynamics, which is, for example, used in planning for space applications (Pralet and Verfaillie, 2009). In contrast to PDDL for classical planning, there does not exist yet a standard language for specifying planning problems using timelines.

So far, we discussed a “flat” approach to planning where actions (operators) were not structured and the planning task consisted of connecting the actions via causal relations to form a plan. A different approach to planning is called *hierarchical task networks* (Erol et al., 1994). There are still actions changing the world state (via the preconditions and effects), but the actions are grouped together to form partial plans to perform some tasks. More specifically, in addition to operators, there are compound tasks describing how the operators are connected together to accomplish some job. For example, to go from city X to city Y, we can board the plane in city X, fly from X to Y, and deplane at city Y. Alternatively, we can take a train from city X to city Y. Each of these sequences of operators describes how to accomplish the task of going from city X to city Y. Note that these sequences may also contain tasks so we obtain a hierarchical structure (hence the name hierarchical task networks). A particular way to satisfy the compound task is called a *method*. The planning problem is then given by a set of tasks (goal tasks) and the initial state and the problem is to find a method for each compound task until the primitive actions are obtained and these actions form a valid plan (the preconditions of actions are satisfied).

39.2.1.2 Planning Techniques

A straightforward way to find plans is by searching the state space either from the initial state to some goal state or from the goal states to the initial state. This is called *state-space planning* (Fikes and Nilsson, 1971). Currently, the most widely used planning technique is based on forward state search when the algorithm starts with the initial state, selects some applicable action, and moves to the next state defined by the function succ . This process is repeated until some goal state is found. The A* algorithm is frequently used to implement the search procedure, where the heuristic function estimates the number of actions to the goal. The systems FF (Hoffmann and Nebel, 2011) and Fast Downward (Helmert, 2006) are two examples of successful planners based on this idea.

Backward planning going from the goal to the initial state is also possible though slightly more complicated because it starts from a set of goal states rather than from a single state. The idea of backward planning was first proposed for the pioneering STRIPS system (Fikes and Nilsson, 1971), but it is less

frequently used today. The backward search algorithm is exploring the search states defined as sets of world states, which is a major difference from forward search. The search state is defined using a set of predicates and it represents all the states that contain all these predicates. The initial search state is given by the goal condition so it corresponds to all the goal states. We say that an action A is *relevant* for a search state represented by the set of predicates G if $\text{PosEff}(A) \cap G \neq \emptyset$ and $\text{NegEff}(A) \cap G = \emptyset$. It means that action A contributes to the goal G and does not “destroy” it. Such an action can be the last action in the plan before reaching the goal G . If A is relevant for G , then we can define the new goal $\text{prev}(G,A) = (G \setminus \text{PosEff}(A)) \cup \text{Prec}(A)$. Briefly speaking, if we have a world state satisfying the goal condition $\text{prev}(G,A)$, then A is applicable to this state (obviously the precondition of A is satisfied by this state), and after applying A to such a state, we obtain a state satisfying the goal condition G . Hence, the backward search starts with the goal condition, selects an action relevant for this goal, and moves to the next search state (the previous goal) defined by the function prev . The algorithm stops when the initial state satisfies the goal condition given by the search state. The backward search can be modified by a technique called *lifting*. Assume that we want to reach the state where $\text{hold}(\text{block}A)$ is true. This can be done by many grasp actions that pick up the $\text{block}A$ from some other block (these actions are relevant to the goal $\text{hold}(\text{block}A)$), for example, $\text{grasp}(\text{block}A, \text{block}B)$ and $\text{grasp}(\text{block}A, \text{block}C)$. We may decide later from which block we will grasp the $\text{block}A$ so we can use a partially instantiated operator $\text{grasp}(\text{block}A,Y)$ instead of the actions in the planning procedure. This approach decreases the branching factor in the search procedure but introduces variables to the search states that must be handled properly. For example, when checking whether the initial state S satisfies the goal condition G , we need to use a substitution σ of variables: $\exists \sigma G\sigma \subseteq S$. This substitution instantiates the variables in the operators from the plan.

We defined the plan as a sequence of actions, but primarily we require that causal relations between the actions hold (Sacerdoti, 1990). The causal relation between actions A and B says that action A has some predicate P among its positive effects that is used as a precondition of action B ; we write $A \rightarrow^P B$. Hence, the action A must be processed before the action B in the plan and there must not be any action between A and B that deletes the predicate P . To capture the causal relations in the plan, it is enough to specify a partial order of actions rather than the linear order. This is the basic idea behind plan-space planning where we are exploring partial plans until we obtain a complete plan (Penberthy and Weld, 1992). The initial partial plan consists of two actions only: the initial state S is modeled using a special action A_0 such that $\text{Prec}(A_0) = \text{NegEff}(A_0) = \emptyset$, $\text{PosEff}(A_0) = S$, the goal G is modeled using a special action A_1 such that $\text{Prec}(A_1) = G$ and $\text{PosEff}(A_1) = \text{NegEff}(A_1) = \emptyset$, and action A_0 is before A_1 . Now, the planning process consists of modifying the partial plan by adding new actions, precedence, and causal constraints. The aim is to find a causal relation for each predicate in the preconditions of actions in the partial plan. In the initial plan, the preconditions of action A_1 modeling a goal are not provided by any action. Such preconditions are called *open goals*. We can find a causal relation leading from an action that is already in the partial plan (causal relations also define a partial order between the actions) or we can add a new action to the plan that has a given predicate among its effects. The new actions must always be after A_0 and before A_1 in the partial order of actions. Notice that a causal relation $A \rightarrow^P B$ can be threatened by another action C in the partial plan that deletes P and can be ordered between A and B in the partial order. This *threat* can appear when we add a new causal relation to the partial plan or when we add a new action to the plan. The threat of action C for the causal relation $A \rightarrow^P B$ can be resolved either by ordering C before A or by ordering C after B . If lifting is used in the planning procedure, then we can resolve the threat also by instantiating certain variables so the negative effect of C is no more identical to P . In summary, plan-space planning is based on exploring the space of partial plans starting with the initial plan containing only the actions A_0 and A_1 and refining the plan by adding causal relations for open goals, which may also add new actions to the plan, and removing threats until we obtain a plan with no open goals and no threats. It is possible to prove that a partial plan with no threats and no open goals is a solution plan; in particular, any linearly ordered sequence of actions that follows the partial order is a plan. Notice that the plan-space approach does not use explicitly the world states;

only the initial state is encoded in the action A0. The systems UCPOP (Penberthy and Weld, 1992) and CPT (Vidal and Geffner, 2004) are two famous partial order planners (partial order planning is another name for plan-space planning).

State-space planning and plan-space planning are two most widely used approaches to solve classical planning problems. In 1995 Blum and Furst proposed a radically new approach to planning based on the notion of a *planning graph*. The original algorithm was called Graphplan (Blum and Furst, 1997). This approach exploits two core principles. First, instead of looking for a sequence of actions, the Graphplan system looks for a parallel plan, which is a sequence of sets of independent actions (we shall define the independence later). The classical plan is then obtained by any ordering of actions in the sets. The second core principle is a reachability analysis realized by the planning graph constructed from the initial state and available actions where the negative (delete) effects are temporally ignored. The *planning graph* is a layered graph where the first layer consists of predicates in the initial state, the second layer consists of actions applicable to the initial state, the third layer consists of predicates from the positive effects of actions in the previous layer (and all predicates from the first layer), and so on until a layer containing all goal predicates is found. Hence, the layers with predicates interleave with the layers with actions. To simplify notation, *no-op actions* are used to transfer predicates between the layers (the no-op action for predicate P has the predicate P as its precondition and also as its sole positive effect). The planning graph defines the search space where we are looking for the parallel plan; the sets of actions are being selected from the action layers. To ensure that actions selected to a single set in the plan can be ordered in any way, the actions must be independent.

Actions A and B are *independent* if $\text{Prec}(A) \cap (\text{PosEff}(B) \cup \text{NegEff}(B)) = \emptyset$ and $\text{Prec}(B) \cap (\text{PosEff}(A) \cup \text{NegEff}(A)) = \emptyset$. Selection of the plan from the planning graph is then realized in the backward way by going from the last predicate layer and finding an action for each goal predicate (the no-op actions can also be used). The selected actions must be pairwise independent. After selecting the actions in one layer, the procedure continues with the preconditions of selected actions and finding actions for them in the previous layer and so on until the first layer is reached. If no plan is found, one layer is added to the planning graph and the procedure is repeated. The ideas of planning graphs are nowadays used mainly in heuristics for forward planning.

So far we presented the dedicated algorithms for solving planning problems. There also exists another planning approach based on translating the planning problem to a different formalism, for example, to Boolean satisfiability or constraint satisfaction problems (CSPs). This method was introduced by Kautz and Selman (1992) who showed how the planning problem could be converted to a sequence of Boolean satisfiability (SAT) problems. The idea is that the problem of finding a plan of a given length can be naturally encoded as a SAT formula. If this formula is not satisfiable, then the plan (of a given length) does not exist; otherwise the plan can be decoded back from the model of the formula (from the instantiation of the variables in the formula). However, we do not know the plan length in advance. Hence, the whole planning system works as follows. We encode the problem of finding a plan of length one as a SAT formula. If the plan does not exist, then we continue with the plan of length two and so on until the plan is found (or some fix point is reached and then no plan exists). There exist various encodings of planning problems to SAT; the original approach from Kautz and Selmann (1992) used the encoding of sequential plans, the more recent planners such as SATPLAN (Kautz and Selmann, 1999) used encodings based on a planning graph, and the state-of-the-art SAT-based planners such as SASE (Huang et al., 2010) use multivalued state variables. Several encodings to CSPs were also proposed (Barták, 2011, Barták and Toropila, 2008).

39.2.2 Automated Scheduling

Scheduling deals with the allocation of scarce resources to activities with the objective of optimizing some performance measures. Depending on the situation, resources could be machines, humans, runways, processors etc.; activities could be manufacturing operations, duties, landings and takeoffs,

computer programs, etc.; and objectives could be minimization of the schedule length, maximization of resource utilization, minimization of delays, and others.

39.2.2.1 Scheduling Task

As we already mentioned, there are many classes of scheduling tasks. Resources, activities, and the performance measure are three major concepts in each scheduling task so we can define components of the scheduling task as follows. There is a set of n jobs that can run on m machines. Each job i requires some processing time p_{ij} on a particular machine j . This part of a job is usually called an *operation*; we also used the notions of activity or action in the text. The schedule of each job is an allocation of one or more time intervals (operations) to one or more machines. The scheduling task is to find a schedule for each job satisfying certain restrictions and optimizing a certain given set of objectives. The start time of job j can be restricted by a *release date* r_j , which is the earliest time at which job j can start its processing. The release date models the time when the job arrives to the system. Similarly, a *deadline* d_j can be specified for job j , which is the latest time by which the job j must be completed. The release date and the deadline specify the time window in which the job must be processed. To specify an expected time of job completion, a *due date* δ_j for job j is used. The major difference from the deadline is that the job can complete later or earlier than the due date, but it will incur a cost. Let C_j be the completion time of job j . Then the lateness of job j is defined as $L_j = C_j - \delta_j$ and the tardiness of job j is defined as $T_j = \max(0, L_j)$. The completion time, lateness, and tardiness are three typical participants in the objective functions expressing the quality of the schedule. The most widely used objective function is minimization of the maximal completion time—a so-called *makespan*. The idea is to squeeze production to as early times as possible. A more practically important objective is minimization of the maximal lateness or tardiness that corresponds to on-time delivery. Sometimes, the number of late jobs is used instead of the tardiness and the objective is to minimize the number of late jobs. Other objectives also exist, for example, minimization of the number of used resources.

The jobs (operations) require certain resource(s) for their processing. Operations can be preassigned to particular resources and then we are looking for time allocation only. Or there may be several alternative resources to which the operation can be allocated and then resource allocation is a part of the scheduling task. Such alternative resources can be either identical then we can union them into a so-called *cumulative resource* that can process several operations in parallel until some given capacity, or the alternative resources can be different (e.g., the processing time may depend on the resource). The resource, which can process at most one operation at any time, is called a *unary* or a *disjunctive* resource. If the processing of an operation on a machine can be interrupted by another operation, and then resumed possibly on a different machine, then the job is said to be *preemptible* or *interruptible*. Otherwise, the job is *non-preemptible* (*non-interruptible*).

It is also possible to specify precedence constraints between the jobs, which express the fact that certain jobs must be completed before other jobs can start processing. In the most general case, the precedence constraints are represented by a directed acyclic graph, where each vertex represents a job, and if job i precedes job j , then there is a directed arc from i to j . If each job has at most one predecessor and at most one successor, then we are speaking about *chains*; they correspond to serial production. If each job has at most one successor, then the constraints are referred to as an *in-tree*. This structure is typical for assembly production. Similarly, if each job has at most one predecessor, then the constraint structure is called an *out-tree*. This structure is typical for food or chemical production where from the raw material we obtain several final products with different “flavors.”

There exists a specific class of scheduling problems with a particular type of precedence constraints, the so-called *shop problems*. If each job has its own predetermined route to follow, that is, the job consists of a chain of operations where each operation is assigned to a particular machine (the job may visit some machines more than once or never), then we are talking about *job-shop* scheduling (JSS). If the machines are linearly ordered and all the jobs follow the same route (from the first machine to the last machine), then the problem is called a *flow-shop* problem. Finally, if we remove the precedence

constraints from the flow-shop problem, that is, the operations of each job can be processed at any order, then we obtain an *open-shop* problem.

To keep track of various classes of scheduling problems, Graham et al. (1979) suggested a classification of scheduling problems using the notation consisting of three components $\alpha | \beta | \gamma$.

The α field describes the machine environment, for example, whether there is a single machine (1), m parallel identical machines (Pm), job-shop (Jm), flow-shop (Fm), or open-shop (Om) environment with m machines. The β field characterizes the jobs and the scheduling constraints and it may contain no entry or multiple entries. The typical representatives are restriction of the release dates (r_j) and deadlines (d_j) for jobs, assuming the precedence constraints (prec) and allowing preemption of jobs (pmtn). Finally, the γ field specifies the objective function to optimize; usually, a single entry is present but more entries are allowed. The widely used objectives are minimization of the makespan (C_{\max}) or minimization of the maximal lateness (L_{\max}).

39.2.2.2 Scheduling Techniques

There exists a vast amount of various scheduling techniques proposed for particular scheduling problems (Brucker, 2001, Pinedo, 2002). We will present here just two representatives showing some typical techniques from the scheduling algorithms. In particular, we will present an exact polynomial algorithm for solving the problem $1 | r_j, \text{pmtn} | L_{\max}$ to demonstrate a classical scheduling rule and then we will show an exact exponential algorithm for the problem $1 | r_j | L_{\max}$ explaining the branch-and-bound method that uses solutions of the relaxed problems to obtain a good bound.

The scheduling problem $1 | r_j | L_{\max}$ consists of a single machine where jobs have arbitrary release dates and the objective is to minimize the maximal lateness. This problem is important because it appears as a subproblem in heuristic procedures for flow-shop and job-shop problems; unfortunately, the problem is known to be strongly NP-hard (Pinedo, 2002, p. 43). However, if all release dates are identical, or all due dates are identical, or preemption is allowed, then the problem becomes tractable. These tractable problems can be solved in polynomial time by applying the earliest due date (EDD) rule by Jackson (1955) that says “select the job with the smallest due date and allocate it to the resource.” We will present the preemptive version of the EDD rule for the problem $1 | r_j, \text{pmtn} | L_{\max}$. In the preemptive case, we collect all not-yet finished jobs with the earliest release date and among them we select the job with the EDD for processing and allocate the job to the earliest possible time. Processing of this job continues until the job is finished or another job becomes available (i.e., the next release date is reached). At this point, the next job for processing is selected using the same principle. It could be the current job or a different job in which case the previous job is interrupted (unless it is already finished). Hence, we may interrupt a job when another job with an earlier due date becomes available. Notice that if the schedule constructed does not have any preemptions, then the schedule is optimal also for the problem $1 | r_j | L_{\max}$. Otherwise, the preemptive schedule defines a lower bound of the objective function (L_{\max}) for the non-preemptive problem (obviously, if preemption is not allowed, we cannot obtain a better schedule). These two observations can be used for solving the problem $1 | r_j | L_{\max}$. Basically, the algorithm explores possible permutations of jobs that are constructed from left to right (from earlier time to later time). Assume that we already have an upper bound for the maximal lateness (it could be plus infinity at the beginning) and a set of jobs to schedule. We first generate a schedule using the algorithm for the preemptive case. If the maximal lateness of this schedule is greater than a given upper bound, we can stop and report that there does not exist any schedule with the maximum lateness lower than the given bound. Otherwise, we check if the schedule constructed has preemptions. If the schedule is not preemptive, then we are done and we can report that schedule as the optimal schedule. However, if none of the earlier condition holds, we take a job J such that no other job can be completely finished before the release date of job J , we allocate job J to its earliest possible start time, and then we allocate the remaining jobs using the same process as described earlier. Such allocation gives a feasible schedule whose maximal lateness is used as a new upper bound when trying the other jobs J at the

first position in the schedule. Note also that if we find a schedule whose maximal lateness equals the lower bound obtained from the preemptive schedule, then the schedule is optimal.

```

solve(Jobs; T; Bound)
// Jobs is a set of jobs to be scheduled
// T is the first possible start time (initialized to 0 for nonnegative release dates)
// Bound is a value of the objective function for the best solution so far (initialized to  $\infty$ )
  (Sched; LB)  $\leftarrow$  solvePreempt(Jobs; T) // find a schedule using the preemptive EDD rule
  if LB  $\geq$  Bound then return (fail, Bound) // no schedule better than Bound
  if Sched is non-preemptive then return (Sched, LB) // optimum found
  First  $\leftarrow$  {j  $\in$  Jobs |  $\neg \exists i \in$  Jobs: max(T, ri) + pi  $\leq$  rj}
  Best  $\leftarrow$  fail
  foreach j  $\in$  First do
    (Sched; L)  $\leftarrow$  solve(Jobs - {j}; max(T, ri) + pj; Bound)
    if L = LB then return (Sched; L) // lower-bound schedule is optimal
    if L < Bound then (Best; Bound)  $\leftarrow$  (Sched; L)
  endfor
return (Best, Bound)

```

Though we mentioned that scheduling algorithms are typically dedicated to particular classes of scheduling problems, there also exists a general scheduling approach based on constraint satisfaction—this is called *constraint-based scheduling* (Baptiste et al., 2001). The idea is that a scheduling problem is represented as a CSP (Dechter, 2003) and constraint satisfaction techniques are used to solve this problem. This is similar to solving planning problems by converting them to a CSP, but the major difference is that we know the number of actions in the scheduling task so we can encode the task as a single CSP. Recall that the scheduling problem is given by a set of operations that are connected via precedence (temporal) and resource constraints. The task is to allocate these operations to particular times and resources. Hence, the CSP variables can describe the start time of each operation and the resource to which the operation is allocated. So the release date and the deadline define the domain of the start time variable (the set of all possible start times) and the domain of the resource variable consists of identifiers of resources to which the operation can be allocated. Other models are also possible, for example, using a list of 0–1 variables describing if a given operation runs at a given time. This is useful for modeling interruptible (preemptible) operations. The scheduling constraints are directly translated to relations between the variables. For example, the precedence constraint between operations A and B is encoded as $\text{start}(A) + p_A \leq \text{start}(B)$. Many special constraints have been developed to model resources in scheduling. For example, a unary resource is modeled by a constraint stating that operations are not overlapping in time. The semantic of such a constraint (for non-preemptible operations) can be described by a set of disjunctions defined between all pairs of operations allocated to that resource: $\text{start}(A) + p_A \leq \text{start}(B) \vee \text{start}(B) + p_B \leq \text{start}(A)$. The unary resource constraint itself uses techniques such as edge finding (Baptiste and Le Pape, 1996) and not first/not last (Tores and Lopez, 2000) to filter out values from the domains of variables that violate the constraint. There exist resource constraints for preemptible operations as well as for cumulative resources (Baptiste et al., 2006) and also constraints where the operations are not pre-allocated to resources (Vilím et al., 2005).

39.3 Impact on Practice

There is no doubt that scheduling techniques have a great impact on many areas of human endeavor starting from manufacturing scheduling, going through personal scheduling, and finishing with computer task scheduling. These examples are obviously not exhaustive and there are many others where scheduling plays an important role, for example, scheduling sport tournaments. There are companies

such as SAP and i2 Technologies (now owned by JDA Software) that provide complete solutions to solve scheduling problems such as SAP Advanced Planner and Optimizer (APO) and other companies providing tools to solve scheduling problems such as ILOG CP Optimizer by IBM.

The planning techniques are visible mainly in the research areas. The biggest success is probably in space exploration. NASA's Deep Space 1 (DS1) mission was one of the first significant applications of automated planning. The DS1 project successfully tested 12 novel advanced technologies including the autonomous remote agent (RA) (Muscettola et al., 1998). The goal of RA was to plan, execute, and monitor operations of the space probe. Several conclusions were drawn from this experiment including the necessity to validate the formal models, to develop techniques that work in real time, and to provide simple but expressive language to specify goals. The experience from DS1 project was used for developing the EUROPA system (Jonsson et al., 2000) that was applied to do planning for famous Mars Rovers Spirit and Opportunity and later to do planning for underwater autonomous vehicles (McGann et al., 2008). MEXAR and RAXEM (Cesta et al., 2007) are other examples of successful applications of integrated planning and scheduling techniques to plan and schedule communication between the Mars Express orbiter and Earth.

39.4 Research Issues

We mentioned several times that planning and scheduling tasks are quite different problems and different approaches are being used to solve these problems. Nevertheless, complex real-life problems frequently included both types of problems—what to do and how to do it. This demands for approaches that *integrate planning and scheduling*.

Though planning deals mainly with the causal relations between the actions and suppresses the role of time and resources, there already exist planning techniques that involve time and resource reasoning. Plan-space planning can naturally be extended to work with time by using simple temporal constraints (Dechter et al., 1991). The IxTeT planner (Ghallab and Laruelle, 1994) is an example of a planner that uses the so-called *chronicles* to model evolutions of state variables in time. The EUROPA system (Jonsson et al., 2000) is another modern planner that supports time and resources. Both these planners were strongly motivated by practical applications, which justifies that this research direction is highly important for practice.

Similarly, the research in the area of scheduling focuses on time and resource allocation and the question of how to determine the set of scheduled activities is left unsolved. A straightforward approach based on the description of the environment, for example, using the description of the processes to manufacture a given part, is typically used to generate the set of activities for scheduling. If there are some options, for example, alternative processes such as outsourcing, the decision is done by a human operator outside the scheduling process. As the current production environments are becoming more flexible and complicated, the number of options to select the possible activities is increasing and hence the choice of the “right” activities to be scheduled is becoming important. This means that some ideas from planning might be applicable to scheduling as well, for example, in flexible manufacturing environments. There exist attempts to include the so-called *optional activities* in the scheduling process so the scheduling algorithm selects which activities will be scheduled. This direction was pioneered by Beck and Fox (2000) and further extended by Kuster et al. (2007) and Barták and Čepek (2007). The FlowOpt system (Barták et al., 2011) supports optional activities and the recent versions of IBM/ILOG CP Optimizer (Laborie, 2009) provide a strong support for optional activities in the filtering algorithms for resource constraints.

Currently, the research on integrating planning and scheduling is driven mainly by the planning community. This is probably because there is a higher demand from the applications where autonomous agents such as robots are being used.

One of the critical issues when applying planning and scheduling technology is to identify a proper formulation of the problem to be solved. Researchers usually assume that a problem is already given, for example, most planners assume the problem formulation in PDDL is given as the input, and in

scheduling the notation of the form $\alpha \mid \beta \mid \gamma$ is assumed for the problem definition. Surprisingly little attention is devoted to the problem of representing real-life problems in a formal model that can be later processed by automated planners and schedulers. The research area that deals with this issue is called *knowledge engineering for planning and scheduling*. This area deals with the acquisition, design, validation and maintenance of domain models, and the selection and optimization of the appropriate machinery to work on them. These processes impact directly on the success of real automated P&S applications. There is also a clear need for modeling tools that bridge the gap between real-life problems and P&S technology. Currently the human modeler must be an expert in the application domain as well as in P&S techniques. This is a rare combination of skills that significantly restricts applicability of the P&S technology. The modeling tools, such as GIPO (Simpson et al., 2001) and itSIMPLE (Vaquero et al., 2007), show a possible way for making the planning technology more accessible; the EUROPA system (Jonsson et al., 2000) also provides many routines for knowledge engineering tasks. The FlowOpt project (Barták et al., 2011) has similar ambitions in the area of scheduling. The main goal of such tools is supporting the modeling process starting with an informal description of the problem and finishing with a precise formal model that can be passed to a planner or a scheduler. The tool should hide the technical complexity of P&S algorithms while providing enough flexibility to describe various real-life problems. Users would greatly benefit from tools that guide the user to design models that are easier to solve.

A closely related topic to knowledge engineering is the gap that is extending between real-life problems and academic solutions. Researchers are going deeper and deeper to understand the problems and proposing techniques to solve them, but the problems to be solved are becoming too far (too artificial) from the real-life problems, which opens the question of practical applicability of current research results. In the previous paragraphs, we pointed out several assumptions made about the problems to be solved and these assumptions are frequently violated in real-life problems. There already exists research that relaxes these assumptions and attempts to solve more realistic problems. For example, solving planning problems under uncertainty is an important topic to make the planning techniques closer to real-life problems. Markov decision processes (MDPs) are currently a typical model to deal with nondeterminism of actions and environment and with partial observability of the world. Instead of plans defined as a sequence of actions, MDPs work with policies that recommend which action should be executed in a given state. Though these techniques are very promising to describe the real-world problems precisely, they do not scale up well to problems of realistic size. Similarly, stochastic scheduling has received attention in the scheduling community where researchers are also interested in online scheduling (not all information is available at the beginning, e.g., new jobs may arrive later). This avenue of research also relates to rescheduling methods where the existing schedule needs to be modified to reflect changes in the problem specification (such as broken machines, late arrival of jobs).

39.5 Summary

Many real-life problems involve planning and scheduling tasks so the knowledge of how to model and solve such problems is becoming increasingly more important. This chapter gave a short overview of classical approaches to formally describe and solve planning and scheduling problems. It is not meant to be exhaustive; for example, we omitted several promising approaches for solving problems such as metaheuristics that are often successful in practical applications (see Chapter 12). The aim was to present the area to a general audience, to introduce the key notions to understand the terminology, and to give several representative examples of techniques involved in solving problems. We also identified three topics, namely, integration of planning and scheduling, knowledge engineering for planning and scheduling, and extensions of existing models toward uncertainty and dynamicity as research areas that are likely to receive more attention in near future due to their relevance for solving practical problems.

Key Terms

A*: A heuristic search algorithm where each search state x is evaluated using the function $g(x) + h(x)$, where $g(x)$ is the length of the path from the initial state to x and $h(x)$ is an estimate of the length of the path from x to some goal state.

Constraint satisfaction problem: A combinatorial optimization problem formulated as a set of variables, each variable has a set of possible values, and constraints, which are relations restricting possible combinations of values; the solution is an assignment of values to variables satisfying the constraints.

Planning: A process of creating an organized set of actions, a plan, that can be executed to achieve a desired goal from a given initial situation (state).

SAT: A Boolean satisfiability problem is the problem of determining if the variables of a given Boolean formula can be assigned in such a way as to make the formula evaluate to *true*.

Scheduling: A process of assigning a set of tasks to resources over time.

40.1 Introduction

One of the unique characteristics of human intelligence is the ability to process and understand language. It is a specific human capacity, although the word “language” has been applied more loosely to communication modes used by other animals, for example, dolphins. A key aspect of language is that it is used for communication. However, there is also evidence that it is used for conceptualization. In computing, the word “language” is mostly used within the context of programming, where programs are written in a “computer language” that the computer can process as a set of precise instructions to accept some input and generate some output. In this chapter, when we say “language” we mean human language or “natural language” to distinguish them from artificial languages such as those used in computer programming. Attempts at getting computers to understand natural language began almost as soon as computers were invented. The field of artificial intelligence has its roots in pioneering work in natural language processing (henceforth NLP)—what can be a more convincing demonstration of intelligence in a computer system than its ability to interact with a human being using language? In 2011, when IBM’s Watson program convincingly won the Jeopardy tournament, it was seen as a major triumph for NLP. Going back in the past, many of the earliest attempts at building intelligent systems involved some form of language processing. For example, the Turing test required a computer to behave in a manner that is indistinguishable from a human being, and all interactions were to be done in natural language.

