Register allocation: This is the most important and pervasive issue in the generation of quality code. Keeping temporaries in registers is indispensable, especially for RISC architectures. In order to extend register allocation to include local variables, parameters, and global variables, a compiler may permanently allocate certain registers to heavily used quantities. An alternative is to build an interference graph and assign registers by graph coloring, permitting noninterfering variables to share the same register. Good global register allocation also requires some form of dataflow analysis in order to identify values that have no further uses in subsequent code and that can be safely overwritten if they are in registers.

Common subexpression elimination: This refers to the identification of expression values that are recomputed one or more times in a program and the avoidance of such recomputation by suitable storing and reuse of the computed value. While one might naively think that a good programmer should not write code that contains common subexpressions, in fact, most common subexpressions are due to address computations of array and record references that cannot be expressed adequately in source code and that therefore require elimination by an optimizer. Common subexpressions are relatively easy to identify in straight line code; the principal difficulty in the general case is to determine what subexpressions may have changed between two computations of the same expression. Thus, a compiler may choose to perform only local common subexpression elimination.

Copy propagation: This optimization tracks code regions in which two or more variables have the same value. After an assignment $x = y$ (in C syntax), x and y have the same value in subsequent expressions until one of them acquires a new value; in this region, any use of x can be replaced by a use of y , which can lead to better code if, for example, y is already in a register. As with common subexpressions, copy statements may exist in the intermediate code even when they are not written by the programmer. A special case of copy propagation is constant propagation: after an assignment such as $x = 2$, uses of x can be replaced by the constant 2. As with common subexpressions, copy propagation may be done either as a local or global optimization.

Reduction in strength: This refers to the replacement of arithmetic expressions by equivalent expressions that execute faster. A typical example is the replacement of multiplication or division by a power of 2 with a shift operation. Another example occurs in loop optimization, where a linear combination calculation is replaced by a simple addition (see the subsequent paragraph on loop optimization).

Jump optimization: Opportunities for improving jump code occur when a sequence of jumps can be replaced by a single jump, or when a jump can be eliminated by rearranging the code. For instance, the code sequence

```

    goto lab1
...
lab1:  if x = y goto lab2
lab3:  ...
can be replaced by the more efficient
    if x = y goto lab2
    goto lab3
...
lab3:  ...

```

Algebraic laws: An optimizer can look for special cases in expressions such as $x * 1$ and $x + 0$ (replacing these with x). Sometimes, it is also worthwhile to replace a computation $x + y$ or $x * y$ with its commutative equivalent $y + x$ or $y * x$. More difficult is to discover opportunities to use distributive laws, such as replacing $x * y + z * y$ with the more efficient $(x + z) * y$.

Loop optimization: Loops are traditionally an area where a great deal of attention has been paid to making code as efficient as possible, because programs tend to spend a lot of time in loops. In programs with goto statements, it is a non-trivial operation to even discover loops, and this usually must be done by building the flow graph. Fortunately, in modern languages, it is reasonable to depend on syntax (such as keywords *while* and *do*) to locate loops. Typical loop optimizations include attempting to discover invariant computations inside loops (i.e., those that always yield the same value, regardless of the loop iteration) and moving their computation to just before the loop entry. Another optimization seeks to discover so-called induction variables, which are linear combinations $a * i + b$, where i is the loop control variable. Since such an expression is incremented by a fixed amount with each iteration, its computation can be reduced in strength to a simple addition. Finally, loop unrolling can be applied: this seeks to reduce the delays (and possible cache misses) caused by the backward jumps in loop iterations by dividing the loop bounds by fixed amounts and inserting the missing iterations as linear code.

Constant folding: This optimization seeks to replace constant expressions (e.g., $3 + 5$) by their resulting values (e.g., 8). Such an optimization could, in theory, replace all computations whose results are predictable at compile time by their results alone. In practice, this would involve repeated applications of constant propagation and folding, so this optimal result is rarely achieved.

Dead code elimination: This optimization seeks to skip code generation for those statements that are either never reached during execution or whose actions have no effect on the results of the program.

The first case happens when compile-time constants are set to select certain actions over others (e.g., to suppress the collection of run-time statistics). The second occurs if common subexpression elimination or copy propagation makes a computation or assignment unnecessary.

68.3.9 Error Recovery

An important practical problem in the design of a translator is its response to errors in the input program. Although many translators have been constructed so that they stop at the first error encountered, it is generally considered better to attempt to discover as many errors as possible in the input before halting. Thus, the response to errors includes error recovery, so that translation may continue, as well as the generation of informative error messages. A further step in an error handler may also be error repair, where the translator attempts to correct at least some of the errors. Because it is difficult to infer from an erroneous program what the actual intended program was, error repair is usually not attempted, except in special cases, such as missing punctuation.

Errors may be classified into lexical, syntactic, semantic, and run-time errors. An interpreter must have a reasonable response to runtime errors that involves at least generating an error message and exiting gracefully. A compiler needs only to recover from static errors, although it may need to generate code to report run-time errors. Semantic errors are relatively easy to recover from, because the syntax tree can still be used to guide the remainder of translation. Lexical errors can be simply passed to the parser by the scanner as error tokens. Thus, the principal difficulty in building an error handler occurs in dealing with parsing errors, where the structure of the input is disturbed, and there may be no obvious way to restart the parser.

Several criteria apply to any method for recovery from parse errors. First, it is useful to try to detect errors as early as possible, because continuing to process the input can make it more difficult to determine where the error occurred and to generate an appropriate error message. Second, the translator should attempt to discard as little input as possible when recovering from an error, because discarding input can lead to other errors, as well as mislead the programmer. Third, the translator should avoid generating large numbers of error messages caused by a single error. In particular, a translator must never get into an infinite loop when recovering from an error. This usually requires that at least some input be discarded during error recovery.

A standard technique for error recovery is called *panic mode*, in which tokens are simply discarded, and the parsing stack accordingly adjusted until the parse can resume. This method can be made sophisticated enough so that it becomes better than its name implies. It can be used either as the standard error recovery technique or as a fall-back technique for a more complex method. The important feature of panic mode is the proper computation of a synchronizing set of tokens, which are used to determine when the parser should stop discarding the input and attempt to resume the parse. Panic mode in recursive-descent parsing is discussed in Wirth (1976 [Section 5.9]). A slightly different method is used by Yacc/Bison, in which an error pseudotoken is made available, with which important error recovery locations can be marked in so-called error productions in the input grammar. For example, in the Bison definition file of Table 68.5, the error production

```
session : session error '\n' {yyerrok;}
```

was included in the specification. Yacc/Bison's behavior on encountering an error is as follows. First, it sets a flag to enter an error phase, and then it begins popping the parsing stack until a state is found where the error pseudotoken can be successfully shifted. Then input tokens are discarded until three consecutive tokens can be shifted successfully, whence the error phase is canceled and normal parsing is resumed. The error phase can also be canceled manually by calling the Yacc/Bison procedure `yyerrok`. For example, the previous error production for a calculator session causes Bison to discard all tokens until a newline is reached, and then to resume the parse. The result is that any incorrect line of

input is deleted. (Yacc/Bison also automatically calls `yyerror` whenever the error phase is entered, which can perform other actions and print an error message.)

Other error recovery and repair mechanisms are discussed in Graham (1979), Roehrich (1980), Dion (1982).

68.4 Incremental Compilation

Not only must compilers generate high-quality code they also must do it in a reasonable amount of time. Historically, the speed of compilation was often inversely proportional to the quality of the generated code, with the compilation of a large program under full optimization sometimes taking hours or even days. With modern processors, compilation speed has become less of an issue, but strong optimization still requires significant amounts of processor time. For this reason, compilers usually offer an unoptimized mode that not only avoids code improvements but is also tuned to the speediest possible generation of runnable code; such an option can be very useful for development or instructional work. Even so, large programs can require significant amounts of time to recompile if all of the code must be retranslated during each compilation step. A significant improvement in compiler technology is therefore the ability of a compiler to operate incrementally, that is, to avoid recompilation of code that has not changed since the previous compilation step. Alternatively, compilers that are linked to an editor as part of an interactive development environment (IDE) can compile program text in the background as it is entered by the programmer. Either of these mechanisms is called *incremental compilation*.

One of the original motivations for separate compilation and linking was to allow a form of incremental compilation, where only files that had changed needed to be recompiled, and the results of this recompilation would be combined with previously compiled files by a linker. Of course, this approach is subject to error, because the linker usually has no knowledge of the source language and cannot find incompatibilities between the recompiled code and the unchanged code. Additionally, the programmer has to keep track manually of which files have changed and which have not.

The first major advance over this situation was the Unix *make* utility (Feldman, 1979), varieties of which are part of virtually every IDE today (usually called *build* or *make project*). *Make* itself is still heavily in use in command-line development environments. *Make* keeps track automatically of file changes by using file system time stamps: a later time stamp on a source code file over its corresponding object code file indicates the need for recompilation. Additionally, *make* can keep track of dependencies in a set of source code files (made necessary by the convention of using file inclusion to check incompatibilities in C), although such dependencies must still be maintained manually by a programmer (in a so-called *makefile*). The *make*-like features that are built into IDEs usually automate the process of maintaining dependencies even further, particularly in languages with strong interface requirements like Ada and Java (but unlike C or C++).