The broad interdisciplinary area of NLP has significant intersections with fields such as computational linguistics, speech recognition, phonetics, semantics, cognitive science, logic, and philosophy.

Each field focuses on certain facets of language processing. For example, in speech recognition and synthesis, the input/output is exclusively audio. This leads to an entire class of problems and issues, solutions to which are discussed in Chapter 41. However, in the current chapter, we shall focus on language processing research where the input/output is textual in nature. Such written languages are different from spoken languages (as in speech processing) and visual languages such as sign languages and gestures. A written language is characterized by a script. There are thousands of languages in the world, and almost as many scripts. Many languages tend to share scripts. For example, the romance languages (the major ones are French, Italian, Portuguese, and Spanish) use a script derived from Latin. Most research in NLP is done with English, the lingua franca, but the methods and technologies can often be applied to other languages. When focused on text, NLP tends to overlap somewhat with another field called *text-mining* or *text-analytics*. The main difference is that text-mining deals with text at a very superficial level, whereas NLP goes deeper into the structure of the text and its components.

The ubiquity of word-processors and document preparation systems ensures that most text data originates in digital form. This, and the fact that the Internet and World Wide Web allow easy access and dissemination of textual data, ensures that there is no shortage of data for NLP. As we shall see, these large volumes of digital text have led to the increasing dominance of statistical methods within NLP. However, this does not make the so-called classical approaches to NLP irrelevant or dated. They play an increasingly important role in providing direction for the statistical methods.

Comparing NLP to other fields that are covered in this section, it would seem that NLP could be useful in building a language-processing blackbox. For example, expert systems and robots might be easier to interface with if they were to understand commands and give their responses in natural language. Indeed, one of the earliest applications of NLP was as a front-end to a database where queries are posed in natural language rather than SQL. Analysis of images in computer vision can benefit from using NLP methods on the text in which the image is embedded. Since many problems in biomedical informatics share similarities to the ones in NLP, it is not surprising that there is significant cross-fertilization of ideas between these two communities. Some other fields within artificial intelligence can be seen as sources for NLP techniques. For example, building a statistical machine translation (henceforth MT) system would require good machine learning algorithms from decision tree and neural network research communities. New research avenues have arisen in the process of solving some of the problems faced in NLP. For example, the programming language PROLOG (which stands for PROgramming LOGic) was developed primarily to serve the NLP community and was later found to be useful in many other scenarios as well. Programming languages are covered in detail later in this book and are not discussed in this chapter.

As mentioned earlier, the field of NLP is as old as computing itself. Research in MT (a subfield of NLP) has been going on since the 1950s. The first meeting of the Association of Computational Linguistics was held in the early 1960s. Hence, one can imagine that there are quite a number of surveys and textbooks and handbooks that describe NLP in great depth. This chapter does not intend to replace them, but rather it gives a quick introduction to the field and its literature, covers the key principles, the notable applications, and outlines future research challenges. The resources section at the end of this chapter will point readers to the most significant ones for further details.

The availability of web-based data and the emergence of mobile computing and cloud-based infrastructure have resulted in a flood of innovative applications of existing NLP techniques and the rapid development of new ones. Tasks in NLP that were considered “too hard” just a decade ago are now done by apps on mobile devices. It is truly an exciting time to be in NLP.

The rest of this chapter is organized as follows: In the next section, we shall discuss the underlying principles upon which the field is based. As mentioned earlier, our focus shall be on the text. Then we shall do a quick survey of the most important applications and the commercial impact of NLP. Following this, we shall identify the major research challenges for the future. Finally, we shall summarize by providing a glossary of terms that may be unfamiliar to the readers and an annotated list of resources (both online and offline) that the reader will find useful in learning more about this field.

40.2 Underlying Principles

A popular view of NLP is that of a series of transducers that decompose the task into a series of stages of increasing abstraction. The eventual goal of NLP is to articulate the text's intended meaning, and the stages break down the complexity of the task with each stage solving a bit of the problem or preparing data for the following stage. These stages are inspired by work in theoretical linguistics where one can analyze the syntax, semantics, and pragmatics of text. These stages are typically understood as a pipeline—the output of one stage fed as input into the next stage with minimal backtracking. At the lowest level, the text is just a sequence of characters, which must be tokenized and segmented into words and sentences. So the first stage, often referred to as text preprocessing, aims to transform the text into words and sentences. The output of this stage is then fed as input to the next stage—the syntax processor. In this stage, the words are subjected to lexical analysis and taken apart to understand them better. This understanding will be useful for later stages. The sentences are also subject to analysis in this stage. This involves putting a structure on top of the words in the sentence such that the relationships between the words are made explicit. This structure is called a *parse* and is often a tree or a directed graph. The parse is based on a grammar of the language, which can be understood as a finite set of rules that govern how words come together to form sentences. Syntactic parsing is a very well-studied topic, and it would be difficult to find a NLP system that did not involve the use of some parsing technique at some stage. At the end of the syntax stage, the text is now transformed into a sequence of structured sentences. The next stage, probably the most difficult one at the moment, attempts to ascribe meaning to the sentences. The notion of meaning in NLP is multifaceted. At a surface level, we are interested in knowing what the sentences say about the various objects/concepts that are the focus of the text. This is the literal meaning of the text and is often described using logic-based formalisms. The techniques are part of semantic analysis. At a more deeper level, we are interested in knowing the intended meaning of the text, which is often more broader than the surface level meaning of the sentence. The context of the sentence, other sentences, is considered, and this sub-field of NLP is called *Pragmatics*. For example, if we consider a text that consists of a conversation between two people, a semantic analysis would tell us the meaning of the individual sentences, but pragmatics (in this example, discourse analysis) would be what tells us whether the text is an argument between the two and whether it ended in an agreement and what was the nature of the agreement or whether it was question and answer session in which one person was asking questions that the other person was answering and whether the session was “satisfactory” from the questioner's perspective.

While such a pipeline of stages is helpful to manage the complexity of NLP, in practice, there is some feedback between stages. For example, a parsing failure may require that sentence segmentation be redone. The availability of faster/distributed computational resources also allow for multiple possibilities to be explored, and the best (most probable) solution be selected. We now explore each of these stages in more detail and describe the underlying principles and issues in each.

40.2.1 Text Preprocessing: Words and Sentences

Digital texts are essentially a stream of bits that must be converted into linguistically meaningful entities—first characters, then words, and sentences. Typically, there are two sub-stages: Document triage, the process of converting a binary file into a well-defined text document, and text segmentation. For the stream of bits to be interpreted as a stream of characters, it is necessary that the character encoding be identified. Optionally, the encoding may need to be changed depending on the kind of algorithms to be used later. There are a number of popular encoding schemes available; and depending on how the digital text was generated, different documents may need to be processed differently. The most common encoding scheme is 7-bit ASCII, which has 128 characters and is usually sufficient for English. Historically, this encoding was so popular that many languages forced their characters to be encoded using ASCII. For example, texts for European languages with accented characters opted to

use two ASCII characters to encode the single accented character. Languages such as Arabic required far more elaborate ascification or romanization of their characters so as to be encoded using 7-bit ASCII. Later on, 8-bit character sets arose for virtually most languages. However, since this gives only 256 possibilities, the different character sets for the languages overlap, and prior knowledge of the encoding used is necessary to interpret a given document. The situation is even more complex for languages such as Chinese and Japanese that have several thousand characters. Historically, 2-byte (16 bit) character sets were used to represent them. Further complications happen when multiple encodings are used within the same document. For example, a Chinese document might have an English acronym or a number that is encoded using 1-byte characters. The Unicode standard attempts to eliminate all this complexity by specifying a universal character set that has over 110,000 characters covering over 100 scripts. It also provides a way to consistently deal with issues such as character properties (e.g., lower and upper case), display order (Arabic and Hebrew are right-to-left, unlike English, which is left-to-right), etc. The most common implementation of this standard is in the UTF-8 encoding, which is a variable length character encoding scheme. With no overlap of character sets, it solves the problem of properly interpreting a multilingual document without any outside information. However, despite the rapid adoption of Unicode, the use of different encoding schemes means that an encoding identification algorithm must model the different encoding schemes to figure out which one of them best fits the given file.

A related problem is that of language identification. In some cases, the character set will uniquely identify the language, and if it is a monolingual document, the problem is solved. However, many languages share common characters, and unless one has outside information about the language used, one must look at the distribution of characters in the document and compare it to that of the possible languages to determine which one is most likely. For multilingual documents, this is even more critical since different (language-dependent) word/sentence segmentation algorithms would be applied for different segments of the text.

Texts obtained off the Internet cause additional problems since they are ill-formed and do not follow the traditional language rules. Twitter logs, for instance, use novel spellings and abbreviations. Internet documents also contain a lot of markup and display-specific text that should be filtered out. A non-trivial problem is how to clean the document of the extraneous text.

All these issues become especially important when a corpus of documents is being created for statistical analysis or for model-creation in applications.

Once the text is interpreted as a sequence of characters in a particular language, the next task is to identify the words and sentences. The process of clumping the characters into words is called *tokenization*. The algorithms for doing this are very much language-dependent. Space-delimited languages, such as English, a fixed set of whitespace characters typically delimit words, but there are many special cases and different kinds of texts need custom-built tokenizers. In unsegmented languages such as Chinese and Thai, additional information is needed about what character sequences are legitimate words. The concept of word need not be restricted to a sequence of characters delimited by whitespace. Many tokenization algorithms also extract multi-word expressions such as *New York* or *de facto*, which should to be treated as one token/word.

Once words are extracted, they can be subjected to lexical analysis. This aims to understand the structure of each word. For example, it can help tag the word worked as essentially the word work with a suffix of -ed that signifies the past tense. This is called *inflectional analysis* and can be quite non-trivial. For example, the word ran is really run inflected with a past tense.

A critical unit for NLP is the sentence. Once words are extracted, it is typical to chunk them into sentences. This process is called *sentence segmentation* and is very much language-dependent. Thai, for example, has few punctuation marks and segmentation can be challenging. In a well-formed English document, almost all sentences can be segmented out by applying a set of simple rules. However, for informal English documents, the segmentation can be quite hard as there can be considerable variation in the use of the standard end-of-sentence markers such as periods and exclamation marks. Near perfect

results can be obtained by using machine learning techniques on a corpus of documents to build classifiers that decide when a character such as a period is ending a sentence.

Once sentences are obtained, additional interesting word-based processing is possible. One example is part-of-speech (henceforth POS) tagging where every word is labeled with its correct lexical category in the sentence. Unlike lexical analysis, POS tagging deals solely with POS labels. It has been extensively studied and is considered a solved problem for many languages.

With or without lexical analysis, and without further NLP stages, words can be used in many interesting ways. One major focus has been probabilistic word-based models called *N-gram models*. These try to predict a word from the previous $N-1$ words. These N -grams have been the basis of so-called language models that predict the probability of sequences of words, for example, a sentence. These models rely on counts of words, or sequences of words, in a representative corpus of documents. Models based on N -grams have seen very broad usage in a variety of tasks ranging from spelling correction to MT.

40.2.2 Syntax: Parsing and Structure

A central aspect of NLP is syntactic analysis: determining the structure of a word sequence (typically a sentence) based on a formal grammar. The concept of a grammar for a given language comes from linguistics. It refers to a set of finite rules that define well-formed (valid) strings in the language. The correspondence is typically seen in a generative manner—the grammar rules generate strings in the language and nothing more. The so-called *Chomsky Hierarchy* organizes many of the most well-known grammars into a hierarchy of increasingly powerful (in a generative sense) formalisms. Context-free grammars (henceforth CFG) are particularly interesting and widely studied as useful approximations of natural languages. These are if-then generative rules involving words and constituents (word categories such as noun, verb, etc.) that specify how a constituent might be composed of other constituents and words. In a CFG, the rules do not have a context of application. For example, a rule that says a noun phrase consists of a determiner followed by a noun can be applied regardless of where the noun phrase appears in the string. Given a grammar and a string (sentence), the process of parsing aims to determine how the string was generated by the grammar. Effectively, this reverses the generative process. The result of parsing is a structure that shows exactly how the word string was generated by the grammar. There are many types of parsers available and most are based on the idea of searching through a space of possible structures compatible with the grammar to find one that fits the word string. Two broad classes of such parsers for CFGs are top-down and bottom-up parsers. Efficient parsers such as table-driven parsers combine ideas from both classes using dynamic programming techniques. Another aspect of parsers is how they handle ambiguity such as multiple possible parses of the same string. This leads to probabilistic solutions and specialized methods for processing weighted grammar rules. Increasingly, the field has been moving toward the use of statistical parsing techniques in which samples of text are used to determine various aspects of the underlying grammar.

Grammar theories have led to a wide variety of different grammars for different languages and consequently different parsing algorithms for each. Of particular interest are dependency grammars (and the associated dependency parsing techniques), which have been particularly useful for languages other than English. Unlike phrase-structure grammars, dependency grammars result in flatter structures and considerably ease the eventual goal of most NLP systems—extracting the intended meaning of the text.

40.2.3 Semantics and Meaning

Obtaining the syntactic structure of a word sequence is only a means to the end goal of determining what the word sequence really means. This is the objective of semantic analysis. There are several dimensions to consider. First and foremost, a decision needs to be made as to how should meaning be represented. A number of formalisms, mostly based on first-order logic, have been used for this purpose. They rely on a model-theoretic framework that provides a bridge between linguistic content and knowledge of

the real world. The use of first-order logic provides for a computationally tractable mechanism to support inferences and to describe events as state changes. Other representational challenges are how to represent beliefs and common-sense knowledge. One of the most well-studied approaches to semantic analysis is an approach called *compositional semantics*, which is based on the idea that the meaning of a sentence can be obtained (composed) from the meaning of its parts. In this approach, ‘parts’ refers to both the syntactic components as well as the relationships between them that are the output of they syntactic analysis. With these as inputs, the semantic analyzer will output a meaning representation of the sentence. The way this is done is by augmenting the grammar rules with semantic attachments, which specify how to compute the meaning representation of the construct solely on the basis of the meaning of the constituents. Much of the work in this line of research has focused on correctly representing and reasoning with ambiguity.

Beyond sentences, there has been a rich body of research in the area of discourse representation theory that aims to capture the semantics of coherent sequences of sentences and entire texts. These theories rely on first-order-based structures of discourse and mapping linguistic constructs to operations on these structures so that as the sentences are processed, the structure changes in the way the reader’s mental representation of the text referents might change.

Slightly orthogonal to these attempts to understand the meaning of entire sentences and texts is the large body of research called *lexical semantics*, the study of word meanings. Of particular interest is the study of word senses and how to disambiguate among them. A well-known example is the word bass, which has at least eight different interpretations such as a fish or a part of a musical range. Relationships between word senses can be established. Some common relationships are synonymy, antonymy, hypernymy, and hyponymy. Entire databases have been created of such graphs of relationships between words. One of the most well-known examples is WordNet, which is based on the idea that the meaning of a word sense can be understood with reference to synonymous word senses. WordNet exists for multiple languages and is widely used in practical applications. A generalization of the binary concept of synonymy is word similarity. Popular approaches to learning word similarity rely on the notion that similar words have a similar distribution of words around them. WordNet is an instance of an ontology. Early ontologies were painstakingly handcrafted, but more recently, using documents on the Internet, automatic (and semi-automatic) approaches have been used to construct very large general-purpose ontologies as well as domain-specific ones. These ontologies have been important building blocks in the so-called *semantic web*, a term used to describe a network of data elements that can be processed directly by machines. Word sense disambiguation has been a vigorous topic of research in lexical semantics with word-sense classifiers learned from labeled or, lately, unlabeled data. Another important focus of research in lexical semantics has been in modeling events by specifying restrictions and constraints on event predicates. For instance, the agent of an eating event must typically be an animate actor. Such selection restrictions on roles are increasingly being learned from large volumes of text obtained on the Internet.

All the semantic approaches mentioned so far have major problems with processing and modeling pervasive constructs such as idioms and metaphors. For example, to understand the meaning of (or even to accept as valid) the sentence, “Flickr is bleeding to death.” the underlying metaphor must be recognized.

The task of recognizing textual entailment refers to determining if one text fragment’s truth implies that of another text fragment. This task is at the heart of understanding the meaning of text and making inferences. It has many applications in question answering (henceforth QA), MT, text summarization, etc.

40.2.4 Pragmatics and Discourse Analysis

In the previous section on semantics, we mentioned discourse representation theory as well the problem of recognizing text entailment. These two go beyond words and sentences and focus on understanding

an entire block of text. For the purposes of analysis, such a block is referred to as a discourse, and the field is referred to as pragmatics or discourse analysis. Work in this area has been somewhat sparse except for specific applications such as text summarization. Even there, much of the work is applicable only for English-like languages. Part of the reason is that the emergence of statistical techniques in NLP caused a re-examination of many of the problems in syntax and semantics and so discourse analysis was placed on a backburner. However, the problems have not disappeared and remain important to the eventual goal of understanding the intended meaning of the text. Typically, a document does not consist of unrelated sentences but has a coherency to it. In fact, one characteristic of a well-written document is high coherency. A dialogue or conversation between two or more parties is also a form of discourse and can be analyzed in terms of the communication goals of the participants. In such a discourse, there are natural segments as different parties contribute to the text. In a monologue too, even one with high coherency, there is a natural segmentation of the text into subtopics. The movement from topic to topic is governed by coherence relations. These relations might be obtained from a body of research called *rhetorical structure theory*, which identifies a small set of coherence relations normally used in text. Besides looking at coherence, which is a semantic concept dealing with meaning of textual units, one can also examine cohesiveness of text to identify the different segments in it. The intuition is that text within the same segment is more cohesive than across neighboring segments. So if one measures cohesiveness between adjacent sentences, there will be a dip in cohesiveness at topic boundaries.

Besides discourse segmentation, another important task in discourse analysis is co-reference resolution. The idea here is to find the entities that are being talked about irrespective of how they are referred to in individual sentences. For example, a text about Hillary Clinton may refer to her by “Hillary Clinton” in some sentences, by the pronouns “she” or “her” in some others, by just “Clinton” in some others and by “the US Secretary of State” in some others. All these references should be resolved to one and the same person. The simpler task of pronoun resolution, in which one finds the referent to a single pronoun, has been widely studied, and several algorithms exist that do an impressive job. These algorithms rely on parse information of the sentences involved and also various lexical features of potential referents. As mentioned earlier, text summarization has been an important application area for discourse analysis research. In its simplest form, the goal is to decide which sentences are the key ones in the text, and this can be somewhat achieved by examining surface features such as position of sentences and the existence of cue phrases.

40.3 Best Practices: Applications and Outcomes

In this section, we shall do a quick survey of the most prominent practical results and the commercial impact of NLP within computing. Five classes of applications have been identified as the most prominent: MT, information retrieval (IR) and QA, information extraction (henceforth IE), natural language generation (henceforth NLG), and sentiment analysis. For lack of space, many other positive outcomes and applications cannot be covered, and the reader is referred to additional resources at the end of the chapter.

40.3.1 Machine Translation

The most visible and prominent application of NLP is in translation. What would be a better demonstration of a deep understanding of a couple of languages than to accurately translate texts from one into the other? Furthermore, given the multi-billion-dollar size of the translation and interpretation market, it is not surprising that almost every major development in NLP, be it word-level N-grams or sentence-level parsing or semantic analysis, has found its way into MT systems. Early MT systems were rule-based and relied heavily on “deep” knowledge encoded by human experts. The most primitive of these did a word-level translation using dictionaries, while the most sophisticated ones obtained a deep conceptual structure (called *interlingua*) of the text in the source language and then translated the interlingua into

the target language. These systems did not do very well on real-world texts outside the narrow domains for which they were designed. The 1990s saw breakthrough techniques in statistical MT and since then both rule-based and statistical approaches have been combined in robust and useful MT systems that are deployed in the real-world. For high-volume translation jobs, such as translations of manuals or regulations, MT systems can be used to assist human translators by quickly providing a draft translation that can then be rapidly fixed manually.

Modern MT systems are heavily statistical in nature and rely on the availability of parallel texts, which are texts available in two languages. Such texts are routinely produced in countries that require government documents be available in all official languages. For example, the proceedings of the Canadian Parliament are kept in both French and English. As another example, Hong Kong legislative records are in both English and Chinese. By aligning such parallel texts, an MT system can obtain enough statistical evidence for now to translate a new piece of text. Early MT systems relied on word-level information, but modern state-of-the-art MT systems extract phrase-level mappings from the parallel texts and use these to translate the new text. Commercial MT systems, such as Google Translate, Systran, etc. have been widely deployed and provide acceptable quality in many scenarios. The availability of open-source MT toolkits, such as Moses, has spurred development of MT systems for new language pairs. Generation of parallel texts too has become easier using low-cost crowd-sourcing techniques. The central issue with parallel texts is how to align them. The so-called *alignment problem* can be addressed at various levels of granularity: paragraphs, sentences, words, and even characters. While many of the alignment algorithms are fairly general and apply for any two language pairs, high performance is obtained by customization to linguistic features. Parsing, especially dependency parsing, can be very useful in aligning texts by matching (i.e., aligning) parse trees/graphs. Parts of the text that cannot be aligned reliably are discarded from the analysis.

A major problem in MT system development has been the issue of evaluation. Ideally, the evaluation must be done by human beings, but this can be very costly and time consuming. Various measures of fidelity, informativeness and intelligibility have been proposed in the past. Modern automatic measures such as bilingual evaluation understudy and TER are useful when comparing similar systems or incremental changes to a system.

Commercial MT systems are not just for end-users. As we shall see in the next section, they can also be effective in multilingual IR as well as many other NLP applications that require collating text in more than one language.

40.3.2 IR and QA

Perhaps the most visible and successful application of NLP is IR and its related cousin QA. Both IR and QA focus on finding information buried within unstructured texts and providing to the end-users in response to a query, which may be posed as a series of keywords (in IR) or a natural language question (in QA). Typically, the texts are pre-processed and auxiliary structures and indices are created in advance to facilitate the task of providing answers in real time. The indices can be extremely large, especially in the case of web-scale search, and pose significant engineering challenges for NLP algorithms. Users of IR systems, such as search engines, tend to write short and ambiguous keywords to describe their needs. There are additional issues of misspellings and the context (search is an iterative process and recent previous queries by the same user can provide valuable additional clues as to what the user is not looking for). Synonyms and multiple word senses pose additional challenges in trying to provide the user with the “correct” set of documents and web pages. Finally, ranking the output by relevance is another challenge that requires the use of NLP methods to assess similarity of queries to texts. At the back-end of IR systems, creating auxiliary structures and indices around the searchable texts requires the use of NLP. A morphological analysis of the text is quite routine so that texts that contain variations of the same word are all indexed in the same manner. The texts need not abide by the same spelling rules and can contain errors as well. Concept ontologies are used to ensure that texts that contain similar concepts are readily fetched in response to user queries. In web-scale IR, an additional consideration is

that of multiple languages. The user may pose a query using keywords in English but the most relevant page might well be in French. In such a case, either the page can be automatically translated or else it may be provided to the user without further processing if the user profile suggests that the user is fluent in French. Multilingual IR can be done either by translating the query into multiple languages in real-time or by preprocessing multilingual texts to create a unified index in the language of the user queries.

The use of keywords as a way to query IR systems is ultimately a compromise based on limitations of existing technologies. Ideally, people would like to pose a question and have the system understand the question, do a search of the relevant documents, extract the relevant information, and construct the best possible answer, possibly by consulting multiple documents. A well-known example of this is the Watson system that won the Jeopardy contest. This had the additional complexity of having to reason about its confidence in its answers and also developing strategies to win the overall game. The process of QA is often broken down into three stages: (1) question analysis, (2) text selection, and (3) answer extraction and construction. In the first stage, the most critical part is question classification, which determines the type of answer that should be provided. This can be done by something as simple as a set of rules that map question patterns to question (and hence) answer types. In English, this may be flagged by the presence of question words/phrases such as where, what, how many, etc. The question text also serves as a basis for constructing a set of query words that are sent to a search engine to retrieve a set of relevant documents. The documents can then be analyzed to obtain candidate answers. Textual entailment techniques have been explored for ranking the different answers and summarization methods have been used to build an answer from information in multiple documents. Recent trends in QA have also explored approaches such as similar question finding, which exploit the existence of question answer pairs on the web, many of the answers having been provided by human beings and hence probably of high quality.

40.3.3 Information Extraction

We saw in the previous section, how QA systems rely on extracting information from documents in order to construct an answer. The more general task of IE sees applications in a broad spectrum of tasks where structured information is required. A prototypical IE application is database creation by template filling. From unstructured texts of house-for-sale notices, a predefined template's slots might be filled up: location, number of rooms, number of bathrooms, total area, age, price, gas or electric kitchen, parking, etc.

The most common scenario for IE is named entity recognition (NER), which is often seen as the first stage of more advanced relationship extraction. State-of-the-art NER systems are quite good; and many commercial products are deployed in domains such as military intelligence, news analysis, and biomedicine. Generic NER systems extract entities such as people, places, and organizations from newswire articles. More specialized ones for biomedical applications may extract specific genomic entity types from highly technical papers that might refer to these entities using complex and confusing terminology. Most NER systems are designed as a set of classifiers that label the text sequence word by word. In this view, the task is quite similar to POS tagging that we discussed earlier. Practical NER systems use a combination of human-specified patterns, rules, and automatically constructed sequential classifier models.

Once entities are extracted, the next goal of IE is to find the relationships between them. Usually, a predefined list of relationships is considered based on the domain. For example, in intelligence applications, one may be interested in the relationship BELONGS-TO between a PERSON entity and an ORGANIZATION entity. Seed patterns are used to bootstrap the process of extracting additional patterns that specify when the relationship holds between entities. The template-filling application mentioned at the start of this section can be seen as the process of extracting complex n -array relationships. For narrow domains, template filling algorithms work very well and are based on sequential labeling approaches.

More recent applications of IE have been in temporal analysis. These involve recognizing temporal expressions (an important goal in QA where a question may start with the word “when”) such as absolute dates, relative expressions, and durations. Besides pattern-based rules, chunking approaches that use a set of sequential classifiers have been effective for this task. Another important problem is event detection. Verbs typically flag events, and there is usually a temporal expression to specify when the event happened. Event recognition is domain-specific and begins with a set of seed patterns that feeds into a bootstrapping process that extracts new patterns based on the usage of entities from earlier patterns.

Most of what has been mentioned earlier applies to single-document IE. Emerging multi-document IE systems also take advantage of aspects such as redundancy of information to acquire broadly applicable knowledge. Such open-domain IE systems also provide new challenges for standard NLP tasks. For example, the task of co-reference resolution becomes much harder in the cross-document scenario: when are two documents about the same entities?

Biomedical language processing, also known as BioNLP, is a key IE application. Building NER systems for this domain has been particularly challenging because of the unique and highly technical nature of the texts. Common entities are gene and protein names, and the challenge in the field is that these entities are sometimes referred to by names, other times by symbols, and, to make matters even more confusing, sometimes by the corresponding gene/protein. The names themselves are not unique either and vary based on the organism, function, etc. A unique problem for NER systems in this field is to perform gene normalization—relate different mentions of a gene to some specific gene in a database. The problem is cast as a word sense disambiguation task.

40.3.4 Natural Language Generation

NLG is the process of expressing thoughts using language. Synthesis of language is the flip-side of analysis and shares many of the same concerns and solutions. Just as a simplistic analysis of language can be achieved using patterns, a simple synthesis of text can be achieved by instantiating a parametrized template. In an MT system that translates text from German to English, NLG occurs when English text is generated based on the information/thoughts extracted from an analysis of the German text. In many other scenarios where text is generated, the process is merely one of selecting some fragments (as in text summarization) or instantiating a template (as in QA). It is tempting to view NLG as the analytical process in reverse. In fact, the field of NLG is quite distinct with its own concerns and issues that revolve around speaker intentions, listener models and text planning.

A domain-specific application of NLG is report generation where the process is somewhat the opposite of template filling in IE: take as input some structured data and produce a natural language text that describes/interprets the data in a manner consistent with how a human being would. For example, in a weather report, the input data may contain information about wind speed in km/h; however, a report generator would present this more qualitatively. Furthermore, depending on the strength of the wind speed, it may be necessary to feature it quite prominently at the start of the report, or mention it in passing at the end.

Some of the most exciting developments emerging in NLG are in education and health care. In intelligent tutoring systems, it has been shown that providing more succinct and abstract feedback to students facilitates more learning. Thus, the NLG front-end should take this into account in planning the feedback to be delivered to the student. In health care, the goal of engaging the patient in a dialogue is to persuade them to alter behavior. For example, to adopt a better diet or to quit smoking. Hence, the NLG module must generate text that is based on an argumentation theory that supports this. Patients can be represented as a finite state model of states, and their progress through this model can be tracked as the dialogue proceeds, and the system generating appropriate text based on this analysis.

NLG has also been used to give textual summaries of complex graphs of clinical data. These summaries have been found to improve decision-making and patient care. The reasons should be intuitively clear. A patient’s medical history contains so many numeric data from laboratory tests over irregular

intervals of time that it becomes difficult to visualize it all. By integrating textual summaries into the visualization process, it is possible to make sense of the data more rapidly and deliver better quality care more effectively.

In generating text, an important consideration is that it be coherent. This is usually ensured by using a top-down planning approach to the construction of the text. At a sentence level, it is important that the text makes use of referring expressions such as pronouns, especially when the reference is unambiguous. Algorithms are available that err on the side of wordiness. It is better to eschew the use of pronouns unless the reference can be identified clearly and unambiguously.

It is extremely hard to evaluate NLG systems. One measure of evaluation is the naturalness of the text. This can be done by human experts. Necessarily subjective, the process would typically be done by multiple experts and inter-annotator agreement recorded. Obviously, such a process is expensive and slow. More recently, there have been attempts at evaluating aspects of NLG instead of treating the entire process as a blackbox. Evaluation of referring expression generation has been explored systematically by setting up a validation set to compare different algorithms. In general though, evaluation and comparison in NLG is very hard to objectify.

40.3.5 Sentiment Analysis

Sentiment analysis or opinion mining is the study of opinions, sentiments, and emotions in text. It has seen extremely rapid growth in recent years and is one of the highest impact applications of NLP.

In general, text can be classified as factual or opinionated. For a long time, people were concerned more with facts and objective information in text. Most search engines, for example, are more concerned with facts than with opinions. We saw earlier how QA systems are primarily concerned with extracting facts from documents and using these fragments of objectivity to construct “correct” answers to questions. With the growth of the web and the rise of social media, however, there has been an increased interest in opinions and feelings. The web has certainly made it easier for people to express their opinions. In addition, social media has made it easy for us to find out what our friends and others we care about and trust have written. When contemplating an expensive purchase, even if we do not care for the opinion of someone we have never met, we just might be interested in what a close friend might have to say about their personal experience using the product. For a company, it is no longer necessary to conduct an expensive survey or organize a focus group to find out how its products are being perceived by consumers. They can simply mine the many blogs, forums, and discussion groups to find out what people are saying. Extracting sentiments is not an easy task. In most cases, opinions are embedded in broader discussions and may even be indirectly expressed. There are no obvious data-sources to access—user-generated content is everywhere and anywhere. As people have realized that their opinions are being harvested, many have started to manipulate the system by inserting opinions as spam into popular Internet sources.

Broadly speaking, sentiment analysis is about classification—what are the good things being said, what are the bad things—but before that can be done, a more fundamental question must be answered: which text fragments are objective and which are subjective. This field of research, called *subjectivity analysis*, seeks to separate the facts from the opinions. Typically, it works at the sentence-level, but due to referring expressions and contextual issues, extra information must be included. Once subjective text is identified, there are several aspects of the opinion that must be extracted: who is the opinion holder, what object is the opinion about, is there any particular aspect or feature of the object that the opinion focuses on, is the opinion positive or negative or something in-between, is it a direct opinion about the object, or is it a comparative opinion with reference to another object. In the early days of sentiment analysis, to find the opinion polarity, word-based approaches were popular. Lists of positive and negative words were constructed, and one could simply count the number of words in the text that came from these two lists and use some function of their difference to assign an overall sentiment polarity to the text. More recently though, better results are obtained by using modules from various parts of the

NLP pipeline. For instance, NER systems assist in finding the object of the sentiment and its aspects. Co-reference resolution comes in handy to disambiguate pronouns and collate multiple opinions of the same object. Parsing techniques and POS-tagging help identify the most important indicator words that flag opinions. Classifiers are constructed for combining the multiple sources of opinion within the text fragment to obtain an overall score.

Similar to regular web search, opinion search is another application area of great use. In principle, it should be a straightforward task to restrict regular search to subjective documents only; however, the task of ranking (and maybe aggregating) the different opinionated pages is more complex than ranking factual pages.

Most sentiment analysis research applies to English. However, methods exist to transfer the knowledge gleaned from English texts to perform sentiment analysis in other languages as well.

40.4 Research Issues

We have described the key areas of NLP and commercially significant applications. In this section, we project into the future and identify major challenges that the field will face. Our discussion of research issues is not intended to be comprehensive. For any area of NLP, there will always be an exploration of alternatives and new approaches. The research literature can be accessed at any time to examine current trends. We have used our judgment in selecting themes where NLP will have the maximum impact and hence see the most vigorous research. For some of these themes, techniques will become standardized and mature with routine applications; for others, progress will be made but they will continue to be on research agendas.

40.4.1 Large-Scale NLP

A recent trend in NLP has been the dominance of statistical approaches. The reason for this dominance has been the relatively easy access to text corpora. Instead of relying on humans to encode deep knowledge about language into programs that process text, statistical approaches use corpora to figure out the deep knowledge directly. With corpora sizes growing at an exponential rate, current statistical NLP approaches, primarily based on classical statistics with a small-data view of the world, are increasingly reaching the limits of their usefulness. The routine deployment of distributed systems to handle large-scale data and the emergence of novel computing paradigms are presaging the need for new ways to examine many of the older problems. Beyond the simple application of newer big data analytical tools, this calls for a fundamental new way of looking at problems. For example, approaches to extract ontologies from text need to be self-directed and require minimal human intervention if they are to scale up to the sizes of future text collections. However, these approaches also result in ontologies that are so large and complex that current application scenarios of these ontologies become impractical and these too must be supplanted by new scenarios that are better able to use the ontologies. Algorithms that run on single computers and require all the data to be in one place become irrelevant when the data are necessarily distributed (e.g., due to privacy issues), and the tasks they solve must be rethought at a very fundamental level. In the past, the scaling up of NLP was led by large companies such as Google with the resources and computational horsepower to store and process big data. Many of the published results could not even be replicated or compared by other researchers. Now, with the emergence of cloud-computing, as its use becomes more widespread and costs go down, the same resources will be available to anyone, and we can expect to see an explosion of new ideas and research as big data analytics becomes more widespread in the NLP community.

40.4.2 Multilingual and Cross-Lingual Approaches

The English language is the dominant lingua franca of the world and so, not surprisingly, most NLP research has focused on English. If one examines the amount of available digital text in various

languages, English is by far the most common. Part of the reason for this is the so-called digital-divide. Many people from non-English backgrounds simply could not afford computers, and most of the tools and programs that were used to generate digital texts were focused on English. Most population estimates already have Chinese and Spanish as the languages with more native speakers than English. Furthermore, growth projections into the future have estimated that Arabic and Hindi may become more dominant. None of this is to imply that English is going to become insignificant in our lifetimes, but it does imply that as computer usage becomes more widespread, digital text collections in other languages are going to grow rapidly and match in size the collections in English. This is going to result in strong growth of NLP research in other languages. Signs of this are already present. For example, while sentiment analysis used to focus almost exclusively on English text, its application on text in other languages has seen rapid growth. Even in MT, there is evidence of a shift in research from translations to/from English to languages that do not involve English at all. One of the key reasons for the explosion of research in dependency parsing is that dependency grammars are more suited for a wide variety of languages.

A huge focus in multilingual NLP has been in language-independent techniques. The allure of this is that the same technique can then be applied to many different languages. In the future, this may see very rapid growth as English-specific approaches will be found to be less than adequate for other languages. A related approach is language adaptation, where techniques for one language are adapted and modified to work with another language.

The goal of cross-lingual NLP approaches is to be able to work with text in multiple languages simultaneously. For example, in a cross-lingual IE system, the information extracted may come from texts in any of a set of languages. With the rise of user-generated content on the Internet, it is becoming increasingly common to find pages with text in multiple languages without any special tags specifying the switch in languages.

A final issue is the emergence of specialized languages (or sublanguages) in particular domains and scenarios. For example, mobile devices have resulted in the rise of a whole new way of writing text with phonetic abbreviations and special codes. As another example, consider how for-sale postings use a combination of tables, phrases, and visual formatting to convey textual information in an eye-catching manner rather than following the traditional rules of the language. As user-generated content becomes even more widespread, all the familiar steps in a NLP pipeline must be developed for such specialized languages, or existing approaches must be modified to properly process such text.

40.4.3 Semantics

As we saw earlier, semantics is the holy grail of NLP. All the processing that is done to a piece of text has one goal—to understand its meaning. As we saw earlier, most of the current approaches have been limited in scope and scale. Part of the reason has been that there were many issues to solve with regard to syntax. As approaches for that have matured, research has increasingly turned to semantics, and we expect the trend to accelerate in the future. Programs such as IBM's Watson have provided evidence that current approaches can be effective even when competing against human beings. A revival of ambitious projects to map all of human common-sense reasoning knowledge has also added to this trend of vigorous research in semantic processing. As research in general-purpose semantic processing matures, we are likely to see more fielded applications in narrow domains. Fields such as biomedical text processing are indeed ripe for a more semantic analysis. Sentiment analysis too is likely to move from a superficial word-based approach to a deeper understanding using semantics. This trend is already in progress as research is moving from a simplistic positive/negative binary sentiment view to a more fine-grained analysis that examines multiple dimensions such as attitudes and intentions and how they interact with cultural issues and relationships between speakers.

Lexical semantics is another area that is likely to see huge growth. Ontologies such as WordNet are already mature enough to be used in applications as blackboxes. The automated construction and

maintenance of such graphs and networks of words is going to become an increasingly important topic of research as demands for larger and more sophisticated versions come from applications.

40.4.4 Discourse Analysis

Discourse analysis has long been the least understood aspect of NLP. Considered the final stage of NLP, research in this area has patiently awaited maturity in earlier stages. Part of the problem has been a lack of tools and proper corpora for testing and evaluation. The more serious problem has been that researchers were still trying to sort out sentence-level semantics before tackling the meaning of an entire discourse. However, lately with some stability in the way semantics is understood, the time is ripe for increased research in this area. The rise of social media has also increased the amount of data available on discourse arising from groups of people. As these data become more prevalent, we can expect more research to be conducted on understanding the many facets of discourse. We mentioned earlier that in education and health care, there is a strong need for automated systems that interact with humans in a situation-appropriate manner. For this, a good understanding of the underlying dialogue structure is critical. Dialogue understanding is also important for building conversational agents embedded in robots and other interfaces that bring humans and computers together. In such settings, the role of several other areas such as NLG and text summarization also could drive research in discourse analysis. With the enormous amounts of text data being generated and recorded, summarizing it in a manner consistent with the needs and abilities of the reader is going to require a much deeper understanding of what makes a piece of text cohesive, coherent, and persuasive. One of the hard problems in NLG and text summarization is evaluation, and we expect that in future there is going to be more vigorous attempts to develop reliable metrics for assessing and comparing quality of the output. Discourse also has social and cultural aspects that we can expect to be explored in more depth in the future. For example, nationality, age, gender, etc. have a strong connection with the overall nature of the discourse. While many of these aspects have been explored by sociolinguists in controlled and somewhat artificial laboratory settings involving mostly students (i.e., people of a narrow age group) in small numbers, we can expect social media and other online forums to provide a wealth of data for a wider and more in-depth analysis. We also expect to see more widespread applications of discourse analysis. Already, there is anecdotal and sporadic evidence of its use in author identification, lie detection, personality analysis, etc. The role of punctuation in a discourse is also poorly understood. For example, if a person writes “SORRY!!” instead of “sorry,” it clearly has a different meaning. These issues have been somewhat explored by psycholinguists using heuristic approaches that rely on counts and cues; however, a more thorough statistical analysis is likely in the future with the availability of decent-sized corpus.

40.5 Summary

In this chapter, we have given a birds-eye view of the field of NLP and its role in the discipline of computing. We abstractly defined the key principles upon which the field is based and cast them within a pipeline of stages that takes a piece of text as the input and produces the meaning of the text as the output. These stages process the text from a character-based stream to form words and sentences, which are further structured before being subject to semantic analysis to extract meaning. We then surveyed the most prominent practical results to illustrate the commercial impact of the field. The applications range from MT to sentiment analysis. There have been many notable successes, the most recent one being of IBM’s Watson program in the television quiz show *Jeopardy!* where it competed against and defeated two record-holding human champions. Finally, we identified the major challenges and research issues that are likely to shape the field in the future. These challenges deal with scaling up NLP to handle real-world problems with minimal human intervention.

Key Terms

In this section, we give a selection of NLP-specific terms listed in alphabetic order. This selection is by no means complete, and the bibliography will provide additional information on other terms.

Anaphora: An expression whose reference depends on another (usually previous) expression. For example, in the text “John didn’t go to work today. He was not feeling well.” the word “He” is an anaphor that refers to John. While an anaphora is usually a pronominal expression, it can also be phrase. For example, the reference to “the queen” depends on the context in which it occurs.

BLEU: A widely-used metric for evaluation of MT systems. It stands for bilingual evaluation understudy. The metric assesses the quality of the machine-translated text in terms of closeness to text generated by professional human translators.

Chomsky hierarchy: An organization of formal grammars in terms of their generative powers. Languages higher up in the hierarchy are more expressive than the lower ones. Grammars for natural languages are based on this formal structure.

Coherence: A concept, used in discourse analysis, which refers to how the meaning of different text units can be combined into a meaning of the combined text.

Cohesion: A concept, quite distinct from coherence, which refers to how different text units are linked together using linguistic constructs. Unlike coherence, it does not consider the meaning of the texts or the linking constructs.

Dependency grammar: A kind of grammar based on modern syntactic theories that give primacy to the dependency relationship between words in a sentence. They result in structures that are considered closer to the meaning of the sentence and are quite distinct from phrase structure grammars from the Chomsky hierarchy.

Document triage: Refers to the process of interpreting a set of digital files as text documents. Involves deciding how to decode the bits into characters, how to attribute a language to the character stream, how to segment out the actual textual content from the other elements, such as images and markup, etc.

Interlingua: Deep conceptual structure that captures the meaning of a text independent of the language. Used in MT systems to enable translation between two languages—the text from one language is converted into interlingua from where it is converted into the other language. The conversions to/from interlingua are simpler, and the use of interlingua provides a more scalable approach to translating between multiple languages.

Morphological analysis: Refers to understanding words in terms of their composition from smaller units. It typically involves identifying the morpheme and its relationship to the surface word based on inflection, derivation, compounding, and cliticization.

***N*-grams:** Contiguous blocks of *N* words. When *N* = 1, they are called *unigrams*. Analysis of a text based on its *N*-grams has been a popular approach to building language models that have been widely used in applications ranging from spelling correction to machine translation.

Parsing: Process of imposing a structure on a sentence. The structure is usually a tree or a graph that encodes how the sentence could be understood in terms of a grammar for the language in which it is generated.

POS tagging: Refers to tagging each word in a sentence with a part-of-speech tag from a finite set of possibilities. Is usually solved as a classification problem. The tags provide valuable information for other NLP tasks such as parsing, named-entity recognition, etc.

Unicode: An industry standard for consistently encoding and handling text from different languages.

Annotated Bibliography and Additional Resources

In this section, we list sources that can provide readers more detailed information on the issues and topics discussed in this chapter. The list includes websites as well as books. We sought to provide

authoritative resources. There is obviously some overlap in the information provided by these resources, but we believe that they cater to slightly different needs and so, between them, most readers will be covered. Since NLP is a fast evolving field, books and articles become outdated rather quickly. Websites too tend to disappear, URL's change or become outdated as their maintainers move on to other organizations. We have tried to list resources that will remain relevant for the lifetime of this handbook. Still, for the latest results, the reader may need to consult other resources. We have tried to minimize this issue by listing the most recent publications at the time of writing. We preferred books and surveys since they provide an overview as well as pointers to the most significant and relevant papers in conferences and journals.

1. <http://www.aclweb.org> (accessed on October 10, 2013).

The Association of Computational Linguistics portal is an excellent place to get access to publications in NLP and is a top resource for all professionals and graduate students in NLP. It should be the first stop for anyone serious about working in NLP. Most of the conferences and workshops in the field put their papers in the ACL anthology, which can be browsed as well as searched. Many important journals are accessible here as well. Anything substantive and relevant to NLP usually lands up in the ACL anthology.

2. Indurkha, N. and Damerau, D. 2010. *Handbook of Natural Language Processing*, 2nd edn. Chapman & Hall/CRC Press, Taylor & Francis Group, Boca Raton, FL.

This edited collection written by over 40 of the leading experts in NLP provides detailed information of the tools and techniques for implementing NLP systems. Besides surveying classical techniques, it also covers statistical approaches in great detail and discusses emerging applications. The handbook is a good place to delve into subareas of NLP that may interest the readers. The individual chapters are mostly self-contained and each has a very extensive bibliography of the most important papers in the area covered.

3. Jurafsky, D. and Martin, J. 2008. *Speech and Language Processing: An Introduction to Natural Language Processing, Speech Recognition and Computational Linguistics*, 2nd edn. Prentice-Hall, Upper Saddle River, NJ.

A very comprehensive textbook for NLP that covers the full range of technologies used and relates them to one another. It is the basis of many graduate courses in NLP and is an ideal introduction and reference for NLP.

4. Bird, S., Klein, E., and Loper, E. 2009. *Natural Language Processing with Python*. O'Reilly Media, Sebastapol, CA.

This is the well-known NLTK book and is a very hands-on introduction to NLP using the open-source freely-available natural language toolkit. Prior knowledge of Python is not required to read this book as it introduces the language features at appropriate places in the book. A nice feature of this book is that it has a very extensive set of exercises, the code is all open-source and there is a lot of online support making it very suitable for self-study. It can be read in conjunction with either the handbook of NLP or the Jurafsky and Martin textbook mentioned earlier. To get NLTK, see the website <http://www.nltk.org> which is also a useful resource for learning more about NLP.

5. Manning, C. and Schutze, H. 1999. *Foundations of Statistical Natural Language Processing*. MIT Press, Cambridge, MA.

An excellent in-depth tour of the early work in the field of statistical NLP. It is a bit dated now, but remains an invaluable reference and source for foundational work in this area.

6. <https://www.coursera.org/course/nlp> (accessed on October 10, 2013).

This free, online course, taught by Dan Jurafsky and Chris Manning, is a good place to begin learning about NLP.

7. Blackburn, P. and Bos, J. 2005. *Representation and Inference for Natural Language, A First Course in Computational Semantics*. CSLI, Stanford, CA.

One of most accessible discussions of computational semantics. Not only does it clarify, with great elegance, many of the theoretical results in semantics but also provides a very practical perspective with source code for a series of increasingly sophisticated PROLOG programs that implement the ideas discussed in the text.

8. Bunt, H., Merlo, P., and Nivre, J. 2011. *Trends in Parsing Technology*. Springer, New York.

This is an edited collection written by top researchers in parsing methods. It provides a nice overview of the state-of-the-art in three very important subareas of parsing: dependency parsing, domain adaptation and deep parsing. A must-read for anyone wishing to start active research in this area.

9. Ferucci, D. et al. 2010. Building Watson: An overview of the DeepQA Project. *AI Magazine* 31(3), 59–79. Fall, 2010.

One of the few in-depth technical descriptions of IBM's high-profile Watson program that won the Jeopardy! Tournament. More publications should appear in the future. Look in the ACL anthology.

10. <http://www ldc.upenn.edu/> (accessed on October 10, 2013).

Did you say you need data for NLP research? This portal of the Linguistic Data Consortium is the place to visit first. It has a very extensive collection of data and tools. The quality of the data is very high, and it would be difficult to get comparable data elsewhere or to create it yourself.

11. <http://wordnet.princeton.edu/> (accessed on October 10, 2013).

The place to get the latest WordNet, a very popular, and highly regarded lexical database.

12. <http://www.eacl.org/> (accessed on October 10, 2013).

Much of the information on the European chapter of the ACL is available from [aclweb](http://aclweb.org). However, for readers interested in European languages, this portal may provide an easier access to the relevant resources.

41.1 Introduction

Spoken language understanding (SLU) is an emerging research area between artificial intelligence, speech, and language processing. The term “SLU” has largely been coined for understanding human speech directed at computers, although understanding human/human conversations is also a vibrant area of SLU. Having a semantic representation for SLU that is both broad in coverage and simple enough to be applicable to several different tasks and domains is challenging, hence most SLU tasks and approaches depend on the application and environment (such as mobile vs. TV) they have been designed for.

Given that speech is the most natural medium people use to communicate with each other, it is hardly used when interacting with computers. Recently, with the advancements in automatic speech recognition (ASR) and natural language processing (NLP) technologies, there is a strong interest—both commercial and academic—in understanding human speech.

SLU applications range from interpreting a small set of commands to complex requests involving a number of steps and reasoning. Most commercial systems employ knowledge-based approaches, such as mainly building hand-crafted grammars or using finite sets of commands, and they have already been deployed in various environments such as smartphones, cars, call centers, and robots. In the near future, we can expect more complex applications, like robots better understanding what we say instead of reacting to a finite number of predefined commands, or we will be able to ask our mobile devices a nontrivial set of requests from a broader range of domains.

Unlike speech recognition, which aims to automatically transcribe the sequence of spoken words, SLU is not a clearly defined task. At the highest level, its goal is to extract “meaning” from natural language. In practice, this may mean any practical application allowing its users to perform some task with speech. As one of the pioneers of statistical spoken language processing, Fred Jelinek,

FIGURE 41.1 A conceptual architecture of a human/machine interactive system.

once put it: “The human analogy is misguided because machines do things differently than biological beings. Airplanes don’t flap their wings”.

The conceptual components of human/machine conversational interaction system are shown in Figure 41.1, following [53]. At each turn, the user’s speech, S_i , is recognized and semantically parsed into a task-specific semantic representation of the user’s intention, U_i .

For example, if the user asks “*When is the next showing of Hunger Games around here?*” the system should be able to interpret the intent and the associated arguments (slots), such as

Find_Showtimes(movie = Hunger Games, location = (latitude,longitude))

If a statistical model is used, U_i is estimated as

$$\hat{U}_i = \arg \max_{U_i} P(U_i | S_i)$$

Then the dialog manager (DM) updates the belief state using semantic context, C_i , such as the previous belief state of the system (which may include a user goal and actions, as well as dialog history); user-specific meta-information, such as geo-location and personal preferences; and other contextual and lexical information. More formally,

$$\hat{B}_i = \arg \max_{B_i} P(B_i | C_i, \hat{U}_i, S_i)$$

The system decides on the most appropriate system action, A_i . In the statistical approaches, this decision is made based on the expected reward over belief states, which are estimated using the previous machine action and belief state, as well as the observations the machine receives from the user. Then, a response is generated in spoken or multimodal fashion. For instance, if the DM decides to present the information of showtimes with theaters, the generation needs to decide on whether to show a map or list and/or speak this information to the user using text-to-speech synthesis (TTS).

41.2 Impact on Practice

SLU systems can be grouped into three categories based on their high-level approaches. The first category is chatbot systems, like ELIZA, where the system does not really understand what is said but just mimics understanding. ELIZA was built at MIT in the 1960s [49] and has been the most popular artificial intelligence program, even though there was no intelligence but instead the system relied on simple pattern matching. A typical interaction may have such excerpts as shown in Figure 41.2.

There are more complex versions of ELIZA, such as ALICE,* which are moving toward embedding more sophisticated language processing technologies within the same framework.

The understanding systems in the second category are rooted in artificial intelligence. They are using deeper semantics and are demonstrated to be successful for very limited domains. These systems are typically heavily knowledge-based and rely on formal semantic interpretation defined as mapping sentences into their logical forms. In its simplest form, a logical form is a context-independent representation of

* <http://alicebot.blogspot.com/>

User: I need some help
System: Why do you say you need some help?
User: I am depressed
System: Are you depressed often?

FIGURE 41.2 An example chitchat interaction with ELIZA.

a sentence covering its predicates and arguments. For example, if the sentence is “John loves Mary,” the logical form would be “love(john,mary).”

During the 1970s, the first systems for understanding continuous speech were developed with interesting approaches for mapping language features into semantic representations. For this purpose, *case grammars* were proposed for representing sets of semantic concepts with thematic roles such as agent or instrument. The ICSI FrameNet project, for instance, focused on defining semantic frames for each of the concepts [23]. For example, in the “commerce” concept, there is a “buyer” and a “seller” and other arguments such as the “cost” and “good.” Therefore, two sentences “A sold X to B” and “B bought X from A” are semantically parsed as the same, with both sentences corresponding to the “commerce” frame. Following these ideas, some researchers worked toward building universal semantic grammars (or interlingua), which assume that all languages have a shared set of semantic features [5]. Such interlingua-based approaches have also heavily influenced machine translation field until the late 1990s before statistical approaches began to dominate the field. [1] may be consulted for more information on the artificial intelligence-based techniques for language understanding.

The last category of understanding systems is the main focus of this chapter, where understanding is reduced to a (mostly statistical) language processing problem. This corresponds to attacking “targeted” speech understanding tasks instead of trying to solve the global machine understanding problem. A good example of targeted understanding is detecting the arguments of an intent given a domain as in the Air Travel Information System (ATIS) project [36]. ATIS was a popular DARPA-sponsored project, focusing on building an understanding system for the airline domain. In this task, users utter queries related to flights such as *I want to fly to Boston from New York next week*. In this case, understanding was reduced to the problem of extracting task-specific arguments in a given frame-based semantic representation involving, for example, *destination* and *departure date*.

In the United States, the study of the frame-based SLU started in the 1970s in the DARPA Speech Understanding Research (SUR) and then the Resource Management (RM) tasks. At this early stage, natural language understanding (NLU) techniques like finite state machine (FSM) and augmented transition networks (ATNs) were applied for SLU [50]. The study of targeted frame-based SLU surged in the 1990, with the DARPA ATIS evaluations [8,21]. Multiple research labs from both academia and industry, including AT&T, BBN Technologies (originally Bolt, Beranek, and Newman), Carnegie Mellon University, MIT, and SRI, developed systems that attempted to understand users’ spontaneous spoken queries for air travel information (including flight information, ground transportation information, and airport service information) and then obtain the answers from a standard database. ATIS is an important milestone for the frame-based SLU, largely thanks to its rigorous component-wise and end-to-end evaluation, participated by multiple institutions, with a common test set.

While ATIS focused more or less on the understanding of a single-turn utterance, the more recent DARPA Communicator Program [45] focused on the rapid and cost-effective development of multimodal speech-enabled dialog systems, in which general infrastructures for dialog systems were developed, where different component systems for ASR, SLU, DM, and TTS can be plugged in and evaluated. Naturally, many SLU technologies developed in ATIS were used in the SLU component of the Communicator program. Eight systems from AT&T, BBN Technologies, University of Colorado, Carnegie Mellon University, IBM, Lucent Bell Labs, MIT, and SRI participated in the 2001 evaluation [46]. In the meantime, the AI community had separate efforts in building a conversational planning agent, such as the TRAINS system [2].

Parallel efforts were made on the other side of the Atlantic. The French EVALDA/MEDIA project aimed at designing and testing the evaluation methodology to compare and diagnose the context-dependent and context-independent SLU capability in spoken language dialogs [4]. Participants included both academic organizations (IRIT, LIA, LIMSI, LORIA, VALORIA, CLIPS) and industrial institutions (FRANCE TELECOM R&D, TELIP). Like ATIS, the domain of this study was restricted to database queries for tourist and hotel information.

The more recent LUNA project sponsored by the European Union focused on the problem of real-time understanding of spontaneous speech in the context of advanced telecom services [17]. Its major objective is the development of a robust SLU toolkit for dialog systems, which enhances users experience by allowing natural human/machine interactions via spontaneous and unconstrained speech. One special characteristic of the project, which is absent in similar projects in the United States, is its emphasis on multilingual portability of the SLU components.

While the concept of using semantic frames (templates) is motivated by the case frames of the artificial intelligence area, the slots are very specific to the target domain and finding values of properties from automatically recognized spoken utterances may suffer from ASR errors and poor modeling of natural language variability in expressing the same concept. For these reasons, SLU researchers employed known classification methods for filling frame slots of the application domain using the provided training data set and performed comparative experiments. These approaches used generative models such as hidden Markov models [34], discriminative classification methods [27], knowledge-based methods, and probabilistic context-free grammars [38,47].

Almost simultaneously with the semantic template filling-based SLU approaches, a related SLU task, mainly used for machine-directed dialog in call center interactive voice response (IVR) systems, has emerged. In IVR systems the interaction is completely controlled by the machines. Machine-initiative systems, ask users-specific questions and expect the users-input to be one of predetermined keywords or phrases. For example, a mail delivery system may prompt the user to say *schedule a pick-up, track a package, get rate, or order supply* or a pizza delivery system may ask for the possible toppings (see Figure 41.2). Such IVR systems are typically extended to form a machine-initiative directed dialog in call centers and are now widely implemented using established and standardized platforms such as VoiceXML (VXML) (Figure 41.3).

The success of these IVR systems has triggered more sophisticated versions of this very same idea of *classifying users' utterances into predefined categories* (called as *call types* or *intents*). [14] has published the AT&T *How May I Help You?* system description paper in 1997. HMIHY is essentially a call routing system. The users of the system are greeted by the open-ended prompt *How May I Help You*, encouraging them to talk naturally. This system has also been deployed for AT&T's call center (known as 0300) and used nationwide with great success [13]. The system was capable of categorizing an incoming call into one of the six specific call types (such as *billing or rates and plans*) plus an *other* for the remaining intents along with generic intents such as talking to a human agent or greetings. The calls are then routed to corresponding specialized departments. If the initial utterance of the user is not specific (such as *I have a question*), not informative (such as

```
<vxml version="2.0">
  <form id= "get_pizza_topping">
    <field name= "pizza_topping">
      <prompt> What kind of topping would you like to have? </prompt>
      <grammar> olive | pepperoni | mushroom </grammar>
      <noinput> Please say the topping you wish to have. </noinput>
      <nomatch> I didn't understand that. </nomatch>
      <filled> Thank you, I added <value expr= "pizza_topping" />
      <submit next="next_document.vxml" /> </filled>
    </field>
  </form>
</vxml>
```

HMIHY: How may I help you?
 User: Hi, I have a question about my bill (*Billing*)
 HMIHY: OK, what is your question?
 User: May I talk to a human please? (*CSRepresentative*)
 HMIHY: In order to route your call to the most appropriate department can you tell me the specific reason you are calling about?
 User: There is an international call I could not recognize (*Unrecognized_Number*)
 HMIHY: OK, I am forwarding you to the human agent. Please stay on the line.

FIGURE 41.4 A conceptual example dialog between the user and the AT&T HMIHY system.

Good afternoon), or asks for a human agent, the system reprompts the user accordingly to get some specific intent for their call (Figure 41.4).

Figure 41.2 shows a typical HMIHY dialog for AT&T call centers. The utterance level intents are shown in parentheses next to each user utterance, for a better understanding.

Following the HMIHY system, a number of similar systems have been built, such as the Lucent call routing system [6], the BBN call director [33], AT&T Helpdesk [10], AT&T VoiceTone [15], and the France Telecom 3000 [9] systems.

The biggest difference between the call classification systems and semantic frame filling systems is that the former does not care much about the arguments provided by the user. The main goal is *routing* the call to the appropriate call center department. The arguments provided by the user are important only in the sense that they help make the right classification. For example, if the user specifies the name of a drug in a system used for medical insurance call center, this can improve the confidence for routing to prescription renewal or refill departments. While this is a totally different perspective for the task of SLU, it is actually complementary to frame filling. For example, there are utterances in the ATIS corpus asking about ground transportation or the capacity of planes on a specific flight; hence, the users may have other intents than basically finding flight information.

41.3 Underlying Principles

In this section, we mainly cover the key tasks of SLU as used in human/machine conversational systems. These include utterance classification tasks for domain detection or intent determination and semantic template filling. We will also briefly cover the aspects of a DM interacting with them.

Then, we briefly cover other SLU tasks used in other human/machine applications, like question answering (like IBM Watson) and in human/human speech processing systems like dialog act tagging or summarization.

41.3.1 Domain Detection and Intent Determination

The semantic utterance classification tasks of domain detection and intent determination aim at classifying a given speech utterance X_r into one of M semantic classes, $\hat{C}_r \in \mathcal{C} = \{C_1, \dots, C_M\}$ (where r is the utterance index). Upon the observation of X_r , \hat{C}_r is chosen so that the class-posterior probability given X_r , $P(C_r|X_r)$, is maximized. Formally,

$$\hat{C}_r = \underset{c_r}{\arg \max} P(C_r|X_r) \quad (41.1)$$

Semantic classifiers require operation with significant freedom in utterance variations. A user may say “*I want to fly from Boston to New York next week*” and another user may express the same information by saying “*I am looking to fly from JFK to Boston in the coming week.*” In spite of this freedom of expression, utterances in such applications have a clear structure that binds the specific pieces of information together. Not only is there no *a priori* constraint on what the user can say, but the system should

be able to generalize well from a tractably small amount of training data. For example, the phrase “*Show all flights*” and “*Give me flights*” should be interpreted as variants of a single semantic class “Flight.” On the other hand, the command “*Show me fares*” should be interpreted as an instance of another semantic class, “Fare.” Typically, binary or weighted n -gram features with $n = 1,2,3$ to capture the likelihood of the n -grams are generated to express the user intent for the semantic class C . Traditional text categorization techniques devise learning methods to maximize the probability of C_r given the text W_r , that is the *class-posterior* probability $P(C_r|W_r)$. Other semantically motivated features like domain gazetteers (lists of entities), named entities (like organization names or time/date expressions), and contextual features (such as the previous dialog turn) can be used to enrich the feature set.

HMIHY SLU intent classifier heavily depends on portions of input utterances, namely, *salient phrases*, which are salient to some call types. For example, in an input utterance such as “*I would like to change oh about long distance service two one charge nine cents a minute,*” the salient phrase “*cents a minute*” is strongly related to the call-type *calling plans*.

The salient phrases are automatically acquired from a corpus of transcribed and labeled training data. The salience of a word n -gram, f , is computed using the formula, that is

$$S(f) = \sum_{c_k} P(c_k|f) I(f, c_k)$$

where c_k is a call type and $I(x, y)$ is the mutual information between x and y :

$$I(x, y) = \log \frac{P(x, y)}{P(x)}$$

Note that salience fragments are call-type independent. The phrases such as *I would like* still get high salience scores as these are used to improve the language model used for speech recognition.

The selected salient phrases are then clustered into salient grammar fragments (SGFs) [14,51]. The rationale for this clustering is better generalization. Assume two salient phrases *a wrong number* and *the wrong number*; they may be grouped together if they indicate the same call type. Once the SGFs are trained, it is then straightforward to classify an utterance. The SGFs are first compiled in the format of FSMs. Figure 41.5 shows an example simplified SGF. The ASR output (lattice or word confusion network) or input text, s , is then searched for the occurrences of the SGFs, using FSM operations. This is a left-to-right search that searches for the longest matching phrases. This results in a transduction from s to salient phrases, $f_i \in F$. The classification algorithm then chooses the call type with maximum peak value of the a posteriori probability distribution, that is,

$$K(s) = \arg \max_{c_k} P(c_k | f_{i(s)})$$

FIGURE 41.5 An example SGF.

where

$$i(s) = \arg \max_i \left(\max_{c_k} P(c_k | f_i) \right)$$

If this overall peak is less than some threshold, $P(c_k | f_{i(s)}) < \theta$, then the utterance is rejected and classified as *other*.

One of the earliest yet very successful approaches for call classification, adopted by the Bell Labs, is motivated by the information retrieval (IR)-based vector state model [6]. In this approach, first stop-words are removed; stemming is performed on the remaining words, following the usual practice in IR. Then a $F \times K(s)$ term–document matrix is created, where a term can be a word or a word phrase and documents are actually the classes or routes the call is routed to. Each term is weighted according to the well-known *tf.idf* (term frequency–inverse document frequency) paradigm. New user requests are then converted and formed as a vector in a similar fashion. The baseline algorithm simply chooses the class where the cosine distance between the user utterance and the route is the minimum as in traditional IR. The original system paper suggests two improvements on top of this baseline system. First, the similarity scores are mapped to between 0 and 1 by fitting a nondecreasing sigmoid function using the least-squares method so as to get confidence scores. The second improvement was employing singular value decomposition (SVD) to improve efficiency especially when the training corpus is not small. In SVD, the routing matrix, W , is decomposed so as to $W = USV^T$, where U and V are orthonormal matrices and S is a diagonal matrix of eigenvalues.

Later [7] have proposed extending this approach via latent semantic analysis (LSA). LSA is also based on using SVD to find a compact subspace for the routing matrix. In LSA, after SVD, top R eigenvalues are retained and others are discarded. Then, all the processing is done in the reduced subspace.

With the advances in machine learning, especially in discriminative classification techniques, in the last decade, researchers have worked on framing intent determination as a classification task. While the traditional solution to intent determination is the bag-of-words approach used in IR, typically word n -grams are used as features after preprocessing with generic entities, such as dates, locations, or phone numbers. Because of the very large dimensions of the input space, large margin classifiers such as SVMs [44] or Adaboost [37] were found to be very good candidates.

Early work has been done by [37] on the AT&T HMIHY system using the Boostexter tool, an implementation of the AdaBoost.MH multiclass multilabel classification algorithm. Boosting is an iterative algorithm; on each iteration, t , a weak classifier, h_t , is trained on a weighted training set, and at the end, the weak classifiers are combined into a single, combined classifier [12]. For example, for text categorization, one can use word n -grams as features, and each weak classifier (e.g., decision stump, which is a single node decision tree) can check the absence or presence of an n -gram. The performance of the classifier closely matched with the salience-based classification approach and beat it especially on high false alarm rates.

Another pioneering work was from the Bell Labs. [28] have proposed the use of discriminative training on the routing matrix, which significantly improved their vector-based call routing system described earlier [6], especially for low rejection rates. Their approach is based on using the minimum classification error (MCE) criterion. To solve the nonlinear optimization problem of achieving MCE, they used the generalized probabilistic descent (GPD) algorithm. The goal is adjusting the routing matrix elements so as to achieve maximum separation of the correct class from competing classes with an iterative approach. Later, they extended this approach so as to cover boosting and automatic relevance feedback (ARF) [56]. They have tested these approaches along with MCE, and proposed a novel combination method of boosting and MCE. While MCE happens to provide the best result among these three discriminative classification approaches, they obtain further gain from the combination of MCE with boosting.

The next category of discriminative call classification systems employed large margin classifiers, such as support vector machines, which were initially demonstrated on binary classification problems. With such classifiers, the definition of the margin is typically unambiguous, and the reasons why this margin leads to good generalization are reasonably well understood. Usually, the performance of SVMs can be reduced to a single number: the binary classification accuracy. Unfortunately, to generalize these binary SVM classifiers to multiclass call classification problems is not straightforward. [16] have proposed a global optimization process based on an optimal channel communication model that allows a combination of *heterogeneous* binary classifiers. As in Markov modeling, computational feasibility is achieved through simplifications and independence assumptions that are easy to interpret. Using this approach, they have managed to decrease the call-type classification error rate for AT&T’s HMIHY natural dialog system significantly, especially on the false rejection rates.

41.3.2 Slot Filling

The semantic structure of an application domain is defined in terms of the *semantic frames*. Figure 41.6 shows a simplified example of three semantic frames in the ATIS domain. The semantic frame contains several typed components called “*slots*.”

The task of slot filling is then to instantiate the semantic frames. Check Figure 41.7 for a semantic parse for the sentence “Show me flights from Seattle to Boston on Christmas Eve.” In this case, the semantic frame is represented as a flat list of *attribute–value pairs*, similar to [35], or *flat concept* representation.

Some SLU systems have adopted a hierarchical representation, as that is more expressive and allows the sharing of substructures. This is mainly motivated by syntactic constituency trees. An example tree for the same sentence is shown in Figure 41.8.

```

<frame name="Flight">
  <slot name="DCity" surface="Departure City">
  <slot name="ACity" surface="Arrival City">
  <slot name="DDate" surface="Departure Date">
  <slot name="Airline" surface="Airline">
  <slot name="NumStops" surface="Number of Stops">
  ...
</frame>

```

FIGURE 41.6 A simplified semantic class schema in the ATIS domain.

“Show me flights from <DCity> Seattle <DCity> to <ACity> Boston <ACity> on <DDate> Christmas eve <DDate>”

FIGURE 41.7 An example flat semantic parse.

FIGURE 41.8 An example hierarchical semantic parse tree.

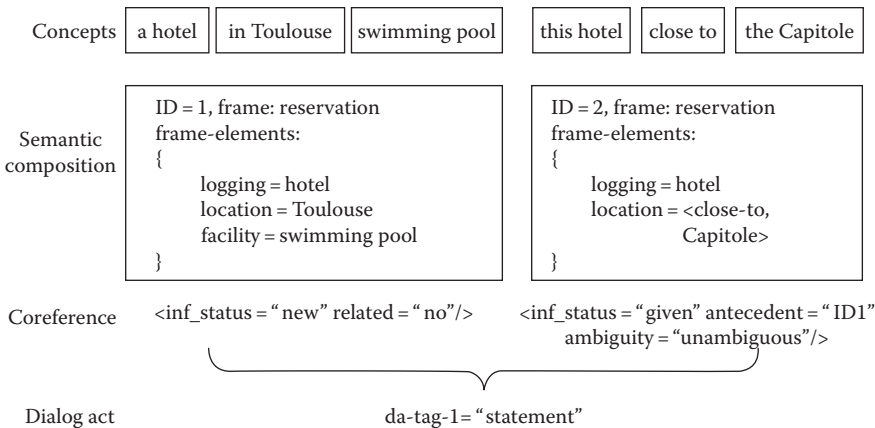

FIGURE 41.9 The multilevel semantic representation for the utterance “a hotel in Toulouse with a swimming pool um this hotel must be close to the Capitole” in the European LUNA project. (Reproduced from Bechet, F., Processing spontaneous speech in SLU systems: A survey, In *Proceedings of the IEEE Spoken Language Technologies (SLT) Workshop*, Goa, India, 2008.)

The semantic representation in the early French MEDIA project adopts an attribute–value list to represent the hierarchical semantic information [4]. This representation, used in the official annotation and evaluation, is ostensibly quite different from the frame-based representation.

The attempt of using this flat attribute–value representation for hierarchical semantics makes the meaning representation quite complicated. In the European LUNA project, a different representation was adopted, in which the MEDIA portion of data was re-annotated according to the new annotation protocol [3]. The semantic annotation protocol adopts a multilevel semantic representation, as illustrated by Figure 41.9. Here the concept level represents the concepts that bear important meanings in the input. The semantic composition level represents the utterance level meaning with semantic frames. A FrameNet-based semantic representation is adopted as an attempt for better generalization beyond a single application domain. The co-reference level annotation depicts the discourse information between the two related frames, while the fourth level models the dialog act (e.g., statement, Y/N question, Wh-question, confirmation).

In the statistical frame-based SLU, the task is often formalized as a pattern recognition problem. Given the word sequence W , the goal of SLU is to find the semantic representation of the meaning M that has the maximum a posteriori probability $P(M | W)$. In the generative model framework, the following decision rule is used:

$$\hat{M} = \arg \max_M P(M | W) = \arg \max_M P(W | M)P(M) \tag{41.2}$$

And the objective function of a generative model is to maximize the joint probability $P(W, M) = P(W | M)P(M)$ given a training sample of W and its semantic annotation M .

The first generative model, used by both CHRONUS [35] and the Hidden Understanding Model [32], assumes a deterministic one-to-one correspondence between model states and the segments, that is, there is only one segment per state, and the order of the segments follows that of the states.

As another extension, in the hidden vector state model, the states in the Markov chain represent encode all the structure information about the tree using stacks, so the semantic tree structure (excluding words) can be reconstructed from the hidden vector state sequence. The model imposes a hard limit on the maximum depth of the stack, so the number of the states becomes finite, and the prior model becomes the Markov chain in an HMM [19].

The state of the art in modeling slot filling relies on conditional models instead of such generative models. Conditional models are non-generative. A conditional model uses a state sequence $\hat{\mathbf{y}}$ to represent the meaning M of an observation sequence \mathbf{x} . $\hat{\mathbf{y}}$ is obtained according to the following equation:

$$\hat{\mathbf{y}} = \underset{\mathbf{y}}{\operatorname{arg\,max}} P(\mathbf{y} \mid \mathbf{x}) \tag{41.3}$$

Here, \mathbf{y} is directly conditioned on the observation \mathbf{x} . For SLU, conditional random fields (CRFs) or hidden state CRFs (HCRFs) are commonly used conditional models. With CRFs or HCRFs, the conditional probability of the entire state (label) sequence \mathbf{y} given the observation sequence follows an exponential (log-linear) model, with respect to a set of features. A feature $f_k(\mathbf{y}, \mathbf{x})$ in the set is a function of the observation sequence \mathbf{x} and the associated label sequence \mathbf{y} :

$$P(\mathbf{y} \mid \mathbf{x}; \Lambda) = \frac{1}{Z(\mathbf{x}; \Lambda)} \exp \left\{ \sum_k \lambda_k f_k(\mathbf{y}, \mathbf{x}) \right\} \tag{41.4}$$

Here $\Lambda = \{\lambda_k\}$ is a set of parameters. The value of λ_k determines the impact of the feature $f_k(\mathbf{y}, \mathbf{x})$ on the conditional probability. $Z(\mathbf{x} : \Lambda) = \sum_{\mathbf{y}} \exp\{\sum_k \lambda_k f_k(\mathbf{y}, \mathbf{x})\}$ is a partition function that normalizes the distribution.

The CRF in Equation 41.4 is unconstrained in the sense that the feature functions are defined on the entire label sequence \mathbf{y} . Because the number of all possible label sequences is combinatorial, the model training and inference of an unconstrained CRF is very inefficient. Because of that, it is common to restrict attention to the linear-chain CRFs [29]. The linear-chain CRFs impose a Markov constraint on the model topology and, as a consequence, restrict the feature functions to depend only on the labels assigned to the current and the immediately previous states, in the form $f(y_{t-1}, y_t, \mathbf{x}, t)$. The restrictions enable the application of efficient dynamic programming algorithms in model training and inference yet still support potentially interdependent features defined on the entire observation sequence \mathbf{x} .

Figure 41.10 shows the difference between the HMMs and the linear-chain CRFs in graphic model representations. First, since HMMs are generative models, the graph is directed, which points to the direction of the generative process. The state at time t , represented by the random variable y_t , depends on the state at time $t - 1$, y_{t-1} , \mathbf{x}_t , and the observation at time t is generated with the dependency on y_t . CRFs, on the other hand, are represented by undirected graphs since they are direct, non-generative models. Second, observations in HMMs are generated one at a time in a uniform way, while in CRFs the observation sequence is given, so at each slice of time it can employ features that depend on the entire observation sequence.

The parameters Λ in CRFs can be optimized according to the objective function with numeric algorithms like stochastic gradient decent or L-BFGS. In a straightforward application of CRFs for the frame-based SLU, \mathbf{x} consists of a transcribed utterance, and \mathbf{y} is the semantic label sequence assigned to \mathbf{x} . Non-slot filler words are assigned a null state, as illustrated by Figure 41.11.

FIGURE 41.10 The graphic model representations for (a) HMMs (generative model) and (b) CRFs (conditional model). A generative model is a directed graph that points to the direction of the generative process, and observations are generated frame by frame in a uniform way. Conditional models are represented by undirected models, where the entire observation sequence \mathbf{o} is observable for every state in the model.

list	twa	flights	from	washington	to	philadelphia
null	AirlineCode	null	null	ACity	null	DCity

FIGURE 41.11 Frame-based SLU as a sequential labeling problem: words are assigned labels representing their meaning.

Typical features used by the CRFs for SLU include the transition features, the n -gram features, and the class membership (aka word list) features. The transition features model the dependency among adjacent states, which capture the influence of context on the tag assigned to a given word. The n -gram features often include the lexical features to capture the relation between the current state and the identity of the current (and previous) words. The class member features check if the current word is part of an entry in the lexicon of a syntactic or semantic class.

As an attempt to joint modeling slot filling and intent determination, triangular CRF models have been proposed [24]. These models jointly represent the sequence and meta-sequence labels in a single graphical structure that both explicitly encodes their dependencies and preserves uncertainty between them. While such models jointly optimize both tasks, it requires the training data to be the same, which may be a limiting factor in some applications.

The recent work on semantic parsing heavily relies on mining big data found on the web, web queries, and implicit user feedback, instead of clean transcribed and annotated data for each domain. For example, [18] employed queries mined from search engine query logs to improve domain detection in SLU. Extending the label propagation algorithm, a graph-based semi supervised learning approach is proposed to incorporate noisy domain information estimated from search engine that links the users click following their queries. Furthermore, the semantic web community is building and populating big-scale knowledge bases, with structured and unstructured meta information. By aligning the slots with the nodes and the intents with the edges in the knowledge graph, it is possible to directly leverage the structure of the semantic graphs to automatically specify a semantic representation for a given domain [20,42]. The corresponding natural language surface forms are mined from search queries or web pages and used to automatically train SLU systems in an unsupervised manner that cover the knowledge represented in the semantic graph.

41.3.3 Semantic Parsing for Dialog Management

As shown in Figure 41.1, the output of SLU is fed into the DM. Counterintuitively, the brain of a human/machine conversational system is not the semantic parsing but instead the DM. However, the DM heavily relies on the SLU output given the context (like the previous utterance, dialog context, meta-information about the user and the location, and any other knowledge integrated into the system).

Interestingly, the field of dialog management has emerged somewhat independently from the SLU area. In most cases, the assumption has been a machine-directed dialog and the models are usually trained with simulated data [43].

The key task in a DM is deciding on the next action (A_t) given the SLU output (U_t). The first step for doing this is updating the so-called *belief state*. A belief state, $s \in S$, is an instance of a semantic representation in that context. Usually, the same semantic representation is used as SLU. In most advanced dialog systems, instead of relying on a single belief state, a probability distribution over all possible states is maintained.

The earliest statistical approach relies on a Markov decision process (MDP) [31], focusing on optimizing the dialog strategies. Later this approach is extended to support uncertainty resulting in partially observable MDPs (POMDPs) [54]. Recent efforts focus on using state clustering or lighter-weight discriminative approaches to overcome the problem of POMDPs.

Aside from research labs, statistical dialog management techniques have not been adopted due to their heavy processing cost and complexity. Most commercial systems (as used in call centers, robots, or mobile devices) rely on rule-based DMs for both belief state update and policy determination.

41.3.4 Spoken Language Understanding in Human/Human Conversations

While the term “SLU” is coined for human/machine conversations, it is not hard to think of other interactive understanding tasks, such as spoken question answering, voice search, or other similar human/human conversation understanding tasks such as named entity extraction or topic classification. Each of these tasks are studied extensively, and the progress is fascinating. An example would be the IBM Watson system for question answering [11].

With respect to human/human communication processing, telephone conversations or multiparty meetings are studied heavily. Some open questions include the following: What information from these interactions would be useful for later use? Does this information depend on user/purpose? How could the transcripts of these conversations be used? The reviewed research activities are grouped in the following areas:

- *Dialog act tagging*: Aims to annotate speech acts such as suggestions and questions jointly with conversational linguistic acts such as acknowledgment and agreement. This task is heavily influenced by annotated corpora from human/human and multiparty meetings such as Switchboard and ICSI/AMI data sets. It is mainly treated as an enabling technology for further conversation processing, such as extracting action items or discussions. Dialog act tagging is generally framed as an utterance classification problem [40,41, among others], following the dialog act segmentation. While mostly lexical and contextual features are used, in some cases, such as agreement and disagreement, prosodic features have been shown to help [52].
- *Dialog act segmentation*: Aims to chop spoken utterances into dialog act units as defined by the dialog act tagging schema. While this task is very close to sentence segmentation, there are certain nuances due to the nature of spontaneous conversational speech. Dialog act segmentation is treated as a binary boundary classification problem using lexical, prosodic, and acoustic features [26,39, among others]. There are also few studies performing joint dialog act segmentation and tagging [48,55].
- *Discourse and topic segmentation*: Aims to chop a conversation into topically coherent units. While topic segmentation of text or prewritten speech is a well-established area, there are relatively fewer studies on processing human/human conversations and multiparty meetings.
- *Summarization*: Aims to generate a compact, summary version of meeting discussions. The summaries can be formed by extracting original speaker utterances (extractive summarization) or by formulating new sentences for the summary (abstractive summarization).
- *Action item and decision detection*: Aims to detect task assignments to people and associated deadlines and decision-making subdialogs during a meeting. These can be used to enter such information into the person’s calendar or to track the status and progress of these action items or decisions in the following meetings. The decisions made in meetings can be used for indexing meetings, and one can go back and access the content of the meeting where a specific decision was made. They can also be used to track the progress and efficiency of meetings.
- *Speaker role detection*: Aims to classify each of the speakers with respect to their institutional roles. While this is an area deeply rooted in the social sciences, most systems have taken a simplistic view and instead focused on professional roles, such as professor vs. student, boss vs. employee, or project manager vs. software engineer.
- *Addressee detection*: An important enabling task in processing conversations is determining who is talking or who the speaker is referring to. This is useful in downstream understanding of conversations in that it provides essential semantic grounding for the analyzed dialog. This task also covers resolving references (especially pronominal references) in utterances.

41.4 Research Issues

The field of SLU is closely related to NLU, a field that has been studied for more than half a century. NLU focus mainly on the understanding of general domain written texts. Because there is not a specific application domain for the general-purpose NLU, the semantics in NLU have to be defined in a broader sense, such as thematic roles (agents, patients, etc.) In contrast, the SLU has, in the current state of technology, focused only on specific application domains. The semantics are defined very specifically according to the application domain, as illustrated by the earlier examples of semantic frames. Many domain-specific constraints can be included in the understanding model. Ostensibly, this may make the problem easier to solve. Unfortunately, there are many new challenges for SLU, including the following:

- *Extra-grammaticality*: Spoken languages are not as well formed as written languages. People are in general less careful with speech than with writings. They often do not comply with rigid syntactic constraints.
- *Disfluencies*: False starts, repairs, and hesitations are pervasive, especially in conversational speech.
- *Speech recognition errors*: Speech recognition technology is far from perfect. Environment noises, speaker's accent, domain-specific terminologies, all make speech recognition errors inevitable. It is common to see that a generic speech recognizer has over 30% word error rates on domain-specific data.
- *Out-of-domain utterances*: A dialog system can never restrict a user from saying anything out of a specific domain, even in a system-initiated dialog, where users are prompted for answers to specific questions. Because the frame-based SLU focuses on a specific application domain, out-of-domain utterances are not well modeled and can often be confused as an in-domain utterance. Detecting the out-of-domain utterances is not an easy task—it is complicated by the extra-grammaticality, disfluencies, and ASR errors of the in-domain utterances. Furthermore, when there are other humans in the environment, it is nontrivial to separate human-addressed speech from machine-addressed.

In summary, robustness is one of the most important issues in SLU. A system should be able to gracefully handle the unexpected inputs. If an input string is not accepted by a grammar/model, it is still desirable to identify the well-formed concepts in the input that carry important information for a given domain. On the other hand, a robust solution tends to over generalize and introduce ambiguities, leading to the reduction in understanding accuracy. A major challenge to the SLU is thus to strike an optimal balance between the robustness and the constraints that prevent the over generalizations and reduce the ambiguities.

41.5 Summary

We have presented a survey of the state of the art in SLU, focusing on human/computer conversational systems. We mainly described two technical areas of SLU, namely, intent determination and slot filling in detail. The state-of-the-art approaches relying on data-driven methods are being heavily used in academic and industrial research labs, though it started to quickly propagate to commercial applications like personal assistants (e.g., Nuance Nina). This is in contrast to knowledge-based methods that dominate the commercial applications.

Regarding human/machine interactive systems, the candidate applications and environments are growing with tremendous speed. We would like to emphasize on two aspects:

- *Multimodal interaction*: Although there were earlier multimodal interactive systems, such as AT&T MATCH, Microsoft MiPad, or ESPRIT MASK [22,25,30, among others], the boom of smart phones resulted in a completely new array of multimodal applications. All the traditional

SLU and dialog management concepts need to be tailored to multimodal interaction from parsing to grounding to belief state optimization to response generation. Moreover, with the multimodal output, several different actions can be performed simultaneously. This seems to be an exciting area for the near future.

- *Personalization*: Interactive systems are now becoming highly personalized. For example, the mobile device can record vast amounts of private information about the user, ranging from contact lists, calendars, to history of geo-locations coupled with time and previous written or spoken communications. This user-specific metadata is waiting to be exploited for “customized” user interaction, instead of a “one size fits all” speech systems, such as voice search or call routing. Personalized mobile systems also enable longitudinal user studies, since users typically continue to use their mobile multimodal applications over a long period of time. One potential application would be using implicit supervision for user adaptation of models, exploiting user behavior patterns.

Key Term

360° Review: Performance review that includes feedback from superiors, peers, subordinates, and clients.

42.1 Introduction

Within the broad scope of the study of artificial intelligence (AI), research in neural networks is characterized by a particular focus on pattern recognition and pattern generation. Many neural network methods can be viewed as generalizations of classical pattern-oriented techniques in statistics and the engineering areas of signal processing, system identification, and control theory. As in these parent disciplines, the notion of “pattern” in neural network research is essentially probabilistic and numerical. Neural network methods have had their greatest impact in problems where statistical issues dominate and where data are easily obtained.

A neural network is first and foremost a graph, with patterns represented in terms of numerical values attached to the nodes of the graph and transformations between patterns achieved via simple message-passing algorithms. Many neural network architectures, however, are also statistical processors, characterized by making particular probabilistic assumptions about data. As we will see, this conjunction of graphical algorithms and probability theory is not unique to neural networks but characterizes a wider family of probabilistic systems in the form of chains, trees, and networks that are currently being studied throughout AI (Spiegelhalter et al. 1993).

Neural networks have found a wide range of applications, the majority of which are associated with problems in pattern recognition and control theory. In this context, neural networks can best be viewed as a class of algorithms for statistical modeling and prediction. Based on a source of *training data*, the aim is to produce a statistical model of the process from which the data are generated, so as to allow the best predictions to be made for new data. We shall find it convenient to distinguish three broad types of statistical modeling problems, which we shall call *density estimation*, *classification*, and *regression*.

For density estimation problems (also referred to as *unsupervised learning* problems), the goal is to model the unconditional distribution of data described by some vector \mathbf{x} . A practical example of the application of density estimation involves the interpretation of x-ray images (mammograms) used for breast cancer screening (Tarassenko 1995). In this case, the training vectors \mathbf{x} form a sample taken from normal (noncancerous) images, and a network model is used to build a representation of the density $p(\mathbf{x})$. When a new input vector \mathbf{x}' is presented to the system, a high value for $p(\mathbf{x}')$ indicates a normal image, whereas a low value indicates a novel input, which might be characteristic of an abnormality. This is used to label regions of images that are unusual, for further examination by an experienced clinician.

For classification and regression problems (often referred to as *supervised learning* problems), we need to distinguish between *input* variables, which we again denote by \mathbf{x} , and *target* variables, which we denote by the vector \mathbf{t} . Classification problems require that each input vector \mathbf{x} be assigned to one of C classes C_1, \dots, C_C , in which case the target variables represent class labels. As an example, consider the problem of recognizing handwritten digits (LeCun et al. 1989). In this case, the input vector would be some (preprocessed) image of the digit, and the network would have 10 outputs, one for each digit, which can be used to assign input vectors to the appropriate class (as discussed in Section 42.2).

Regression problems involve estimating the values of continuous variables. For example, neural networks have been used as part of the control system for adaptive optics telescopes (Sandler et al. 1991). The network input \mathbf{x} consists of one in-focus and one defocused image of a star, and the output \mathbf{t} consists of a set of coefficients that describe the phase distortion due to atmospheric turbulence. These output values are then used to make real-time adjustments of the multiple mirror segments to cancel the atmospheric distortion. Classification and regression problems also can be viewed as special cases of density estimation. The most general and complete description of the data is given by the probability distribution function $p(\mathbf{x}, \mathbf{t})$ in the joint input–target space. However, the usual goal is to be able to make good predictions for the target variables when presented with new values of the inputs. In this case, it is convenient to decompose the joint distribution in the following form:

$$p(\mathbf{x}, \mathbf{t}) = p(\mathbf{t} | \mathbf{x})p(\mathbf{x}) \quad (42.1)$$

and to consider only the conditional distribution $p(\mathbf{t}|\mathbf{x})$, in other words the distribution of \mathbf{t} given the value of \mathbf{x} . Thus, classification and regression involve the estimation of *conditional* densities, a problem that has its own idiosyncrasies.

The organization of the chapter is as follows. In Section 42.2, we present examples of network representations of unconditional and conditional densities. In Section 42.3, we discuss the problem of adjusting the parameters of these networks to fit them to data. This problem has a number of practical aspects, including the choice of optimization procedure and the method used to control network complexity. We then discuss a broader perspective on probabilistic network models in Section 42.4. The final section presents further information and pointers to the literature.

42.2 Representation

In this section, we describe a selection of neural network architectures that have been proposed as representations for unconditional and conditional densities. After a brief discussion of density estimation, we discuss classification and regression, beginning with simple models that illustrate the fundamental ideas and then progressing to more complex architectures. We focus here on representational issues, postponing the problem of learning from data until the following section.

42.2.1 Density Estimation

We begin with a brief discussion of density estimation, utilizing the Gaussian *mixture model* as an illustrative model. We return to more complex density estimation techniques later in the chapter.

Although density estimation can be the main goal of a learning system, as in the diagnosis example mentioned in the Introduction, density estimation models arise more often as components of the solution to a more general classification or regression problem. To return to Equation 42.1, note that the joint density is composed of $p(\mathbf{t}|\mathbf{x})$, to be handled by classification or regression models, and $p(\mathbf{x})$, the (unconditional) real-life datasets that often have missing components in the input vector. Having a model of the density allows the missing components to be filled in an intelligent way. This can be useful both for training and for prediction (cf. Bishop 1995). Second, as we see in Equation 42.1, a model of $p(\mathbf{x})$ makes possible an estimate of the joint probability $p(\mathbf{x}, \mathbf{t})$. This in turn provides us with the necessary information to estimate the inverse conditional density $p(\mathbf{x}|\mathbf{t})$. The calculation of such inverses is important for applications in control and optimization.

A general and flexible approach to density estimation is to treat the density as being composed of a set of M simpler densities. This approach involves modeling the observed data as a sample from a *mixture density*,

$$p(\mathbf{x} | \mathbf{w}) = \sum_{i=1}^M \pi_i p(\mathbf{x} | i, \mathbf{w}_i) \quad (42.2)$$

where

π_i is constants known as *mixing proportions*

$p(\mathbf{x}|i, \mathbf{w}_i)$ is the *component densities*, generally taken to be from a simple parametric family

A common choice of component density is the multivariate Gaussian, in which case the parameters \mathbf{w}_i are the means and covariance matrices of each of the components. By varying the means and covariances to place and orient the Gaussians appropriately, a wide variety of high-dimensional, multimodal data can be modeled. This approach to density estimation is essentially a probabilistic form of clustering.

Gaussian mixtures have a representation as a network diagram, as shown in Figure 42.1. The utility of such network representations will become clearer as we proceed; for now, it suffices to note that not only mixture models, but also a wide variety of other classical statistical models for density estimation, are representable as simple networks with one or more layers of adaptive weights. These methods include *principal component analysis*, *canonical correlation analysis*, *kernel density estimation*, and *factor analysis* (Anderson 1984).

42.2.2 Linear Regression and Linear Discriminants

Regression models and classification models both focus on the conditional density $p(\mathbf{t}|\mathbf{x})$. They differ in that in regression the target vector \mathbf{t} is a real-valued vector, whereas in classification \mathbf{t} takes its values from a discrete set representing the class labels.

The simplest probabilistic model for regression is one in which \mathbf{t} is viewed as the sum of an underlying deterministic function $f(\mathbf{x})$ and a Gaussian random variable ε ,

$$\mathbf{t} = f(\mathbf{x}) + \varepsilon \quad (42.3)$$

where

ε is the *zero mean*, as is commonly assumed

$f(\mathbf{x})$ is the *conditional mean* $E(\mathbf{t}|\mathbf{x})$

It is this function that is the focus of most regression modeling. Of course, the conditional mean describes only the first moment of the conditional distribution, and as we discuss in a later section, a good regression model will also generally report information about the second moment.

FIGURE 42.1 A network representation of a Gaussian mixture distribution. The input pattern \mathbf{x} is represented by numerical values associated with the input nodes in the lower level. Each link has a weight μ_{ij} , which is the j th component of the mean vector for the i th Gaussian. The i th intermediate node contains the covariance matrix Σ_i and calculates the Gaussian conditional probability $p(\mathbf{x}|i, \mu_i, \Sigma_i)$. These probabilities are weighted by the mixing proportions π_i , and the output node calculates the weighted sum $p(\mathbf{x}) = \sum_i \pi_i p(\mathbf{x} | i, \mu_i, \Sigma_i)$.

In a linear regression model, the conditional mean is a linear function of \mathbf{x} : $E(t|\mathbf{x}) = W\mathbf{x}$, for a fixed matrix W . Linear regression has a straightforward representation as a network diagram in which the j th input unit represents the j th component of the input vector \mathbf{x} , each output unit i takes the weighted sum of the input values, and the weight w_{ij} is placed on the link between the j th input unit and the i th output unit.

The conditional mean is also an important function in classification problems, but most of the focus in classification is on a different function known as a *discriminant function*. To see how this function arises and to relate it to the conditional mean, we consider a simple two-class problem in which the target is a simple binary scalar that we now denote by t . The conditional mean $E(t|\mathbf{x})$ is equal to the probability that t equals one, and this latter probability can be expanded via Bayes rule:

$$p(t = 1 | \mathbf{x}) = \frac{p(\mathbf{x} | t = 1)p(t = 1)}{p(\mathbf{x})} \tag{42.4}$$

The density $p(t|\mathbf{x})$ in this equation is referred to as the *posterior probability* of the class given the input, and the density $p(\mathbf{x}|t)$ is referred to as the *class-conditional density*. Continuing the derivation, we expand the denominator and (with some foresight) introduce an exponential:

$$\begin{aligned} p(t = 1 | \mathbf{x}) &= \frac{p(\mathbf{x} | t = 1)p(t = 1)}{p(\mathbf{x} | t = 1)p(t = 1) + p(\mathbf{x} | t = 0)p(t = 0)} \\ &= \frac{1}{1 + \exp\left\{-\ln\left[\frac{p(\mathbf{x} | t = 1)}{p(\mathbf{x} | t = 0)}\right] - \ln\left[\frac{p(t = 1)}{p(t = 0)}\right]\right\}} \end{aligned} \tag{42.5}$$

We see that the posterior probability can be written in the form of the *logistic function*:

$$y = \frac{1}{1 + e^{-z}} \quad (42.6)$$

where z is a function of the likelihood ratio $p(\mathbf{x}|t=1)/p(\mathbf{x}|t=0)$ and the prior ratio $p(t=1)/p(t=0)$. This is a useful representation of the posterior probability if z turns out to be simple.

It is easily verified that if the class-conditional densities are multivariate Gaussians with identical covariance matrices, then z is a linear function of \mathbf{x} : $z = \mathbf{w}^T \mathbf{x} + w_0$. Moreover, this representation is appropriate for any distribution in a broad class of densities known as the exponential family (which includes the Gaussian, the Poisson, the gamma, the binomial, and many other densities). All of the densities in this family can be put in the following form:

$$g(\mathbf{x}; \theta, \phi) = \exp \left\{ \frac{(\theta^T \mathbf{x} - b(\theta))}{a(\phi) + c(\mathbf{x}, \phi)} \right\} \quad (42.7)$$

where

θ is the *location parameter*

ϕ is the *scale parameter*

Substituting this general form in Equation 42.5, where θ is allowed to vary between the classes and ϕ is assumed to be constant between classes, we see that z is in all cases a linear function. Thus, the choice of a linear-logistic model is rather robust.

The geometry of the two-class problem is shown in Figure 42.2, which shows Gaussian class-conditional densities and suggests the logistic form of the posterior probability.

The function z in our analysis is an example of a discriminant function. In general, a discriminant function is any function that can be used to decide on class membership (Duda and Hart 1973); our analysis has produced a particular form of discriminant function that is an intermediate step in the

FIGURE 42.2 This shows the Gaussian class-conditional densities $p(x|C_i)$ (dashed curves) for a two-class problem in one dimension, together with the corresponding posterior probability $p(C_1|x)$ (solid curve), which takes the form of a logistic sigmoid. The vertical line shows the decision boundary for $y = 0.5$, which coincides with the point at which the two density curves cross.

calculation of a posterior probability. Note that if we set $z = 0$, from the form of the logistic function, we obtain a probability of 0.5, which shows that $z = 0$ is a *decision boundary* between the two classes.

The discriminant function that we found for exponential family densities is linear under the given conditions on ϕ . In more general situations, in which the class-conditional densities are more complex than a single exponential family density, the posterior probability will not be well characterized by the linear–logistic form. Nonetheless, it still is useful to retain the logistic function and focus on *nonlinear* representations for the function z . This is the approach taken within the neural network field.

To summarize, we have identified two functions that are important for regression and classification, respectively: the conditional mean and the discriminant function. These are the two functions that are of concern for simple linear models and, as we now discuss, for more complex nonlinear models as well.

42.2.3 Nonlinear Regression and Nonlinear Classification

The linear regression and linear discriminant functions introduced in the previous section have the merit of simplicity but are severely restricted in their representational capabilities. A convenient way to see this is to consider the geometrical interpretation of these models. When viewed in the d -dimensional \mathbf{x} -space, the linear regression function $\mathbf{w}^T \mathbf{x} + w_0$ is constant on hyperplanes, which are orthogonal to the vector \mathbf{w} . For many practical applications, we need to consider much more general classes of function. We therefore seek representations for nonlinear mappings, which can approximate any given mapping to arbitrary accuracy. One way to achieve this is to transform the original \mathbf{x} using a set of M nonlinear functions $\phi_j(\mathbf{x})$ where $j = 1, \dots, M$ and then to form a linear combination of these functions, so that

$$y_k(\mathbf{x}) = \sum_j w_{kj} \phi_j(\mathbf{x}) \quad (42.8)$$

For a sufficiently large value of M , and for a suitable choice of the $\phi_j(\mathbf{x})$, such a model has the desired universal approximation properties. A familiar example, for the case of 1D input spaces, is the simple polynomial, for which the $\phi_j(\mathbf{x})$ are simply successive powers of \mathbf{x} and the w are the polynomial coefficients. Models of the form in Equation 42.8 have the property that they can be expressed as network diagrams in which there is a *single* layer of adaptive weights.

There are a variety of families of functions in one dimension that can approximate any continuous function to arbitrary accuracy. There is, however, an important issue that must be addressed, called the *curse of dimensionality*. If, for example, we consider an M th-order polynomial, then the number of independent coefficients grows as d^M (Bishop 1995). For a typical medium-scale application with, say, 30 inputs, a fourth-order polynomial (which is still quite restricted in its representational capability) would have over 46,000 adjustable parameters. As we shall see in the section on complexity control, in order to achieve good generalization, it is important to have more data points than adaptive parameters in the model, and this is a serious problem for methods that have a power law or exponential growth in the number of parameters.

A solution to the problem lies in the fact that, for most real-world datasets, there are strong (often nonlinear) correlations between the input variables such that the data do not uniformly fill the input space but are effectively confined to a subspace whose dimensionality is called the *intrinsic dimensionality* of the data. We can take advantage of this phenomenon by considering again a model of the form in Equation 42.8 but in which the basis functions $\phi_j(\mathbf{x})$ are *adaptive* so that they themselves contain weight parameters whose values can be adjusted in the light of the observed dataset. Different models result from different choices for the basis functions, and here we consider the two most common examples. The first of these is called the *multilayer perceptron* (MLP) and is obtained by choosing the basis

FIGURE 42.3 An example of a feedforward network having two layers of adaptive weights. The bias parameters in the first layer are shown as weights from an extra input having a fixed value of $x_0 = 1$. Similarly, the bias parameters in the second layer are shown as weights from an extra hidden unit, with activation again fixed at $z_0 = 1$.

functions to be given by linear–logistic functions (Equation 42.6). This leads to a multivariate nonlinear function that can be expressed in the form

$$y_k(\mathbf{x}) = \sum_{j=1}^M w_{kj} g \left(\sum_{i=1}^d w_{ji} x_i + w_{j0} \right) + w_{k0} \tag{42.9}$$

Here, w_{j0} and w_{k0} are *bias* parameters, and the basis functions are called *hidden units*. The function $g(\cdot)$ is the logistic sigmoid function of Equation 42.6. This also can be represented as a network diagram as in Figure 42.3. Such a model is able to take account of the intrinsic dimensionality of the data because the first-layer weights w_{ji} can adapt and hence orient the surfaces along which the basis function response is constant. It has been demonstrated that models of this form can approximate to arbitrary accuracy any continuous function, defined on a compact domain, provided the number M of hidden units is sufficiently large. The MLP model can be extended by considering several successive layers of weights. Note that the use of nonlinear activation functions is crucial, because if $g(\cdot)$ in Equation 42.9 was replaced by the identity, the network would reduce to several successive linear transformations, which would itself be linear.

The second common network model is obtained by choosing the basis functions $\phi_j(\mathbf{x})$ in Equation 42.8 to be functions of the radial variable $\mathbf{x} - \mu_j$ where μ_j is the *center* of the j th basis function, which gives rise to the *radial basis function (RBF) network* model. The most common example uses Gaussians of the following form:

$$\phi_j(\mathbf{x}) = \exp \left\{ -\frac{1}{2} (\mathbf{x} - \mu_j)^T \sum_j^{-1} (\mathbf{x} - \mu_j) \right\} \tag{42.10}$$

Here, both the mean vector μ_j and the covariance matrix Σ_j are considered to be adaptive parameters. The curse of dimensionality is alleviated because the basis functions can be positioned and oriented in input space such as to overlay the regions of high data density and hence to capture the nonlinear correlations between input variables. Indeed, a common approach to training an RBF network is to use a two-stage procedure (Bishop 1995). In the first stage, the basis function parameters are determined

using the input data alone, which corresponds to a density estimation problem using a mixture model in which the component densities are given by the basis functions $\phi_j(\mathbf{x})$. In the second stage, the basis function parameters are frozen, and the second-layer weights w_{kj} are found by standard least-squares optimization procedures.

42.2.4 Decision Trees

MLP and RBF networks are often contrasted in terms of the support of the basis functions that compose them. MLP networks are often referred to as “global,” given that linear–logistic basis functions are bounded away from zero over a significant fraction of the input space. Accordingly, in an MLP, each input vector generally gives rise to a distributed pattern over the hidden units. RBF networks, on the other hand, are referred to as “local,” due to the fact that their Gaussian basis functions typically have support over a local region of the input space. It is important to note, however, that local support does not necessarily mean nonoverlapping support; indeed, there is nothing in the RBF model that prefers basis functions that have nonoverlapping support. A third class of model that does focus on basis functions with nonoverlapping support is the *decision tree* model (Breiman et al. 1984). A decision tree is a regression or classification model that can be viewed as asking a sequence of questions about the input vector. Each question is implemented as a linear discriminant, and a sequence of questions can be viewed as a recursive partitioning of the input space. All inputs that arrive at a particular leaf of the tree define a polyhedral region in the input space. The collection of such regions can be viewed as a set of basis functions. Associated with each basis function is an output value, which (ideally) is close to the average value of the conditional mean (for regression) or discriminant function (for classification, a majority vote is also used). Thus, the decision tree output can be written as a weighted sum of basis functions in the same manner as a layered network.

As this discussion suggests, decision trees and MLP/RBF neural networks are best viewed as being different points along the continuum of models having overlapping or nonoverlapping basis functions. Indeed, as we show in the following section, decision trees can be treated probabilistically as mixture models, and in the mixture approach, the sharp discriminant function boundaries of classical decision trees become smoothed, yielding partially overlapping basis functions.

There are trade-offs associated with the continuum of degree-of-overlap; in particular, nonoverlapping basis functions are generally viewed as being easier to interpret and better able to reject noisy input variables that carry little information about the output. Overlapping basis functions often are viewed as yielding lower variance predictions and as being more robust.

42.2.5 General Mixture Models

The use of mixture models is not restricted to density estimation; rather, the mixture approach can be used quite generally to build complex models out of simple parts. To illustrate, let us consider using mixture models to model a conditional density in the context of a regression or classification problem. A mixture model in this setting is referred to as a “mixtures of experts” model (Jacobs et al. 1991).

Suppose that we have at our disposal an elemental conditional model $p(\mathbf{t}|\mathbf{x}, \mathbf{w})$. Consider a situation in which the conditional mean or discriminant exhibits variation on a local scale that is a good match to our elemental model, but the variation differs in different regions of the input space. We could use a more complex network to try to capture this global variation; alternatively, we might wish to combine local variants of our elemental models in some manner. This can be achieved by defining the following probabilistic mixture:

$$p(\mathbf{t}|\mathbf{x}, \mathbf{w}) = \sum_{i=1}^M p(i|\mathbf{x}, \mathbf{v}) p(\mathbf{t}|\mathbf{x}, i, \mathbf{w}_i) \quad (42.11)$$

Comparing this mixture to the unconditional mixture defined earlier in Equation 42.2, we see that both the mixing proportions and the component densities are now conditional densities dependent on the input vector \mathbf{x} . The former dependence is particularly important: we now view the mixing proportion $p(i|\mathbf{x}, \mathbf{v})$ as providing a probabilistic device for choosing different elemental models (“experts”) in different regions of the input space. A learning algorithm that chooses values for the parameters \mathbf{v} as well as the values for the parameters \mathbf{w}_i can be viewed as attempting to find both a good partition of the input space and a good fit to the local models within that partition.

This approach can be extended recursively by considering mixtures of models where each model may itself be a mixture model (Jordan and Jacobs 1994). Such a recursion can be viewed as providing a probabilistic interpretation for the decision trees discussed in the previous section. We view the decisions in the decision tree as forming a recursive set of probabilistic selections among a set of models. The total probability of target \mathbf{t} given input \mathbf{x} is the sum across all paths down the tree:

$$p(\mathbf{t}|\mathbf{x}, \mathbf{w}) = \sum_{i=1}^M p(i|\mathbf{x}, \mathbf{u}) \sum_{j=1}^M p(j|\mathbf{x}, i, \mathbf{v}_i) \cdots p(\mathbf{t}|\mathbf{x}, i, j, \dots, \mathbf{w}_{ij} \cdots) \quad (42.12)$$

where

i and j are the decisions made at the first level and second level of the tree, respectively

$p(\mathbf{t}|\mathbf{x}, i, j, \dots, \mathbf{w}_{ij} \dots)$ is the elemental model at the leaf of the tree defined by the sequence of decisions

This probabilistic model is a conditional hierarchical mixture. Finding parameter values \mathbf{u} , \mathbf{v}_i , etc., to fit this model to data can be viewed as finding a nested set of partitions of the input space and fitting a set of local models within the partition.

The mixture model approach can be viewed as a special case of a general methodology known as *learning by committee*. Bishop (1995) provides a discussion of committees; we will also meet them in the section on Bayesian methods later in the chapter.

42.3 Learning from Data

The previous section has provided a selection of models to choose from; we now face the problem of matching these models to data. In principle, the problem is straightforward: given a family of models of interest, we attempt to find out how probable each of these models is in the light of the data. We can then select the most probable model (a selection rule known as *maximum a posteriori* [MAP] estimation), or we can select some highly probable subset of models, weighted by their probability (an approach that we discuss in the section on Bayesian methods). In practice, there are a number of problems to solve, beginning with the specification of the family of models of interest. In the simplest case, in which the family can be described as a fixed structure with varying parameters (e.g., the class of feedforward MLPs with a fixed number of hidden units), the learning problem is essentially one of *parameter estimation*. If, on the other hand, the family is not easily viewed as a fixed parametric family (e.g., feedforward MLPs with a variable number of hidden units), then we must solve the *model selection* problem.

In this section, we discuss the parameter estimation problem. The goal will be to find MAP estimates of the parameters by maximizing the probability of the parameters given the data \mathcal{D} . We compute this probability using Bayes rule:

$$p(\mathbf{w}|\mathcal{D}) = \frac{p(\mathcal{D}|\mathbf{w})p(\mathbf{w})}{p(\mathcal{D})} \quad (42.13)$$

where we see that to calculate MAP estimates we must maximize the expression in the numerator (the denominator does not depend on \mathbf{w}). Equivalently we can minimize the negative logarithm of the numerator. We thus define the following *cost function* $J(\mathbf{w})$:

$$J(\mathbf{w}) = -\ln p(\mathcal{D} | \mathbf{w}) - \ln p(\mathbf{w}) \quad (42.14)$$

which we wish to minimize with respect to the parameters \mathbf{w} . The first term in this cost function is a (negative) log *likelihood*. If we assume that the elements in the training set \mathcal{D} are conditionally independent of each other given the parameters, then the likelihood factorizes into a product form. For density estimation, we have

$$p(\mathcal{D} | \mathbf{w}) = \prod_{n=1}^N p(\mathbf{x}_n | \mathbf{w}) \quad (42.15)$$

and for classification and regression, we have

$$p(\mathcal{D} | \mathbf{w}) = \prod_{n=1}^N p(t_n | \mathbf{x}_n, \mathbf{w}) \quad (42.16)$$

In both cases this yields a log likelihood, which is the sum of the log probabilities for each individual data point. For the remainder of this section, we will assume this additive form; moreover, we will assume that the log prior probability of the parameters is uniform across the parameters and drop the second term. Thus, we focus on *maximum likelihood* (ML) estimation, where we choose parameter values \mathbf{w}_{ML} that maximize $\ln p(\mathcal{D} | \mathbf{w})$.

42.3.1 Likelihood-Based Cost Functions

Regression, classification, and density estimation make different probabilistic assumptions about the form of the data and therefore require different cost functions.

Equation 42.3 defines a probabilistic model for regression. The model is a conditional density for the targets t in which the targets are distributed as Gaussian random variables (assuming Gaussian errors ε) with mean values $f(\mathbf{x})$. We now write the conditional mean as $f(\mathbf{x}, \mathbf{w})$ to make explicit the dependence on the parameters \mathbf{w} . Given the training set $\mathcal{D} = \{\mathbf{x}_n, t_n\}_{n=1}^N$, and given our assumption that the targets t_n are sampled independently (given the inputs \mathbf{x}_n and the parameters \mathbf{w}), we obtain

$$J(\mathbf{w}) = \frac{1}{2} \sum_n \|\mathbf{t}_n - f(\mathbf{x}_n, \mathbf{w})\|^2 \quad (42.17)$$

where we have assumed an identity covariance matrix and dropped those terms that do not depend on the parameters. This cost function is the standard least-squares cost function, which is traditionally used in neural network training for real-valued targets. Minimization of this cost function is typically achieved via some form of gradient optimization, as we discuss in the following section.

Classification problems differ from regression problems in the use of discrete-valued targets, and the likelihood accordingly takes a different form. For binary classification the Bernoulli probability model

$p(t | \mathbf{x}, \mathbf{w}) = y^t (1 - y)^{1-t}$ is natural, where we use y to denote the probability $p(t = 1 | \mathbf{x}, \mathbf{w})$. This model yields the following log likelihood:

$$J(\mathbf{w}) = -\sum_n [t_n \ln y_n + (1 - t_n) \ln(1 - y_n)] \quad (42.18)$$

which is known as the *cross-entropy* function. It can be minimized using the same generic optimization procedures as are used for least squares.

For multiway classification problems in which there are C categories, where $C > 2$, the multinomial distribution is natural. Define t_n such that its elements $t_{n,i}$ are one or zero according to whether the n th data point belongs to the i th category, and define $y_{n,i}$ to be the network's estimate of the posterior probability of category i for data point n ; that is, $y_{n,i} \equiv p(t_{n,i} = 1 | \mathbf{x}_n, \mathbf{w})$. Given these definitions, we obtain the following cost function:

$$J(\mathbf{w}) = - \sum_n \sum_i t_{n,i} \ln y_{n,i} \quad (42.19)$$

which again has the form of a cross-entropy.

We now turn to density estimation as exemplified by Gaussian mixture modeling. The probabilistic model in this case is that given in Equation 42.2. Assuming Gaussian component densities with arbitrary covariance matrices, we obtain the following cost function:

$$J(\mathbf{w}) = - \sum_n \ln \sum_i \pi_i \frac{1}{|\Sigma_i|^{1/2}} \exp \left\{ -\frac{1}{2} (\mathbf{x}_n - \boldsymbol{\mu}_i)^T \Sigma_i^{-1} (\mathbf{x}_n - \boldsymbol{\mu}_i) \right\} \quad (42.20)$$

where the parameters \mathbf{w} are the collection of mean vectors $\boldsymbol{\mu}_i$, the covariance matrices Σ_i , and the mixing proportions π_i . A similar cost function arises for the generalized mixture models (cf. Equation 42.12).

42.3.2 Gradients of the Cost Function

Once we have defined a probabilistic model, obtained a cost function, and found an efficient procedure for calculating the gradient of the cost function, the problem can be handed off to an optimization routine. Before discussing optimization procedures, however, it is useful to examine the form that the gradient takes for the examples that we have discussed in the previous two sections.

The i th output unit in a layered network is endowed with a rule for combining the activations of units in earlier layers, yielding a quantity that we denote by z_i and a function that converts z_i into the output y_i . For regression problems, we assume linear output units such that $y_i = z_i$. For binary classification problems, our earlier discussion showed that a natural output function is the logistic: $y_i = 1/(1 + e^{-z_i})$. For multiway classification, it is possible to generalize the derivation of the logistic function to obtain an analogous representation for the multiway posterior probabilities known as the *softmax function* (cf. Bishop 1995):

$$y_i = \frac{e^{z_i}}{\sum_k e^{z_k}} \quad (42.21)$$

where y_i represents the posterior probability of category i .

If we now consider the gradient of $J(\mathbf{w})$ with respect to z_i , it turns out that we obtain a single canonical expression of the following form:

$$\frac{\partial J}{\partial \mathbf{w}} = \sum_i (t_i - y_i) \frac{\partial z_i}{\partial \mathbf{w}} \quad (42.22)$$

As discussed by Rumelhart et al. (1995), this form for the gradient is predicted from the theory of generalized linear models (McCullagh and Nelder 1983), where it is shown that the linear, logistic, and

softmax functions are (inverse) *canonical links* for the Gaussian, Bernoulli, and multinomial distributions, respectively. Canonical links can be found for all of the distributions in the exponential family, thus providing a solid statistical foundation for handling a wide variety of data formats at the output layer of a network, including counts, time intervals, and rates.

The gradient of the cost function for mixture models has an interesting interpretation. Taking the partial derivative of $J(\mathbf{w})$ in Equation 42.20 with respect to μ_i , we find

$$\frac{\partial J}{\partial \mu_i} = \sum_n h_{n,i} \Sigma_i (\mathbf{x}_n - \mu_i) \quad (42.23)$$

where $h_{n,i}$ is defined as follows:

$$h_{n,i} = \frac{\pi_i |\Sigma_i|^{-1/2} \exp\{-1/2 (\mathbf{x}_n - \mu_i)^T \Sigma_i^{-1} (\mathbf{x}_n - \mu_i)\}}{\sum_k \pi_k |\Sigma_k|^{-1/2} \exp\{-1/2 (\mathbf{x}_n - \mu_k)^T \Sigma_k^{-1} (\mathbf{x}_n - \mu_k)\}} \quad (42.24)$$

When summed over i , the quantity $h_{n,i}$ sums to one and is often viewed as the “responsibility” or “credit” assigned to the i th component for the n th data point. Indeed, interpreting Equation 42.24 using Bayes rule shows that $h_{n,i}$ is the posterior probability that the n th data point is generated by the i th component Gaussian. A learning algorithm based on this gradient will move the i th mean μ_i toward the data point \mathbf{x}_n , with the effective step size proportional to $h_{n,i}$.

The gradient for a mixture model will always take the form of a weighted sum of the gradients associated with the component models, where the weights are the posterior probabilities associated with each of the components. The key computational issue is whether these posterior weights can be computed efficiently. For Gaussian mixture models, the calculation (Equation 42.24) is clearly efficient. For decision trees there is a set of posterior weights associated with each of the nodes in the tree, and a recursion is available that computes the posterior probabilities in an upward sweep (Jordan and Jacobs 1994). Mixture models in the form of a chain are known as *hidden Markov models (HMMs)*, and the calculation of the relevant posterior probabilities is performed via an efficient algorithm known as the Baum–Welch algorithm.

For general layered network structures, a generic algorithm known as backpropagation is available to calculate gradient vectors (Rumelhart et al. 1986). Backpropagation is essentially the chain rule of calculus realized as a graphical algorithm. As applied to layered networks, it provides a simple and efficient method that calculates a gradient in $O(W)$ time per training pattern, where W is the number of weights.

42.3.3 Optimization Algorithms

By introducing the principle of ML in Section 42.1, we have expressed the problem of learning in neural networks in terms of the minimization of a cost function, $J(\mathbf{w})$, which depends on a vector, \mathbf{w} , of adaptive parameters. An important aspect of this problem is that the gradient vector $\nabla_{\mathbf{w}} J$ can be evaluated efficiently (e.g., by backpropagation). Gradient-based minimization is a standard problem in unconstrained nonlinear optimization for which many powerful techniques have been developed over the years. Such algorithms generally start by making an initial guess for the parameter vector \mathbf{w} and then iteratively updating the vector in a sequence of steps:

$$\mathbf{w}^{(\tau+1)} = \mathbf{w}^{(\tau)} + \Delta \mathbf{w}^{(\tau)} \quad (42.25)$$

where τ denotes the step number. The initial parameter vector $\mathbf{w}^{(0)}$ is often chosen at random, and the final vector represents a minimum of the cost function at which the gradient vanishes. Because

of the nonlinear nature of neural network models, the cost function is generally a highly complicated function of the parameters and may possess many such minima. Different algorithms differ in how the update $\Delta \mathbf{w}^{(t)}$ is computed.

The simplest such algorithm is called *gradient descent* and involves a parameter update which is proportional to the negative of the cost function gradient $\Delta = -\eta \nabla E$ where η is a fixed constant called the learning rate. It should be stressed that gradient descent is a particularly inefficient optimization algorithm. Various modifications have been proposed, such as the inclusion of a *momentum* term, to try to improve its performance. In fact, much more powerful algorithms are readily available, as described in standard textbooks such as Fletcher (1987). Two of the best known are called *conjugate gradients* and *quasi-Newton* (or *variable metric*) methods. For the particular case of a sum-of-squares cost function, the *Levenberg–Marquardt* algorithm can also be very effective. Software implementations of these algorithms are widely available.

The algorithms discussed so far are called *batch* since they involve using the whole dataset for each evaluation of the cost function or its gradient. There is also a *stochastic* or *online* version of gradient descent in which, for each parameter update, the cost function gradient is evaluated using just one of the training vectors at a time (which are then cycled either in order or in a random sequence). Although this approach fails to make use of the power of sophisticated methods such as conjugate gradients, it can prove effective for very large datasets, particularly if there is significant redundancy in the data.

42.3.4 Hessian Matrices, Error Bars, and Pruning

After a set of weights have been found for a neural network using an optimization procedure, it is often useful to examine second-order properties of the fitted network as captured in the Hessian matrix $H = \partial^2 J / \partial \mathbf{w} \partial \mathbf{w}^T$. Efficient algorithms have been developed to compute the Hessian matrix in time $O(W^2)$ (Bishop 1995). As in the case of the calculation of the gradient by backpropagation, these algorithms are based on recursive message passing in the network.

One important use of the Hessian matrix lies in the calculation of error bars on the outputs of a network. If we approximate the cost function locally as a quadratic function of the weights (an approximation that is equivalent to making a Gaussian approximation for the log likelihood), then the estimated variance of the i th output y_i can be shown to be

$$\hat{\sigma}_{y_i}^2 = \left(\frac{\partial y_i}{\partial \mathbf{w}} \right)^T H^{-1} \left(\frac{\partial y_i}{\partial \mathbf{w}} \right) \quad (42.26)$$

where the gradient vector $\partial y_i / \partial \mathbf{w}$ can be calculated via backpropagation.

The Hessian matrix also is useful in pruning algorithms. A pruning algorithm deletes weights from a fitted network to yield a simpler network that may outperform a more complex, *overfitted* network (discussed subsequently) and may be easier to interpret. In this setting, the Hessian is used to approximate the increase in the cost function due to the deletion of a weight. A variety of such pruning algorithms is available (cf. Bishop 1995).

42.3.5 Complexity Control

In previous sections, we have introduced a variety of models for representing probability distributions, we have shown how the parameters of the models can be optimized by maximizing the likelihood function, and we have outlined a number of powerful algorithms for performing this minimization. Before we can apply this framework in practice, there is one more issue we need to address, which is that of model complexity. Consider the case of a mixture model given by Equation 42.2. The number of input

FIGURE 42.4 Effects of model complexity illustrated by modeling a mixture of two Gaussians (shown by the dashed curves) using a mixture of M Gaussians (shown by the solid curves). The results are obtained for 20 cycles of EM.

variables will be determined by the particular problem at hand. However, the number M of component densities has yet to be specified. Clearly, if M is too small, the model will be insufficiently flexible and we will obtain a poor representation of the true density. What is not so obvious is that if M is too large, we can also obtain poor results. This effect is known as *overfitting* and arises because we have a dataset of finite size. It is illustrated using the simple example of mixture density estimation in Figure 42.4. Here a set of 100 data points in one dimension has been generated from a distribution consisting of a mixture of two Gaussians (shown by the dashed curves). This dataset has then been fitted by a mixture of M Gaussians by use of the expectation-maximization (EM) algorithm. We see that a model with 1 component ($M = 1$) gives a poor representation of the true distribution from which the data were generated and in particular is unable to capture the bimodal aspect. For $M = 2$ the model gives a good fit, as we expect since the data were themselves generated from a two-component Gaussian mixture. However, increasing the number of components to $M = 10$ gives a poorer fit, even though this model contains the simpler models as special cases.

The problem is a very fundamental one and is associated with the fact that we are trying to infer an entire distribution function from a finite number of data points, which is necessarily an ill-posed problem. In regression, for example, there are infinitely many functions that will give a perfect fit to the finite number of data points. If the data are noisy, however, the best generalization will be obtained for a function that does not fit the data perfectly but that captures the underlying function from which the data were generated. By increasing the flexibility of the model, we are able to obtain ever better fits to the training data, and this is reflected in a steadily increasing value for the likelihood function at its maximum. Our goal is to model the true underlying density function from which the data were generated since this allows us to make the best predictions for new data. We see that the best approximation to this density occurs for an intermediate value of M .

The same issue arises in connection with nonlinear regression and classification problems. For example, the number M of hidden units in an MLP network controls the model complexity and must be optimized to give the best generalization. In a practical application, we can train a variety of different models having different complexities, compare their generalization performance using an independent validation set, and then select the model with the best generalization. In fact, the process of optimizing the complexity using a validation set can lead to some partial overfitting to the

validation data itself, and so the final performance of the selected model should be confirmed using a third independent dataset called a *test* set.

Some theoretical insight into the problem of overfitting can be obtained by decomposing the error into the sum of bias and variance terms (Geman et al. 1992). A model that is too inflexible is unable to represent the true structure in the underlying density function, and this gives rise to a high bias. Conversely, a model that is too flexible becomes tuned to the specific details of the particular dataset and gives a high variance. The best generalization is obtained from the optimum trade-off of bias against variance.

As we have already remarked, the problem of inferring an entire distribution function from a finite dataset is fundamentally ill posed since there are infinitely many solutions. The problem becomes well posed only when some additional constraint is imposed. This constraint might be that we model the data using a network having a limited number of hidden units. Within the range of functions that this model can represent, there is then a unique function that best fits the data. Implicitly, we are assuming that the underlying density function from which the data were drawn is relatively smooth. Instead of limiting the number of parameters in the model, we can encourage smoothness more directly using the technique of *regularization*. This involves adding penalty term Ω to the original cost function J to give the total cost function \tilde{J} of the following form:

$$\tilde{J} = J + \nu \Omega \quad (42.27)$$

where ν is called a regularization coefficient. The network parameters are determined by minimizing \tilde{J} , and the value of ν controls the degree of influence of the penalty term Ω . In practice, Ω is typically chosen to encourage smooth functions. The simplest example is called *weight decay* and consists of the sum of the squares of all of the adaptive parameters in the model:

$$\Omega = \sum_i w_i^2 \quad (42.28)$$

Consider the effect of such a term on the MLP function (Equation 42.9). If the weights take very small values, then the network outputs become approximately linear functions of the inputs (since the sigmoidal function is approximately linear for small values of its argument). The value of ν in Equation 42.27 controls the effective complexity of the model, so that for large ν the model is oversmoothed (corresponding to high bias), whereas for small ν the model can overfit (corresponding to high variance). We can therefore consider a network with a relatively large number of hidden units and control the effective complexity by changing ν . In practice, a suitable value for ν can be found by seeking the value that gives the best performance on a validation set.

The weight decay regularizer (Equation 42.28) is simple to implement but suffers from a number of limitations. Regularizers used in practice may be more sophisticated and may contain multiple regularization coefficients (Neal 1994).

Regularization methods can be justified within a general theoretical framework known as *structural risk minimization* (Vapnik 1995). Structural risk minimization provides a quantitative measure of complexity known as the *VC dimension*. The theory shows that the VC dimension predicts the difference between performance on a training set and performance on a test set; thus, the sum of log likelihood and (some function of) VC dimension provides a measure of generalization performance. This motivates regularization methods (Equation 42.27) and provides some insight into possible forms for the regularizer Ω .

42.3.6 Bayesian Viewpoint

In earlier sections we discussed network training in terms of the minimization of a cost function derived from the principle of MAP or ML estimation. This approach can be seen as a particular approximation to a more fundamental, and more powerful, framework based on Bayesian statistics. In the ML

approach, the weights \mathbf{w} are set to a specific value, \mathbf{w}_{ML} , determined by minimization of a cost function. However, we know that there will typically be other minima of the cost function, which might give equally good results. Also, weight values close to \mathbf{w}_{ML} should give results that are not too different from those of the ML weights themselves.

These effects are handled in a natural way in the Bayesian viewpoint, which describes the weights not in terms of a specific set of values but in terms of a probability distribution over all possible values. As discussed earlier (cf. Equation 42.13), once we observe the training dataset \mathcal{D} , we can compute the corresponding *posterior* distribution using Bayes' theorem, based on a *prior* distribution function $p(\mathbf{w})$ (which will typically be very broad) and a *likelihood* function $p(\mathcal{D}|\mathbf{w})$:

$$p(\mathbf{w}|\mathcal{D}) = \frac{p(\mathcal{D}|\mathbf{w})p(\mathbf{w})}{p(\mathcal{D})} \quad (42.29)$$

The likelihood function will typically be very small except for values of \mathbf{w} for which the network function is reasonably consistent with the data. Thus, the posterior distribution $p(\mathbf{w}|\mathcal{D})$ will be much more sharply peaked than the prior distribution $p(\mathbf{w})$ (and will typically have multiple maxima). The quantity we are interested in is the predicted distribution of target values \mathbf{t} for a new input vector \mathbf{x} once we have observed the dataset \mathcal{D} . This can be expressed as an integration over the posterior distribution of weights of the following form:

$$p(\mathbf{t}|\mathbf{x}, \mathcal{D}) = \int p(\mathbf{t}|\mathbf{x}, \mathbf{w})p(\mathbf{w}|\mathcal{D})d\mathbf{w} \quad (42.30)$$

where $p(\mathbf{t}|\mathbf{x}, \mathbf{w})$ is the conditional probability model discussed in the Introduction.

If we suppose that the posterior distribution $p(\mathbf{w}|\mathcal{D})$ is sharply peaked around a single most probable value \mathbf{w}_{MP} , then we can write Equation 42.30 in the following form:

$$p(\mathbf{t}|\mathbf{x}, \mathcal{D}) \simeq p(\mathbf{t}|\mathbf{x}, \mathbf{w}_{\text{MP}}) \int p(\mathbf{w}|\mathcal{D})d\mathbf{w} \quad (42.31)$$

$$= p(\mathbf{t}|\mathbf{x}, \mathbf{w}_{\text{MP}}) \quad (42.32)$$

and so predictions can be made by fixing the weights to their most probable values. We can find the most probable weights by maximizing the posterior distribution or equivalently by minimizing its negative logarithm. Using Equation 42.29, we see that \mathbf{w}_{MP} is determined by minimizing a regularized cost function of the form in Equation 42.27 in which the negative log of the prior $-\ln p(\mathbf{w})$ represents the regularizer $\nu\Omega$.

For example, if the prior consists of a zero mean Gaussian with variance ν^{-1} , then we obtain the weight decay regularizer of Equation 42.28.

The posterior distribution will become sharply peaked when the size of the dataset is large compared to the number of parameters in the network. For datasets of limited size, however, the posterior distribution has a finite width and this adds to the uncertainty in the predictions for \mathbf{t} , which can be expressed in terms of error bars. Bayesian error bars can be evaluated using a local Gaussian approximation to the posterior distribution (MacKay 1992). The presence of multiple maxima in the posterior distribution also contributes to the uncertainties in predictions. The capability to assess these uncertainties can play a crucial role in practical applications.

The Bayesian approach can also deal with more general problems in complexity control. This can be done by considering the probabilities of a set of alternative models, given the dataset

$$p(\mathcal{H}_i|\mathcal{D}) = \frac{p(\mathcal{D}|\mathcal{H}_i)p(\mathcal{H}_i)}{p(\mathcal{D})} \quad (42.33)$$

Here, different models can also be interpreted as different values of regularization parameters as these too control model complexity. If the models are given the same prior probabilities $p(\mathcal{H}_i)$, then they can be ranked by considering the *evidence* $p(\mathcal{D}|\mathcal{H}_i)$, which itself can be evaluated by integration over the model parameters \mathbf{w} . We can simply select the model with the greatest probability. However, a full Bayesian treatment requires that we form a linear combination of the predictions of the models in which the weighting coefficients are given by the model probabilities.

In general, the required integrations, such as that in Equation 42.30, are analytically intractable. One approach is to approximate the posterior distribution by a Gaussian centered on \mathbf{w}_{MP} and then to linearize $p(\mathbf{t}|\mathbf{x}, \mathbf{w})$ about \mathbf{w}_{MP} so that the integration can be performed analytically (MacKay 1992). Alternatively, sophisticated Monte Carlo methods can be employed to evaluate the integrals numerically (Neal 1994). An important aspect of the Bayesian approach is that there is no need to keep data aside in a validation set as is required when using ML. In practical applications for which the quantity of available data is limited, it is found that a Bayesian treatment generally outperforms other approaches.

42.3.7 Preprocessing, Invariances, and Prior Knowledge

We have already seen that neural networks can approximate essentially arbitrary nonlinear functional mappings between sets of variables. In principle, we could therefore use a single network to transform the raw input variables into the required final outputs. However, in practice, for all but the simplest problems, the results of such an approach can be improved upon considerably by incorporating various forms of preprocessing, for reasons we shall outline in the following.

One of the simplest and most common forms of preprocessing consists of a simple normalization of the input, and possibly also target, variables. This may take the form of a linear rescaling of each input variable independently to give it zero mean and unit variance over the training set. For some applications, the original input variables may span widely different ranges. Although a linear rescaling of the inputs is equivalent to a different choice of first-layer weights, in practice the optimization algorithm may have considerable difficulty in finding a satisfactory solution when typical input values are substantially different. Similar rescaling can be applied to the output values, in which case the inverse of the transformation needs to be applied to the network outputs when the network is presented with new inputs. Preprocessing is also used to encode data in a suitable form. For example, if we have categorical variables such as red, green, and blue, these may be encoded using a 1-of-3 binary representation.

Another widely used form of preprocessing involves reducing the dimensionality of the input space. Such transformations may result in loss of information in the data, but the overall effect can be a significant improvement in performance as a consequence of the curse of dimensionality discussed in the complexity control section. The finite dataset is better able to specify the required mapping in the lower dimensional space. Dimensionality reduction may be accomplished by simply selecting a subset of the original variables but more typically involves the construction of new variables consisting of linear or nonlinear combinations of the original variables called *features*. A standard technique for dimensionality reduction is principal component analysis (Anderson 1984). Such methods, however, make use only of the input data and ignore the target values and can sometimes be significantly suboptimal.

Yet another form of preprocessing involves correcting deficiencies in the original data. A common occurrence is that some of the input variables are missing for some of the data points. Correction of this problem in a principled way requires that the probability distribution $p(\mathbf{x})$ of input data be modeled.

One of the most important factors determining the performance of real-world applications of neural networks is the use of *prior knowledge*, which is information additional to that present in the data. As an example, consider the problem of classifying handwritten digits discussed in Section 42.1. The most direct approach would be to collect a large training set of digits and to train a feedforward network to map from the input image to a set of 10 output values representing posterior probabilities for the 10 classes. However, we know that the classification of a digit should be independent of its position within the input image. One way of achieving such *translation invariance* is to make use of the

technique of *shared weights*. This involves a network architecture having many hidden layers in which each unit takes inputs only from a small patch, called a *receptive field*, of units in the previous layer. By a process of constraining neighboring units to have common weights, it can be arranged that the output of the network is insensitive to translations of the input image. A further benefit of weight sharing is that the number of independent parameters is much smaller than the number of weights, which assists with the problem of model complexity. This approach is the basis for the highly successful US postal code recognition system of LeCun et al. (1989). An alternative to shared weights is to enlarge the training set artificially by generating virtual examples based on applying translations and other transformations to the original training set (Poggio and Vetter 1992).

42.4 Graphical Models

Neural networks express relationships between variables by utilizing the representational language of graph theory. Variables are associated with nodes in a graph, and transformations of variables are based on algorithms that propagate numerical messages along the links of the graph. Moreover, the graphs are often accompanied by probabilistic interpretations of the variables and their interrelationships. As we have seen, such probabilistic interpretations allow a neural network to be understood as a form of a probabilistic model and reduce the problem of learning the weights of a network to a problem in statistics.

Related graphical models have been studied throughout statistics, engineering, and AI in recent years. HMMs, Kalman filters, and path analysis models are all examples of graphical probabilistic models that can be fitted to data and used to make inferences. The relationship between these models and neural networks is rather strong; indeed, it is often possible to reduce one kind of model to the other. In this section, we examine these relationships in some detail and provide a broader characterization of neural networks as members of a general family of graphical probabilistic models.

Many interesting relationships have been discovered between graphs and probability distributions (Pearl 1988, Spiegelhalter et al. 1993). These relationships derive from the use of graphs to represent conditional independencies among random variables. In an undirected graph, there is a direct correspondence between conditional independence and graph separation: random variables X_i and X_k are conditionally independent given X_j if nodes X_i and X_k are separated by node X_j (we use the symbol X_i to represent both a random variable and a node in a graph). This statement remains true for sets of nodes (see Figure 42.5a). Directed graphs have a somewhat different semantics due to the ability of directed graphs to represent induced dependencies. An induced dependency is a situation in which two nodes that are marginally independent become conditionally dependent given the value of a third node. (see Figure 42.5b). Suppose, for example, that X_i and X_k represent independent coin tosses, and X_j represents the sum of X_i and X_k . Then X_i and X_k are marginally independent but are conditionally

FIGURE 42.5 (a) An undirected graph in which X_i is independent of X_j given X_k and X_l , and X_k is independent of X_l given X_i and X_j . (b) A directed graph in which X_i and X_k are marginally independent but are conditionally dependent given X_j .

dependent given X_j . The semantics of independence in directed graphs is captured by a graphical criterion known as *d-separation* (Pearl 1988), which differs from undirected separation only in those cases in which paths have two arrows arriving at the same node (as in Figure 42.5b).

Although the neural network architectures that we have discussed until now all have been based on directed graphs, undirected graphs also play an important role in neural network research. Constraint satisfaction architectures, including the Hopfield network (Hopfield 1982) and the *Boltzmann machine* (Hinton and Sejnowski 1986), are the most prominent examples. A Boltzmann machine is an undirected probabilistic graph that respects the conditional independency semantics previously described (cf. Figure 42.5a). Each node in a Boltzmann machine is a binary-valued random variable X_i (or, more generally, a discrete-valued random variable). A probability distribution on the 2^N possible configurations of such variables is defined via an *energy function* E . Let J_{ij} be the weight on the link between X_i and X_j , let $J_{ij} = J_{ji}$, let α index the configurations, and define the energy of configuration α as follows:

$$E_\alpha = - \sum_{i < j} J_{ij} X_i^\alpha X_j^\alpha \tag{42.34}$$

The probability of configuration α is then defined via the Boltzmann distribution:

$$P_\alpha = \frac{e^{-E_\alpha/T}}{\sum_\gamma e^{-E_\gamma/T}} \tag{42.35}$$

where the *temperature* T provides a scale for the energy.

An example of a directed probabilistic graph is the HMM. An HMM is defined by a set of *state variables* H_i , where i is generally a time or a space index, a set of output variables O_i , a *probability transition matrix* $A = p(H_i|H_{i-1})$, and an *emission matrix* $B = p(O_i|H_i)$. The directed graph for an HMM is shown in Figure 42.6a. As can be seen from considering the separatory properties of the graph, the conditional independencies of the HMM are defined by the following Markov conditions:

$$H_i \perp \{H_1, O_1, \dots, H_{i-2}, O_{i-2}, O_{i-1}\} | H_{i-1}, \quad 2 \leq i \leq N \tag{42.36}$$

and

$$O_i \perp \{H_1, O_1, \dots, H_{i-1}, O_{i-1}\} | H_i, \quad 2 \leq i \leq N \tag{42.37}$$

where the symbol \perp is used to denote independence.

FIGURE 42.6 (a) A directed graph representation of an HMM. Each horizontal link is associated with the transition matrix A , and each vertical link is associated with the emission matrix B . (b) An HMM as a Boltzmann machine. The parameters on the horizontal links are logarithms of the entries of the A matrix, and the parameters on the vertical links are logarithms of the entries of the B matrix. The two representations yield the same joint probability distribution.

Figure 42.6b shows that it is possible to treat an HMM as a special case of a Boltzmann machine (Luttrell 1989, Saul and Jordan 1995). The probabilistic structure of the HMM can be captured by defining the weights on the links as the logarithms of the corresponding transition and emission probabilities. The Boltzmann distribution (Equation 42.35) then converts the additive energy into the product form of the standard HMM probability distribution. As we will see, this reduction of a directed graph to an undirected graph is a recurring theme in the graphical model formalism.

General mixture models are readily viewed as graphical models (Buntine 1994). For example, the unconditional mixture model of Equation 42.2 can be represented as a graphical model with two nodes—a multinomial hidden node, which represents the selected component, a visible node representing \mathbf{x} , with a directed link from the hidden node to the visible node (hidden/visible distinction discussed subsequently). Conditional mixture models (Jacobs et al. 1991) simply require another visible node with directed links to the hidden node and the visible nodes. Hierarchical conditional mixture models (Jordan and Jacobs 1994) require a chain of hidden nodes, one hidden node for each level of the tree.

Within the general framework of probabilistic graphical models, it is possible to tackle general problems of inference and learning. The key problem that arises in this setting is the problem of computing the probabilities of certain nodes, which we will refer to as *hidden nodes*, given the observed values of other nodes, which we will refer to as *visible nodes*. For example, in an HMM, the variables O_i are generally treated as visible, and it is desired to calculate a probability distribution on the hidden states H_i . A similar inferential calculation is required in the mixture models and the Boltzmann machine.

Generic algorithms have been developed to solve the inferential problem of the calculation of posterior probabilities in graphs. Although a variety of inference algorithms have been developed, they can all be viewed as essentially the same underlying algorithm (Shachter et al. 1994). Let us consider undirected graphs. A special case of an undirected graph is a *triangulated graph* (Spiegelhalter et al. 1993), in which any cycle having four or more nodes has a chord. For example, the graph in Figure 42.5a is not triangulated but becomes triangulated when a link is added between nodes X_i and X_j . In a triangulated graph, the cliques of the graph can be arranged in the form of a *junction tree*, which is a tree having the property that any node that appears in two different cliques in the tree also appears in every clique on the path that links the two cliques (the “running intersection property”). This cannot be achieved in nontriangulated graphs. For example, the cliques in Figure 42.5a are $\{X_i, X_k\}$, $\{X_k, X_j\}$, $\{X_j, X_l\}$, and it is not possible to arrange these cliques into a tree that obeys the running intersection property. If a chord is added, the resulting cliques are $\{X_i, X_j, X_k\}$ and $\{X_j, X_l, X_k\}$, and these cliques can be arranged as a simple chain that trivially obeys the running intersection property. In general, it turns out that the probability distributions corresponding to triangulated graphs can be characterized as *decomposable*, which implies that they can be factorized into a product of local functions (potentials) associated with the cliques in the triangulated graph.* The calculation of posterior probabilities in decomposable distributions is straightforward and can be achieved via a local message-passing algorithm on the junction tree (Spiegelhalter et al. 1993). Graphs that are not triangulated can be turned into triangulated graphs by the addition of links. If the potentials on the new graph are defined suitably as products of potentials on the original graph, then the independencies in the original graph are preserved. This implies that the algorithms for triangulated graphs can be used for *all* undirected graphs; an untriangulated graph is first triangulated (see Figure 42.7). Moreover, it is possible to convert *directed* graphs to undirected graphs in a manner that preserves the probabilistic structure of the original graph (Spiegelhalter et al. 1993). This implies that the junction tree algorithm is indeed generic; it can be applied to any graphical model.

* An interesting example is a Boltzmann machine on a triangulated graph. The potentials are products of $\exp(J_{ij})$ factors, where the product is taken over all (i, j) pairs in a particular clique. Given that the product across potentials must be the joint probability, this implies that the partition function (the denominator of Equation 42.35) must be unity in this case.

FIGURE 42.7 The basic structure of the junction tree algorithm for undirected graphs. The graph in (a) is first triangulated (b), then the cliques are identified (c), and arranged into a tree (d). Products of potential functions on the nodes in (d) yield probability distributions on the nodes in (a).

The problem of calculating posterior probabilities on graphs is NP-hard; thus, a major issue in the use of the inference algorithms is the identification of cases in which they are efficient. Chain structures such as HMMs yield efficient algorithms, and indeed the classical forward–backward algorithm for HMMs is a special, efficient case of the junction tree algorithm (Smyth et al. 1996). Decision tree structures such as the hierarchical mixture of experts yield efficient algorithms, and the recursive posterior probability calculation of Jordan and Jacobs (1994) described earlier is also a special case of the junction tree algorithm. All of the simpler mixture model calculations described earlier are therefore also special cases. Another interesting special case is the state estimation algorithm of the Kalman filter (Shachter and Kenley 1989). Finally, there are a variety of special cases of the Boltzmann machine, which are amenable to the exact calculations of the junction tree algorithm (Saul and Jordan 1995).

For graphs that are outside of the tractable categories of trees and chains, the junction tree algorithm often performs surprisingly well, but for highly connected graphs, the algorithm can be too slow. In such cases, approximate algorithms such as Gibbs sampling are utilized. A virtue of the graphical framework is that Gibbs sampling has a generic form, which is based on the notion of a *Markov boundary* (Pearl 1988). A special case of this generic form is the stochastic update rule for general Boltzmann machines.

Our discussion has emphasized the unifying framework of graphical models both for expressing probabilistic dependencies in graphs and for describing algorithms that perform the inferential step of calculating posterior probabilities on these graphs. The unification goes further, however, when we consider learning. A generic methodology known as the EM algorithm is available for MAP and Bayesian estimation in graphical models (Dempster et al. 1977). EM is an iterative method, based on two alternating steps: an *E step*, in which the values of hidden variables are estimated, based on the current values of the parameters and the values of visible variables, and an *M step*, in which the parameters are updated, based on the estimated values obtained from the *E step*. Within the framework of the EM algorithm, the junction tree algorithm can readily be viewed as providing a generic *E step*. Moreover, once the estimated values of the hidden nodes are obtained from the *E step*, the graph can be viewed as fully observed, and the *M step* is a standard MAP or ML problem. The standard algorithms for all of the tractable architectures described (mixtures, trees, and chains) are, in fact, instances of this general graphical EM algorithm, and the learning algorithm for general Boltzmann machines is a special case of a generalization of EM known as GEM (Dempster et al. 1977).

What about the case of feedforward neural networks such as the MLP? It is, in fact, possible to associate binary hidden values with the hidden units of such a network (cf. our earlier discussion of the logistic function; see also Amari 1995) and apply the EM algorithm directly. For N hidden units, however, there are patterns whose probabilities must be calculated in the *E step*. For large N , this is an intractable computation, and recent research has therefore begun to focus on fast methods for approximating these distributions (Hinton et al. 1995, Saul et al. 1996).

Key Terms

- Boltzmann machine:** An undirected network of discrete-valued random variables, where an energy function is associated with each of the links, and for which a probability distribution is defined by the Boltzmann distribution.
- Classification:** A learning problem in which the goal is to assign input vectors to one of a number of (usually mutually exclusive) classes.
- Cost function:** A function of the adaptive parameters of a model whose minimum is used to define suitable values for those parameters. It may consist of a likelihood function and additional terms.
- Decision tree:** A network that performs a sequence of classificatory decisions on an input vector and produces an output vector that is conditional on the outcome of the decision sequence.
- Density estimation:** The problem of modeling a probability distribution from a finite set of examples drawn from that distribution.
- Discriminant function:** A function of the input vector that can be used to assign inputs to classes in a classification problem.
- Hidden Markov model:** A graphical probabilistic model characterized by a state vector, an output vector, a state transition matrix, an emission matrix, and an initial state distribution.
- Likelihood function:** The probability of observing a particular dataset under the assumption of a given parametrized model, expressed as a function of the adaptive parameters of the model.
- Mixture model:** A probability model that consists of a linear combination of simpler component probability models.
- Multilayer perceptron:** The most common form of neural network model, consisting of successive linear transformations followed by processing with nonlinear activation functions.
- Overfitting:** The problem in which a model that is too complex captures too much of the noise in the data, leading to poor generalization.
- Radial basis function network:** A common network model consisting of a linear combination of basis functions, each of which is a function of the difference between the input vector and a center vector.
- Regression:** A learning problem in which the goal is to map each input vector to a real-valued output vector.
- Regularization:** A technique for controlling model complexity and improving generalization by the addition of a penalty term to the cost function.
- VC dimension:** A measure of the complexity of a model. Knowledge of the VC dimension permits an estimate to be made of the difference between performance on the training set and performance on a test set.

Further Information

In this chapter, we have emphasized the links between neural networks and statistical pattern recognition. A more extensive treatment from the same perspective can be found in Bishop (1995). For a view of recent research in the field, the *Proceedings of the Annual Neural Information Processing Systems (NIPS)*, MIT Press, and conferences are highly recommended.

Neural computing is now a very broad field, and there are many topics that have not been discussed for lack of space. Here, we aim to provide a brief overview of some of the more significant omissions and to give pointers to the literature.

The resurgence of interest in neural networks during the 1980s was due in large part to work on the statistical mechanics of fully connected networks having symmetric connections (i.e., if unit i sends a connection to unit j , then there is also a connection from unit j back to unit i with the same weight value). We have briefly discussed such systems; a more extensive introduction to this area can be found in Hertz et al. (1991).

The implementation of neural networks in specialist very large-scale integrated (VLSI) hardware has been the focus of much research, although by far the majority of work in neural computing is undertaken using software implementations running on standard platforms.

An implicit assumption throughout most of this chapter is that the processes that give rise to the data are stationary in time. The techniques discussed here can readily be applied to problems such as time series forecasting, provided this stationarity assumption is valid. If, however, the generator of the data is itself evolving with time, then more sophisticated techniques must be used, and these are the focus of much current research (see Bengio 1996).

One of the original motivations for neural networks was as models of information processing in biological systems such as the human brain. This remains the subject of considerable research activity, and there is a continuing flow of ideas between the fields of neurobiology and of artificial neural networks. Another historical springboard for neural network concepts was that of adaptive control, and again this remains a subject of great interest.

43.1 Introduction

An important goal of cognitive science is to understand human cognition. Good models of cognition can be *predictive*—describing how people are likely to react in different scenarios—as well as *prescriptive*—describing limitations in cognition and potential ways in which the limitations might be overcome. In a sense, the benefits of having cognitive models are similar to the benefits individuals accrue in building their own internal model. To quote Craik (1943):

If the organism carries a “small-scale model” of external reality and of its own possible actions within its head, it is able to try out various alternatives, conclude which is the best of them, react to future situations before they arise, utilize the knowledge of past events in dealing with the present and future, and in every way to react in a much fuller, safer, and more competent manner to the emergencies which face it. (p. 61)

Among the important questions facing cognitive scientists are how such models are created and how they are represented internally. The Craik quote emphasizes the importance of the predictive power of models, and the ultimate measure of a model’s value is the model’s predictive accuracy. One important value of computers in cognitive science is that computer simulations provide a means to instantiate theories and to concretely test their predictive power. Furthermore, implementation of a theory in a computer model forces theoreticians to face practical issues that they may never have otherwise considered.

The role of computer science in cognitive modeling is not strictly limited to implementation and testing, however. A core belief of most cognitive scientists is that cognition is a form of computation (otherwise, computer modeling is a doomed enterprise), and the study of computation has long been

a source of ideas (and material for debates) for building cognitive models. Computers themselves once served as the dominant metaphor for cognition. In more recent years, the influence of computers has been more in the area of computational paradigms, such as rule-based systems, neural network models, etc.

43.2 Underlying Principles

One of the dangers faced by computer scientists in building cognitive models is falling under the spell of trying to apply computational models directly to cognition. A good example of this is the “mind as computer” metaphor that was once popular but has fallen into disfavor. Computer science offers a range of computational tools designed to solve problems, and it is tempting to apply these tools to psychological data and call the result a cognitive model. As McCloskey (1991) has pointed out, this falls far short of the criteria that could reasonably be used to define a theory of cognition. One replacement for the “mind as computer” metaphor makes this point well. Neurally inspired models of cognition fell out of favor following Minsky and Papert (1969) showed that the dominant neural models at the time were unable to model nonlinear functions (notably exclusive-or). The extension of these models by the parallel distributed processing (PDP) group in 1986 (Rumelhart and McClelland, 1986) is largely responsible for the *connectionist* revolution for the past 25 years. The excitement generated by these models was twofold: (1) they were computationally powerful and simple to use, and (2) as neural-level models, they appeared to be physiologically plausible.

A major difficulty for connectionist theory for the past 25 years has been that, despite the fact that the early PDP-style models (particularly models built upon *feed-forward back-propagation* networks) were proven to be implausible for both physiological and theoretical reasons (e.g., see Lachter and Bever, 1988; Newell, 1990), many cognitive models are still built using such discredited computational engines. The reason for this appears to be simple convenience. Back-propagation networks, for example, can approximate virtually any function and are simple to train. Because any set of psychological data can be viewed as a function that maps an input to a behavior, and because feed-forward back-propagation networks can approximate virtually any function, it is hardly surprising that such networks can “model” an extraordinary range of psychological phenomena. Indeed, because of the versatility of these networks, a running joke in the machine learning community is that “neural networks are the second best way to do anything.” To put this in another way, many cognitive models are written in computer languages like C. Although such models may accurately characterize a huge range of data on human cognition, no one would argue that the C programming language is a realistic model of human cognition. Feed-forward neural networks seem to be a better candidate for a cognitive model because of some of their features: they intrinsically learn, they process information in a manner reminiscent of neurons, etc. In any regard, this suggests that the criteria for judging the merits of a cognitive model must include many more constraints than whether or not the model is capable of accounting for a given data set. While issues such as how information is processed are useful for judging models, they are also crucial for constructing models.

There are a number of sources and types of constraints used in cognitive modeling. These break down relatively well by the disciplines that comprise the field. In practice, most cognitive models draw constraints from some, but not all, of these disciplines. In broad terms, the data for cognitive models come from psychology. “Hardware” constraints come from neuroscience. “Software” constraints come from computer science, which also provides methodologies for validation and testing. Two related fields that are relatively new, and therefore tend to provide softer constraints, are evolutionary psychology and environmental psychology. The root idea of each of these fields is that the evolution process, and especially the environmental conditions that took place during evolution, are crucially important to the kind of brain that we now have. We will examine the impact of each field on cognitive modeling in turn.

43.2.1 Psychology

The ultimate test of any cognitive theory is whether or not it can correctly predict human behavior. Psychology as a field is responsible for the vast majority of data on human behavior. Over the last century, the source of this data has evolved from mere introspection on the part of theorists to rigorous laboratory experimentation. Normally, the goal of psychological experiments is to isolate a particular cognitive factor; for example, the number of items a person can hold in short-term memory. In general, this isolation is used as a means of reducing complexity. In principle, this means that cognitive theories can be constructed piecewise instead of out of whole cloth. It would be fair to say that the majority of work in cognitive science proceeds on this principle. A fairly typical paper in a cognitive science conference proceeding, for example, will present a set of psychological experiments on some specific area of cognition, a model to account for the data, and computer simulations of the model.

43.2.2 Neuroscience

The impact of neuroscience on cognitive science has grown dramatically in conjunction with the influence of neural models in the past 25 years. Unfortunately, terms such as “neurally plausible” have been applied fairly haphazardly in order to lend an air of credibility to models. In response, some critics have argued that neurons are not well understood enough to be productively used as part of cognitive theory. Nevertheless, though the low level details are still being studied, neuroscience can provide a rich source of constraints and information for cognitive modelers. Within the field, there are several different types of architectural constraint available. These include the following:

1. *Information flow.* We have learned from neuroscientists, for example, that the visual system is divided into two distinct parts, a “what” system for object identification and a “where” system for determining spatial locations. This suggests computational models of vision should have similar properties. Furthermore, these constraints can be used to drive cognitive theory as with the PLAN model of human cognitive mapping (Chown et al., 1995). In PLAN, it was posited that humans navigate in two distinct ways, each corresponding to one of the visual pathways. Virtually all theories of cognitive mapping had previously included a “what” component based upon topological collections of landmarks, but none had a good theory of how more metric representations are constructed. The split in the visual system led the developers of PLAN to theorize that metric representations would have simple “where” objects as their basic units. This led directly to a representation built out of “scenes,” which are roughly akin to snapshots. Models based on scenes or views have since become commonplace in the human navigation literature.
2. *Modularity.* A great deal of work in neuroscience goes toward understanding the kinds of processing done by particular areas of the brain, such as the hippocampus. These studies can range from working with patients with brain damage to intentionally lesioning animal brains. In recent years, noninvasive imaging techniques such as functional magnetic resonance imaging (fMRI) have revolutionized the role of neuroscience in cognitive modeling because they can be used directly on humans. While fMRI cannot provide neuroscientists with information on individual neurons, it can track neural activity across relatively small regions of the brain. This work has provided a picture of the brain far more complex than the simple “right brain-left brain” distinction of popular psychology.

The usefulness of fMRI, especially in conjunction with computer science, is exemplified by the work of Just et al. (2010) that examines the question of how and where concepts are represented in the brain. Subjects were presented words, generally concrete nouns for three seconds at a time with rest periods in between. During this time, the subjects were monitored by fMRI and were told to generate a set of properties for each item that the participants were free to choose for themselves. Once the data was collected, a variety of techniques were used to analyze it, notably

including a number of standard machine learning approaches. The results were remarkable and showed, for example, a commonality of patterns across the individuals tested. The authors concluded that not only do people store concepts in particular places in the brain but that these concepts are represented similarly enough across the population that one person's concept representation can be predicted by using other people's activation patterns.

3. *Mechanisms*. Numerous data are simpler to make sense of in the context of neural processing mechanisms. A good example of this would be the *Necker cube*. From a pure information processing point of view, there is no reason that people would only be able to hold one view of the cube in their mind at a time. From a neural point of view, on the other hand, the perception of the cube can be seen as a competitive process with two mutually inhibitory outcomes. Perceptual theory is an area that has particularly benefited from a neural viewpoint.
4. *Timing*. Perhaps the most famous constraint on cognitive processing offered by neuroscience is the "100 step rule." This rule is based upon looking at timing data of perception and the firing rate of neurons. From these, it has been determined that no perceptual algorithm could be more than 100 steps long (though the algorithm could be massively parallel as the brain itself is).

43.2.3 Computer Science

Aside from providing the means to implement and simulate models of cognition, computer science has also provided constraints on models through limits drawn from the theory of computation and has been a source of algorithms for modelers.

One of the biggest debates in the cognitive modeling community is whether or not computers are even capable of modeling human intelligence. Critics, normally philosophers, point to the limitations on what is computable and have gone as far as suggesting that the mind may not be computational. While some find these debates interesting, they do not actually have a significant impact on the enterprise of modeling. On the other hand, there have been theoretical results from computational theory that have had a huge impact on the development of cognitive models. Probably, the best example of this is the previously mentioned work done by Minsky and Papert on Perceptrons (1969). They showed that perceptrons, which are a simple kind of neural network, are not capable of modeling nonlinear functions (including exclusive-or). This result effectively ended the majority of neural network research for more than a decade until the PDP group developed far more powerful neural network models (Rumelhart and McClelland, 1986).

43.2.4 Evolutionary and Environmental Psychology

In recent years, two branches of psychology have come to prominence as providing alternate sources of constraints based upon evolution, and in particular, the kinds of environments in which humans evolved. Evolutionary psychology is most often associated with the work of Tooby and Cosmides (e.g. Tooby and Cosmides, 1992) while environmental psychology is often associated with the work of Steve and Rachel Kaplan (e.g. Kaplan and Kaplan, 1989). What both of these fields have in common is a belief that the brain should not be studied in a vacuum, that some types of context are extremely meaningful.

In the case of evolutionary psychology, the context is provided by evolution. As has been noted in many places, systems that are evolved rather than designed tend to end up looking like the work of a "tinkerer." The eye is a well-known example of a system that is poorly "designed" but is nonetheless functional and can be understood as a series of successive improvements, each adding functionality to the previous iteration (Dawkins, 1986). This example captures the core tenets of evolutionary psychology—that evolution tends to work in piecemeal fashion with each change adding functionality to what existed previously. This does not tend to be a hard constraint on cognitive models, as it can be argued that the evolutionary story behind any particular theory simply has yet to be found.

Nevertheless, the evolutionary view provides a powerful way to think about how pieces of the cognitive system came about and for what purpose.

As the name would suggest, work in environmental psychology focuses on the environment as a source of constraints. Most environmental psychologists focus their research on how people interact with different kinds of environments and how to use this knowledge to design better spaces. Another branch of the field, however, has noted that the environment adds additional meaningful context to evolutionary history. The evolutionary history of the brain is a story of information processing mechanisms that evolved to address the specific needs of our ancestors. The human ability to represent and reason about large-scale space, for example, allowed our ancestors to forage and hunt over large areas of savanna. In turn, once these spatial abilities were in place, they were available for the greater cognitive system and impact cognition of virtually every type (Chown, 1999). The importance in understanding the evolutionary environments that the brain developed in is highlighted by the work of the Kaplans and their colleagues. The Kaplans have shown, for example, that people will recover more quickly in hospitals with views of nature, perform better in workplaces with views of trees, etc. (for reviews see Kaplan, 1993; Kaplan and Peterson, 1993). This is a clear indicator that people do not treat information neutrally. More recently, this work has been extended to look at the impact of different kinds of information on attention and self-regulation (Kaplan and Berman, 2010). The authors make the case that certain kinds of attention are resource limited and that the depletion of these resources has negative cognitive consequences. Meanwhile, certain kinds of activity, for example, walking in nature, can actually support the replenishment of the lost resources. Work of this sort undercuts theories of cognition based on rationality and can help to explain many of the supposed shortcomings in human reasoning.

43.3 Research Issues

Since so much about cognition is still not well understood, this section will focus on two of the key debates driving research in the field. These include: (1) is the brain a symbol processor, or does it need to be modeled in neural terms? (2) Should the field be working on grand theories of cognition or is it better to proceed on a reductionist path?

43.3.1 Are We Symbol Processors?

The connectionist revolution brought a new way of thinking to cognitive science. The critical idea is rather simple—that since the “hardware” of the brain is neural, then models of the brain should be described in neural terms. Lending credence to this position were a series of neural models that had a number of attractive properties that seemed notably lacking in symbolic models of the time (e.g., *content addressable memory*, *graceful degradation*, etc. [Rumelhart and McClelland, 1986]). On the face of it, the argument for neural models seems unassailable given that the brain is a neural system. Symbolists, notably Newell (1990) and Fodor and Plyshen (1988) have attacked these models on a number of grounds. Their arguments are based upon the idea that the brain, like any complex system, is hierarchical. Neural models, so the argument goes, provide appropriate computational descriptions for only the lowest levels of the cognitive hierarchy. From the point of view of the symbolists, these levels of cognition are also less well understood and not as interesting from a behavioral point of view as the so-called *cognitive band* (Newell, 1990). From this point of view, the operation of the cognitive band is nothing like a neural network, but is much more like a traditional symbol system. The argument is akin to finding the appropriate level at which to study computers. It is possible, and occasionally necessary, to look at the performance of a computer from the point of view of gates. When trying to understand the performance of a complicated piece of software, however, it is much more appropriate to study the performance at the level of a high level programming language.

The argument for symbolic models comes from computational theory. It is based upon the idea of computational equivalence. Since symbolic models are Turing-complete, they are equivalent

computationally to any other Turing-complete model. Along these lines, a number of efforts have been made to implement symbolic models in neural hardware. The case can then be made that this is exactly what the brain does. Symbolists see this equivalence as freeing them from the need to worry about mechanisms. Even so, the impact of connectionism and the capability of neural models for pattern recognition have led even strongly symbolic models like Soar (Laird et al., 1987) to use neural networks as pattern recognizers to obtain the symbols.

The freeing up from the constraints of mechanisms has been something of a double-edged sword for symbolic models. On the one hand, symbolic models are easily implemented on computers and relatively easy to expand, debug, etc. Furthermore, in terms of high-level behavior, symbolic models have been shown to be capable of a much wider range of behaviors than their current connectionist counterparts. For example, Soar agents are capable of modeling the flying behaviors of combat pilots (Jones et al., 1999). On the other hand, critics have complained that systems like Soar are little more than symbolic programming languages. As noted earlier, while a computer running C may be Turing-complete, it would be ridiculous to call it a model of human cognition. Clark (2001) refers to this as “surface mimicry” and points out that the Soar model is far more homogeneous than the “Swiss Army Knife” model suggested by Tooby and Cosmides (1992). The critics argue that symbolic models like Soar and ACT-R are under constrained, and therefore they cannot truly be called cognitive models. The lack of constraints goes even further than just mechanisms; symbolic models have also been attacked on evolutionary grounds. It is difficult to see how symbolic constructs like distal memory access could have evolved in any sort of piecemeal fashion.

There are several arguments that symbolists use against neural models. First is the “levels of modeling” argument. This argument posits that we simply do not understand the behavior of neurons well enough to construct credible models from them. To be fair, the majority of neural models do not model the behavior of individual neurons. Other attacks on connectionist models are based upon what current models cannot do. Popular connectionist models, such as feed-forward back-propagation networks, for example, exhibit a number of problems as memory models including “catastrophic forgetting” of old material when presented with new material (McCloskey and Cohen, 1989). While it is certainly appropriate to attack the individual models on these grounds, it is less so to attack the entire connectionist position based on the failure of even its most notable examples. Similarly, other criticisms of connectionism have attacked the models as being nothing more than new versions of the discredited behaviorist position (Lachter and Bever, 1988). Again, this is certainly the case with many connectionist models, and should rightfully lead to a search for better models, but it cannot undermine the general position.

A more interesting criticism focuses upon the way that connectionists have pursued cognitive modeling. The argument is the same as the one against some of the symbolic programs. As McCloskey (1991) put it, connectionists often pursue a path of “simulation in search of theory” (p. 388). McCloskey argues that many of these simulations are little better than “black boxes.” Modelers do not provide insight into what aspects of the network are crucial to its performance with regard to the task. For example, if back-propagation was used to train the network, is that a crucial step, or could another training regime have been used? If back-propagation were crucial, then it would undermine the model if back-propagation were found implausible on other grounds. In other words, connectionist systems are engaged in the same sort of “surface mimicry” as symbolic systems under the guise of “neural plausibility.” McCloskey goes on to complain that connectionist models generally fall short in describing how their networks elucidate the cognitive processes they purport to model. To put it simply, connectionist networks are not well understood enough to tell us exactly how they manage to accomplish what they are trained for.

So far in discussing connectionist systems, we have avoided discussing connectionist “symbols.” While it may be the case that connectionist units represent collections of neurons, they do not normally represent what most computer scientists would think of as symbols. There are, however, connectionist models that recognize the power of symbols as a basic unit of thought. Many of these models trace their lineage to the work of D.O. Hebb’s book *The Organization of Behavior* (1949). Hebb proposed that the “symbols” of thought were cell assemblies, tightly connected groups of neurons capable of functioning

as a unit because of their strong interconnections. The problem with cell assemblies, as originally formulated by Hebb, was that all of the connections between neurons were positive and only became stronger through learning. Hebb omitted inhibition because there was still no hard evidence of it at the time of publication. A later simulation of the cell assembly construct (Rochester et al., 1956) showed that without inhibition, activity in the simulated brain quickly grew out of control. Unfortunately, these results were sufficient to essentially stop research on cell assemblies for more than a decade, even though the same paper showed that with the addition of inhibition the cell assembly construct was viable. In recent years, however, the cell assembly idea has undergone a revival as researchers from a number of domains have proposed models based upon Hebb's original idea but modified with modern understandings of neuroscience (Amit, 1995; deVries, 2004; Kaplan et al., 1991). Recent work of the sort done by Just et al. (2010) using fMRI to examine how concepts are represented in the brain has also supported Hebb's position.

Neural models based upon cell assemblies purport to contain the best of both symbolic and connectionist models. It is difficult to study sequence learning, for example, without something approximating a symbol to serve as a unit in the sequence. Furthermore, many connectionist systems do not address temporal issues at all. Conversely, symbolic models do not ground the symbols in any physical mechanism nor are symbolic systems able to take advantage of the properties of neural hardware. Chown (2002), for example, has shown that some learning results that have defied conventional modeling for nearly 40 years can be fairly easily explained when basic neural properties are accounted for in a cell assembly-based model.

43.3.2 Grand Theories?

In his book *Unified Theories of Cognition*, Allen Newell (1990) called for a return to all-encompassing theories of mind called UTCs after the title of the book. Newell's reasoning echoes McCloskey's (1991) complaints about connectionism, which by operating at too small a scale, cognitive modelers have worked on under-constrained models. While it may be true, for example, that connectionist system X can model psychological data set Y, such models rarely address questions of how they would or could fit into a larger system. Modeling efforts such as these are sometimes attacked on the grounds that they are "doomed to succeed" in much the same way that models with too many parameters can fit all types of curves. Put another way, if a model is Turing complete, the question of whether or not it can be used to fit some data is not particularly interesting. The interesting question is whether or not there is actually evidence for it. McCloskey and others argue that for these reasons, theory should drive simulation rather than the other way around.

Ironically, the two most notable examples of UTCs, Soar and ACT-R, have been attacked on virtually the same grounds—that they are under-constrained. Both systems are built on the same assumption, which at higher levels of cognition the brain is a rule-based system. At the heart of each system is a production system implementing the rule-base that serves as long-term memory. Since production systems are Turing-complete, they are capable of modeling anything. To be fair, however, Soar does make some key theoretical commitments that can be used to judge its merits. First and foremost, Soar is a symbol manipulation system with all that that implies. Second, in Soar deliberative, thought is equated to a search through a problem space. For example, Soar is equipped with all the basic weak search methods including breadth-first, depth-first, etc. At one time, another key constraint associated with Soar was that all learning came as the result of a single mechanism called "chunking" (Laird et al., 1984). It is not clear, however, from recent work in Soar that this is still held as a central tenet of the system. Furthermore, the Soar group seems to be retreating from positioning Soar as a model of human cognition and is instead focusing on Soar as a system capable of exhibiting "human-level" intelligence.

Soar and ACT-R have both been attacked for their commitment to production systems. This criticism actually pre-dates either system and is most famously associated with the philosopher Hubert Dreyfus (1972). The Dreyfus position is that systems based upon rules are too brittle to account for the richness of

human behavior. For example, Dreyfus discusses how knowledge about the health of a jockey's mother might influence how a bettor would make a wager. It seems unlikely that the bettor would have explicit rules dealing with such a situation, and yet humans are capable of dealing with such situations with ease. The response to this criticism has been to test it explicitly, either with Doug Lenat's CYC (Lenat and Feigenbaum, 1992), which aims to capture enough knowledge to perform common sense reasoning, or with the Soar program, which builds more and more complex agents capable of difficult tasks such as flying jet airplanes in combat situations. In part, Dreyfus's criticisms can also be addressed by noting that rules need not all be specified at the same level of generality. For example, while a system for betting on horses might contain many specific rules concerning the records of horses and jockeys, a general cognitive system might reasonably be expected to include rules such as "when something traumatic happens to a person they will not perform at normal levels." Of course, this raises further questions of how such rules are learned, how patterns such as "something traumatic" are recognized, etc. Dreyfus would argue that this leads to an endless cycle for any reasonably complex task.

There are also connectionist programs that work at the level of large theories of cognition. Steven Grossberg, for example, has produced a huge body of work that have never been explicitly put forth as a UTC but which when viewed as a whole have many of the same principles. Probably, the best example of this work is the adaptive resonance theory (ART) model developed in conjunction with Gail Carpenter (see Carpenter and Grossberg, 1987). The SESAME group, operating mainly out of the University of Michigan is also working on a cognitive architecture (Kaplan et al., 1991). The SESAME architecture is based on the cell assembly and is also the only cognitive architecture to include a complete theory of spatial processing (Chown et al., 1995).

43.4 Best Practices

As the previous sections suggest, there are a number of pitfalls involved in putting together a cognitive model. History has shown that there are two problems that crop up again and again. The first is the danger of constructing a simulation without theoretically motivating the details. This is akin to the old saying that "if you have a big enough hammer everything looks like a nail." There is a related danger that once a simulation works (or at least models the data), it is often difficult to say why. Together, these dangers suggest that there should be a close relationship between theory and the simulation process. The goal of a simulation should not be simply to model a dataset, but should also be to elucidate the theory. For example, some connectionist models propose a number of mechanisms as being central to understanding a particular process. These models can be systematically "damaged" by disabling the individual mechanisms. In many cases, the damage to the model can be equated to damage to individuals. This provides a second dataset to model, and provides solid evidence of what the mechanism does in the simulation. Alternatively, models can be built piecemeal mechanism by mechanism. Each new piece of the simulation would correspond to a new theoretical mechanism aiming to address some shortcoming of the previous iteration. This motivates each mechanism and helps to clearly delineate its role in the overall simulation. In the SESAME group, this style of simulation has been termed "the systematic exploitation of failure" by one of its members, Abraham Kaplan.

One of the earliest examples of this approach was done by Booker (1982) in an influential work that has helped shape the adaptive systems paradigm. In an adaptive systems paradigm, a simple creature is placed in a microworld where the goal is survival. Creatures are successively altered (and sometimes the environments are as well) by adding and subtracting mechanisms. In each case, the success of the new mechanism can be judged by improvements in the survival rate of the organism. In addition to providing a way to motivate theoretical mechanisms, this paradigm is also essentially the same one used for the development of genetic algorithms.

The Soar architecture is probably the preeminent symbolic cognitive architecture. Soar is based upon a number of crucial premises that constrain all models written in Soar (which can be considered a kind of programming environment). First, Soar, like its major competition ACT-R, is a rule-based system

implemented as a production system. In the Soar paradigm, the production rules represent long-term memory and knowledge. One effect of a production firing in Soar can be to put new elements into working memory, Soar's version of short-term memory. For example, a Soar system might contain a number of perceptual productions that aim to identify different types of aircraft. When a production fires, it might create a structure in working memory to represent the aircraft it identifies. This structure in turn might cause further productions to fire. Soar enforces a kind of hierarchy through the use of a subgoal system. Productions can be written to apply generally or might only match when a certain goal is active. The combination of goals and productions forms a problem space that provides the basic framework for any task. Finally, the Soar architecture contains a single mechanism for learning called "chunking." Essentially, Soar systems learn when they reach an impasse generally created by not being able to match any productions. When impasses occur, Soar can apply weak search methods to the problem space in order to discover what to do. Once a solution is found, a new production or "chunk" is created to apply to the situation.

Here is an example of a Soar production taken from the Soar tutorial (Laird, 2003). In this example, the agent is driving a tank in a battle exercise.

```
sp {wander*propose*move
    (state <s> ^ name wander
        ^io.input-linked-blocked.forward no)
-->
    (<s>    ^operator <o> + =)
    (<o>    ^name move
        ^actions.move.direction forward)
}
```

In the example, "sp" stands for "Soar production" and starts every production. The production is named "wander*propose*move." The elements that come before the arrow represent the "if" part of the production. In this case, the production fires only if the current subgoal is to wander and the forward direction is not blocked (input comes from a specialized structure tagged ^io). The elements that come after the arrow represent the "then" parts of the production. In this case, a new working memory element is created to represent the operator for moving forward. In a typical production cycle, productions are matched in parallel and can propose operators such as the move operator in this case. Then other productions can be used to select among the proposed operators. This selection can be based upon virtually any criteria; for example, cognitive productions may be selected over more reactive productions. Production matching can be done in parallel to simulate the parallelism of the brain.

Both the Soar and ACT-R communities are engaged in programs of simulating more and more human behavior. These simulations can be done at the level of models of simple psychological experiments, or, as is increasingly the case, they can simulate human performance on complex tasks such as flying airplanes. The implicit argument is that if they can simulate anything that humans can do then they must be modeling human cognition. On one level, this argument has merit, if either architecture can accurately simulate human performance, then it can be used in a predictive fashion. Tac-air Soar (Jones et al., 1999), for example, simulates the performance of combat pilots and is used to train new pilots in a more cost-effective way than if experienced pilots had to be used. On the other hand, equivalent functionality is not the same thing as equivalence. As noted previously, critics point out that both Soar and ACT-R are essentially Turing-complete programming environments and therefore are capable of simulating any computable function given clever enough programmers. The fact that both systems still rely heavily on clever programming is still a major limitation with regard to being considered a fully realized model of human cognition. Although Soar's initial success was due in large part to its learning mechanism, for example, little progress has been made within the Soar community in building agents that exhibit any sort of developmental patterns. It is much simpler to build a Soar system that can fly planes than one that can learn to fly planes.

Gail Carpenter, Stephen Grossberg and their associates have also attacked a wide range of problems, but have done so with much more of an eye toward cognitive theory than applications. While Carpenter and Grossberg have not explicitly developed a unified theory of cognition, they have modeled a remarkable range of cognitive processes and have done so using an approach more sympathetic to a systems view of cognition than is typical in connectionist modelers. A good example of this approach can be found in their ART (Carpenter and Grossberg, 1987; Grossberg, 1987). Superficially, ART looks similar to many connectionist learning systems in that it is essentially a classification system, but it was developed to specifically address many of the shortcomings of such models. A feature vector is the input to Art, which uses it to provide a classification of the input. For example, a typical task would be to recognize hand-written numbers. The features would consist of the presence or absence of a pen stroke at different spatial locations.

One of the problems that ART was designed to address was what Grossberg (1987) referred to as the “stability-plasticity” dilemma. This is essentially a problem of how much new knowledge should impact what has been learned before. For example, a system that has been trained to recognize horses might have a problem when confronted with a zebra. The system could either change its representation of horses to include zebras or it could create a separate representation for zebras. This is a significant issue for neural network models because they achieve a great deal of their power by having multiple representations share structure. Such sharing is useful for building compact representations and for automatic abstraction, but it also means that new knowledge tends to constantly overwrite what has come before. Among the problems this raises is “catastrophic forgetting” as mentioned previously.

The stability-plasticity dilemma was addressed, in part, in ART through the introduction of a vigilance parameter that adaptively changed according to how well the system was performing. In some cases, for example, the system would be extremely vigilant and would require an unusually high degree of match before it would recognize an input as being familiar. In cases where inputs were not recognized as familiar, novel structure was created to form a new category or prototype. Such a new category would not share internal structure directly with previously learned categories. Essentially when vigilance is high, the system creates “exemplars” or very specialized categories, whereas when vigilance is low, ART will create “prototypes” that generalize across many instances. This makes ART systems attractive since they do not commit fully either to exemplar or prototype models, but can exhibit properties of both, as seems to be the case with human categorization.

In ART systems, an input vector activates a set of feature cells within an attentional system, essentially storing the vector in short-term memory. These in turn activate corresponding pathways in a bottom-up process. The weights in these pathways represent long-term memory traces and act to pass activity to individual categories. The degree of activation of a category represents an estimate that the input is an example of the category. In the meantime, the categories send top-down information back to the features as a kind of hypothesis test. The vigilance parameter defines the criteria for whether the match is good enough. When a match is established, the bottom-up and top-down signals are locked into a “resonant” state, and this in turn triggers learning, is incorporated into consciousness, etc.

It is important to note that ART, unlike many connectionist learning systems, is unsupervised—it learns the categories without any teaching signals.

A number of extensions have followed the original ART, including ART1, ART2, ART3, and ARTMAP. Grossberg has also tied it to his FACADE model in a system called ARTEX (Grossberg and Williamson, 1999). These models vary in features and complexity but share intrinsic theoretical properties. All of the ART models are self-organizing (i.e., unsupervised, though ARTMAP systems can include supervised learning) and consist of an attentional and an orienting subsystem. A fundamental property of any ART system (and many other connectionist systems) is that perception is a competitive process. Different learned patterns generate expectations that essentially compete against each other. Meanwhile, the orienting system controls whether or not such expectations sufficiently match the input—in other words it acts as a novelty detector.

The ART family of models demonstrate many of the reasons why working with connectionist models can be so attractive. Among them:

- The neural computational medium is natural for many processes including perception. Fundamental ideas such as representations competing against each other (including inhibiting each other) are often difficult to capture in a symbolic model. In a system like ART, on the other hand, a systemic property like the level of activation of a unit can naturally fill many roles from the straightforward transmission of information to providing different measures of the goodness of fit of various representations to input data.
- The architecture of the brain is a source of both constraints and ideas. Parameters, such as ART's vigilance parameter, can be linked directly to real brain mechanisms such as the arousal system. In this way, what is known about the arousal system provides clues as to the necessary effects of the mechanism in the model and provides insight into how the brain handles fundamental issues such as the plasticity-stability dilemma.

43.5 Summary

Unlike many disciplines in computer science, there are no provably correct algorithms for building cognitive models. Progress in the field is made through a process of successive approximation. Models are continually proposed and rejected; and with each iteration of this process, the hope is that the models come closer to a true approximation of the underlying cognitive structure of the brain. It should be clear from the preceding sections that there is no "right" way to do this.

Improvements in cognitive models come from several sources. In many cases, improvements result from an increased understanding of some aspect of cognition. For example, neuroscientists are constantly getting new data on how neurons work, how they are connected, what parts of the brain process what types of information, etc. In the meantime, models are implemented on computers and on robots. These implementations provide direct feedback about model quality and shortcomings. This feedback often will lead to revisions in the models and sometimes may even drive further experimental work. Because of the complexity of cognition and the number of interactions amongst parts of the brain, it is rarely the case that definitive answers can be found; which is not to say that cognitive scientists do not reach consensus on any issues. Over time, for example, evidence has accumulated that there are multiple memory systems operating at different time-scales. While many models have been proposed to account for this, there is general agreement on the kinds of behavior that those models need to be able to display. This represents real progress in the field because it eliminates whole classes of models that could not account for the different time-scales. The constraints provided by data and by testing models work to continually narrow the field of prospective models.

Key Terms

Back-propagation: A method for training neural networks based upon gradient descent. An error signal is propagated backward from output layers toward the input layer through the network.

Cognitive band: In Newell's hierarchy of cognition, the cognitive band is the level at which deliberate thought takes place.

Cognitive map: A mental model. Often, but not exclusively, used for models of large-scale space.

Connectionist: A term used to describe neural network models. The choice of the term is meant to indicate that the power of the models comes from the massive number of connections between units within the model.

Content addressable memory: Memory that can be retrieved by descriptors. For example, people can remember a person when given a general description of the person.

Feed forward: Neural networks are often constructed in a series of layers. In many models, information flows from an input layer toward an output layer in one direction. Models in which the information flows in both directions are called *recurrent*.

Graceful degradation: The principle that small changes in the input to a model, or that result from damage to a model, should result in only small changes to the model's performance. For example, adding noise to a model's input should not break the model.

Necker cube: A three-dimensional drawing of a cube drawn in such a way that either of the two main squares that comprise the drawing can be viewed as the face closest to the viewer.

UTC: Unified Theory of Cognition.

Further Information

There are numerous journals and conferences on cognitive modeling. Probably, the best place to start is with the annual conference of the Cognitive Science Society. This conference takes place in a different city each summer. The Society also has an associated journal, *Cognitive Science*. Information on the journal and the conference can be found at the society's homepage at <http://www.cognitivesciencesociety.org>.

Because of the lag-time in publishing journals, conferences are often the best place to get the latest research. Among other conferences, Neural Information Processing Systems (NIPS) is one of the best for work specializing in neural modeling. The Simulation of Adaptive Behavior conference is excellent for adaptive systems. It has an associated journal as well, *Adaptive Behavior*.

A good place for anyone interested in cognitive modeling to start is Allen Newell's book, *Unified Theories of Cognition*. While a great deal of the book is devoted to Soar, the first several chapters lay out the challenges and issues facing any cognitive modeler. Another excellent starting point is Dana Ballard's 1999 book, *An Introduction to Natural Computation*. Ballard emphasizes neural models, and his book provides good coverage on most of the major models in use. Andy Clark's 2001 book, *Mindware: An Introduction to the Philosophy of Cognitive Science*, covers much of the same ground as this article, but in greater detail, especially with regard to the debate between connectionists and symbolists.

44.1 Introduction

This chapter surveys the development of graphical models known as Bayesian networks, summarizes their semantical basis, and assesses their properties and applications to reasoning and planning.

Bayesian networks are directed acyclic graphs (DAGs) in which the nodes represent variables of interest (e.g., the temperature of a device, the gender of a patient, a feature of an object, the occurrence of an event), and the links represent causal influences among the variables. The strength of an influence is represented by conditional probabilities that are attached to each cluster of parent–child nodes in the network.

Figure 44.1 illustrates a simple yet typical Bayesian network. It describes the causal relationships among the season of the year (X_1), whether rain falls (X_2) during the season, whether the sprinkler is on (X_3) during that season, whether the pavement would get wet (X_4), and whether the pavement would be slippery (X_5). All variables in this figure are binary, taking a value of either true or false, except the root variable X_1 that can take one of four values: spring, summer, fall, or winter. Here, the absence of a direct link between X_1 and X_5 , for example, captures our understanding that the influence of seasonal variations on the slipperiness of the pavement is mediated by other conditions (e.g., the wetness of the pavement).

FIGURE 44.1 A Bayesian network representing causal influences among five variables.

As this example illustrates, a Bayesian network constitutes a model of the environment rather than, as in many other knowledge representation schemes (e.g., logic, rule-based systems, and neural networks), a model of the reasoning process. It simulates, in fact, the causal mechanisms that operate in the environment and thus allows the investigator to answer a variety of queries, including associational queries, such as “Having observed A , what can we expect of B ?”; abductive queries, such as “What is the most plausible explanation for a given set of observations?”; and control queries, such as “What will happen if we intervene and act on the environment?” Answers to the first type of query depend only on probabilistic knowledge of the domain, while answers to the second and third types rely on the causal knowledge embedded in the network. Both types of knowledge, associative and causal, can effectively be represented and processed in Bayesian networks.

The associative facility of Bayesian networks may be used to model cognitive tasks such as object recognition, reading comprehension, and temporal projections. For such tasks, the probabilistic basis of Bayesian networks offers a coherent semantics for coordinating top-down and bottom-up inferences, thus bridging information from high-level concepts and low-level percepts. This capability is important for achieving selective attention, that is, selecting the most informative next observation before actually making the observation. In certain structures, the coordination of these two modes of inference can be accomplished by parallel and distributed processes that communicate through the links in the network.

However, the most distinctive feature of Bayesian networks, stemming largely from their causal organization, is their ability to represent and respond to changing configurations. Any local reconfiguration of the mechanisms in the environment can be translated, with only minor modification, into an isomorphic reconfiguration of the network topology. For example, to represent a disabled sprinkler, we simply delete from the network all links incident to the node “sprinkler.” To represent a pavement covered by a tent, we simply delete the link between “rain” and “wet.” This flexibility is often cited as the ingredient that marks the division between deliberative and reactive agents, and that enables the former to manage novel situations instantaneously, without requiring retraining or adaptation.

44.2 Historical Background

Networks employing DAGs have a long and rich tradition, starting with the geneticist Sewall Wright (1921). Wright (1921) developed a method called *path analysis* (Wright, 1934), which later became an established representation of causal models in economics (Wold, 1964), sociology (Blalock, 1971;

Kenny, 1979), and psychology (Duncan, 1975). Good (1961) used DAGs to represent causal hierarchies of binary variables with disjunctive causes. *Influence diagrams* represent another application of DAG representation (Howard and Matheson, 1981). Developed for decision analysis, they contain both event nodes and decision nodes. *Recursive models* is the name given to such networks by statisticians seeking meaningful and effective decompositions of contingency tables (Lauritzen, 1982; Wermuth and Lauritzen, 1983; Kiiveri et al., 1984).

The role of the network in the applications previously mentioned was primarily to provide an efficient description for probability functions; once the network was configured, all subsequent computations were pursued by symbolic manipulation of probability expressions. The potential for the network to work as a computational architecture, and hence as a model of cognitive activities, was noted in Pearl (1982), where a distributed scheme was demonstrated for probabilistic updating on tree-structured networks. The motivation behind this particular development was the modeling of distributed processing in reading comprehension (Rumelhart, 1976), where both top-down and bottom-up inferences are combined to form a coherent interpretation. This dual mode of reasoning is at the heart of Bayesian updating and in fact motivated Reverend Bayes' original 1763 calculations of posterior probabilities (representing explanations), given prior probabilities (representing causes), and likelihood functions (representing evidence).

Bayesian networks have not attracted much attention in the logic and cognitive modeling circles, but they did in expert systems. The ability to coordinate bidirectional inferences filled a void in expert systems technology in the late 1970s, and it is in this area that Bayesian networks truly flourished. Over the past 10 years, Bayesian networks have become a tool of great versatility and power, and they are now the most common representation scheme for probabilistic knowledge (Neapolitan, 1990; Spiegelhalter et al., 1993; Darwiche, 2009; Koller and Friedman, 2009). They have been used to aid in the diagnosis of medical patients (Andersen et al., 1989; Geiger et al., 1990; Heckerman, 1991; Jiang and Cooper, 2010) and malfunctioning systems (Fenton and Neil, 2012); to understand stories (Charniak and Goldman, 1991); to retrieve documents (de Campos et al., 2004); to interpret pictures (Levitt et al., 1990); to perform filtering, smoothing, and prediction (Weiss and Pearl, 2010); to analyze gene expressions (Friedman et al., 2000), genetic counseling (Uebersax, 2004), semantic search (Koumenides and Shadbolt, 2012), error-correcting codes (McEliece et al., 1998), and speech recognition (Zweig, 1998); to facilitate planning in uncertain environments (Guestrin, 2003; Beaudry et al., 2010); and to study causation, nonmonotonicity, action, change, and attention. Some of these applications are described in Pearl (1988) Russell and Norvig (2003), and Buede (2009).

44.3 Bayesian Networks as Carriers of Probabilistic Information

44.3.1 Formal Semantics

Given a DAG G and a joint distribution P over a set $X = \{X_1, \dots, X_n\}$ of discrete variables, we say that G *represents* P if there is a one-to-one correspondence between the variables in X and the nodes of G , such that P admits the recursive product decomposition

$$P(x_1, \dots, x_n) = \prod_i P(x_i | \mathbf{pa}_i) \quad (44.1)$$

where \mathbf{pa}_i are the direct predecessors (called *parents*) of X_i in G . For example, the DAG in Figure 44.1 induces the decomposition

$$P(x_1, x_2, x_3, x_4, x_5) = P(x_1) P(x_2 | x_1) P(x_3 | x_1) P(x_4 | x_2, x_3) P(x_5 | x_4) \quad (44.2)$$

The recursive decomposition in Equation 44.1 implies that, given its parent set \mathbf{pa}_i , each variable X_i is conditionally independent of all its other predecessors $\{X_1, X_2, \dots, X_{i-1}\} \setminus \mathbf{pa}_i$. Using Dawid's notation (Dawid, 1979), we can state this set of independencies as

$$X_i \perp\!\!\!\perp \{X_1, X_2, \dots, X_{i-1}\} \setminus \mathbf{pa}_i \mid \mathbf{pa}_i \quad i = 2, \dots, n \quad (44.3)$$

Such a set of independencies is called *Markovian*, since it reflects the Markovian condition for state transitions: each state is rendered independent of the past, given its immediately preceding state. For example, the DAG of Figure 44.1 implies the following Markovian independencies:

$$X_2 \perp\!\!\!\perp \{0\} \mid X_1, \quad X_3 \perp\!\!\!\perp X_2 \mid X_1, \quad X_4 \perp\!\!\!\perp X_1 \mid \{X_2, X_3\}, \quad X_5 \perp\!\!\!\perp \{X_1, X_2, X_3\} \mid X_4 \quad (44.4)$$

In addition to these, the decomposition of Equation 44.1 implies many more independencies, the sum total of which can be identified from the DAG using the graphical criterion of *d*-separation (Pearl, 1988):

Definition 44.1 (*d*-separation)

Let a path in a DAG be a sequence of consecutive edges, of any directionality. A path p is said to be *d*-separated (or blocked) by a set of nodes Z iff

1. p contains a chain $i \rightarrow j \rightarrow k$ or a fork $i \leftarrow j \rightarrow k$ such that the middle node j is in Z , or
2. p contains an inverted fork $i \rightarrow j \leftarrow k$ such that neither the middle node j nor any of its descendants (in G) are in Z

If X , Y , and Z are three disjoint subsets of nodes in a DAG G , then Z is said to *d*-separate X from Y , denoted $(X \perp\!\!\!\perp Y \mid Z)_G$, iff Z *d*-separates every path from a node in X to a node in Y .

In Figure 44.1, for example, $X = \{X_2\}$ and $Y = \{X_3\}$ are *d*-separated by $Z = \{X_1\}$; the path $X_2 \leftarrow X_1 \rightarrow X_3$ is blocked by $X_1 \in Z$, while the path $X_2 \rightarrow X_4 \leftarrow X_3$ is blocked because X_4 and all its descendants are outside Z . Thus, $(X_2 \perp\!\!\!\perp X_3 \mid X_1)_G$ holds in Figure 44.1. However, X and Y are not *d*-separated by $Z' = \{X_1, X_5\}$, because the path $X_2 \rightarrow X_4 \leftarrow X_3$ is rendered active by virtue of X_5 , a descendant of X_4 , being in Z' . Consequently, $(X_2 \perp\!\!\!\perp X_3 \mid \{X_1, X_5\})_G$ does not hold; in words, learning the value of the consequence X_5 renders its causes X_2 and X_3 dependent, as if a pathway were opened along the arrows converging at X_4 .

The *d*-separation criterion has been shown to be both necessary and sufficient relative to the set of distributions that are represented by a DAG G (Geiger et al., 1990; Verma and Pearl, 1990). In other words, there is a one-to-one correspondence between the set of independencies implied by the recursive decomposition of Equation 44.1 and the set of triples (X, Z, Y) that satisfy the *d*-separation criterion in G . Furthermore, the *d*-separation criterion can be tested in time linear in the number of edges in G . Thus, a DAG can be viewed as an efficient scheme for representing Markovian independence assumptions and for deducing and displaying all the logical consequences of such assumptions.

An important property that follows from the *d*-separation characterization is a criterion for determining when two dags are observationally equivalent, that is, every probability distribution that is represented by one of the dags is also represented by the other:

Theorem 44.1

(Verma and Pearl, 1990) Two dags are observationally equivalent if and only if they have the same sets of edges and the same sets of v-structures, that is, head-to-head arrows with nonadjacent tails.

The soundness of the d -separation criterion holds not only for probabilistic independencies but for any abstract notion of conditional independence that obeys the semi-graphoid axioms (Pearl et al., 1990; Verma and Geiger, 1990). Additional properties of DAGs and their applications to evidential reasoning in expert systems are discussed in Pearl (1988, 1993a), Pearl et al. (1990), Geiger (1990), Lauritzen and Spiegelhalter (1988), Spiegelhalter et al. (1993), Darwiche (2009), and Lauritzen (1996).

44.3.2 Inference Algorithms

The first algorithms proposed for probability updating in Bayesian networks used message-passing architecture and were limited to trees (Pearl, 1982) and singly connected networks (Kim and Pearl, 1983). The idea was to assign each variable a simple processor, forced to communicate only with its neighbors, and to permit asynchronous back-and-forth message-passing until equilibrium was achieved. Coherent equilibrium can indeed be achieved this way, but only in singly connected networks, where an equilibrium state occurs in time proportional to the diameter of the network.

Many techniques have been developed and refined to extend the tree-propagation method to general, multiply connected networks. Among the most popular are Schachter's (1988) method of node elimination, Lauritzen and Spiegelhalter's (1988) method of clique-tree propagation, loop-cut conditioning (Pearl, 1988, Section 44.4.3), and iterative conditioning (Dechter, 1999; Darwiche, 2009).

Clique-tree propagation works as follows. Starting with a directed network representation, the network is transformed into an undirected graph that retains all of its original dependencies. This graph, sometimes called a Markov network (Pearl, 1988, Section 44.3.1), is then triangulated to form local clusters of nodes (cliques) that are tree-structured. Evidence propagates from clique to clique by ensuring that the probability of their intersection set is the same, regardless of which of the two cliques is considered in the computation. Finally, when the propagation process subsides, the posterior probability of an individual variable is computed by projecting (marginalizing) the distribution of the hosting clique onto this variable.

Whereas the task of updating probabilities in general networks is NP-hard (Rosenthal, 1975; Cooper, 1990), the complexity for each of the three methods cited earlier is exponential in the size of the largest clique found in some triangulation of the network. It is fortunate that these complexities can be estimated prior to actual processing; when the estimates exceed reasonable bounds, an approximation method such as stochastic simulation (Pearl, 1987; Henrion, 1988) and belief propagation (Weiss and Pearl, 2010) can be used instead. Learning techniques have also been developed for systematic updating of the conditional probabilities $P(x_i|\mathbf{pa}_i)$ so as to match empirical data (Spiegelhalter and Lauritzen, 1990; Darwiche, 2009).

44.3.3 System's Properties

By providing graphical means for representing and manipulating probabilistic knowledge, Bayesian networks overcome many of the conceptual and computational difficulties of earlier knowledge-based systems (Pearl, 1988). Their basic properties and capabilities can be summarized as follows:

1. Graphical methods make it easy to maintain consistency and completeness in probabilistic knowledge bases. They also define modular procedures of knowledge acquisition that reduce significantly the number of assessments required (Pearl, 1988; Heckerman, 1991).
2. Independencies can be dealt with explicitly. They can be articulated by an expert, encoded graphically, read off the network, and reasoned about, yet they forever remain robust to numerical imprecision (Geiger, 1990; Geiger et al., 1990; Pearl et al., 1990).

3. Graphical representations uncover opportunities for efficient computation. Distributed updating is feasible in knowledge structures that are rich enough to exhibit intercausal interactions (e.g., “explaining away”) (Pearl, 1982; Kim and Pearl, 1983). And, when extended by clustering or conditioning, tree-propagation algorithms are capable of updating networks of arbitrary topology (Shachter, 1986; Lauritzen and Spiegelhalter 1988; Pearl, 1988).
4. The combination of predictive and abductive inferences resolves many problems encountered by first-generation expert systems and renders belief networks a viable model for cognitive functions requiring both top–down and bottom–up inferences (Pearl, 1988; Shafer and Pearl, 1990).
5. The causal information encoded in Bayesian networks facilitates the analysis of action sequences, their consequences, their interaction with observations, their expected utilities, and, hence, the synthesis of plans and strategies under uncertainty (Dean and Wellman, 1991; Pearl, 1993b, 1994b).
6. The isomorphism between the topology of Bayesian networks and the stable mechanisms that operate in the environment facilitates modular reconfiguration of the network in response to changing conditions and permits deliberative reasoning about novel situations.

44.3.4 Later Developments

44.3.4.1 Causal Discovery

One of the most exciting prospects in recent years has been the possibility of using the theory of Bayesian networks to discover causal structures in raw statistical data. Several systems have been developed for this purpose (Rebane and Pearl, 1987; Pearl and Verma, 1991; Spirtes et al., 1993, 2000), which systematically search and identify causal structures with hidden variables from empirical data. Technically, because these algorithms rely merely on conditional independence relationships, the structures found are valid only if one is willing to accept weaker forms of guarantees than those obtained through controlled randomized experiments: minimality and stability (Pearl and Verma, 1991; Pearl, 2000, Chapter 2). Minimality guarantees that any other structure compatible with the data is necessarily less specific, and hence less falsifiable and less trustworthy, than the one(s) inferred. Stability ensures that any alternative structure compatible with the data must be less stable than the one(s) inferred; namely, slight fluctuations in experimental conditions will render that structure no longer compatible with the data. With these forms of guarantees, the theory provides criteria and algorithms for identifying genuine and spurious causes, with or without temporal information.

Alternative methods of identifying structure in data assign prior probabilities to the parameters of the network and use Bayesian updating to score the degree to which a given network fits the data (Cooper and Herskovits, 1991; Heckerman et al., 1994). These methods have the advantage of operating well under small sample conditions, but encounter difficulties coping with hidden variables.

Tian and Pearl (2001a,b) developed yet another method of causal discovery based on the detection of “shocks,” or spontaneous local changes in the environment, which act like “nature’s interventions,” and unveil causal directionality toward the consequences of those shocks.

44.3.4.2 Plain Beliefs

In mundane decision making, beliefs are revised not by adjusting numerical probabilities but by tentatively accepting some sentences as “true for all practical purposes.” Such sentences, often named *plain beliefs*, exhibit both logical and probabilistic character. As in classical logic, they are propositional and deductively closed; as in probability, they are subject to retraction and to varying degrees of entrenchment (Spohn, 1988; Goldszmidt and Pearl, 1992).