It is possible, and often even desirable, to go beyond the capabilities of an automated *make* utility in either or both of the two different approaches to incremental compilation mentioned previously. First, a compiler could implement a finer-grained incremental approach than the file-level increments of *make*, such as statement-level or declaration-level increments (i.e., recompiling only those statements or function definitions within a file that have changed, rather than the entire file). Such a mechanism requires much more retained information about code structure than just object files and time stamps, however, and can lead to a significant increase in the amount of storage space required for a program or project. Second, the compiler could run in the background behind an editor, recompiling code as it is edited, rather than waiting for a compile command from the user. (Obviously, this approach makes the most sense if finer-grained incremental compilation is also implemented.) However, this approach can also mean more compiler interference in the process of editing or creating code, where an editor may refuse to accept program text that the compiler cannot understand. This can easily create programmer resistance to the use of such systems.

Examples of compilers that offer incremental compilation are the VisualAge Java compiler from IBM (now part of the Java Development Tool Core of the Eclipse Development Environment;

<http://www.eclipse.org/jdt/core/>) and the Visual Studio C# Compiler from Microsoft. These compilers also provide a contrast in how they mix the two approaches to incremental compilation described in the previous paragraph. The VisualAge compiler is invoked automatically by the IDE whenever a file save operation is performed (or when a file is added or imported into a project). It performs only file-level incremental compilation. However, it immediately reports any compilation problems to the user and will even prevent the completion of a file save operation if syntax errors occur in significant places. In contrast, the C# compiler will perform method-level (function-level) incremental compilation, but only at the direction of the user during a requested build.

68.5 Just-in-Time Compilation

68.5.1 Introduction to Just-in-Time Compilation

Traditionally, application programs were either interpreted or compiled. Interpreters have the advantage of fast start-up; source programs are quickly processed to the point of being executable. This enables highly desired rapid turnaround during program development. However, interpreted code can execute orders of magnitude slower than compiled code. Compilers provide the advantage of fast application program execution by generating native object code that can run at full speed on the target machines. Compilers can also perform optimizations generally not done by interpreters, further improving the execution performance of the application program. But code generation takes time, especially if code optimizations are performed. The generated object code usually requires further processing, such as linking and loading. Therefore, it takes longer for an application program to become executable with a compiler than with an interpreter.

Many compilers for modern programming languages, such as for Java and for Microsoft's .NET family of languages, generate bytecode instead of native code. Bytecode is the "machine language" that implements the instruction set of a virtual machine whose architecture is ideal for the features of a given set of source languages. The virtual machine is simply an interpreter for the bytecode. To execute an application program that has been compiled into bytecode, the virtual machine interprets the bytecode.

The use of bytecode promotes portability. An application program's bytecode can run on any actual machine that implements the virtual machine. A popular example of a virtual machine is the JVM. Once a Java application program has been compiled into bytecode (stored as `.class` files), any actual machine that implements the JVM can execute that program.

Besides interpreting bytecode, it is also possible to translate bytecode into the native object code of an actual machine. This translation can be done much more rapidly than it would take to translate the original source code to native code, since all of the work of scanning and parsing the source code has already been done in order to generate the bytecode.

A *JIT compiler* translates a source application program into bytecode that is interpreted by the virtual machine. While the application is being interpreted, the compiler can step in to dynamically translate blocks of bytecode "on the fly" into native machine code. Such dynamic translation is JIT because a block of bytecode (such as for a function or a method) can be translated into native code just as that code is about to be executed. Then whenever that block of code is executed again, the native code will run at full machine speed. In contrast, a traditional compiler does ahead-of-time (AOT) or static translation.

68.5.2 Advantages of Just-in-Time Compilers

A JIT compiler offers the best of both worlds for the application program developer: fast turnaround by an interpreter and fast program execution by the native code. Since the virtual machine architecture and the bytecode are ideally designed for the source language, a bytecode compiler can translate an application program into bytecode rapidly, and then the virtual machine can execute the bytecode immediately via interpretation. At application run time, the JIT compiler can rapidly translate blocks of bytecode into native machine code that executes at full machine speed.

While dynamic translation from bytecode to native code can be very rapid, it does take time, especially if code optimization is involved. Such a translation, if done serially with the virtual machine, would cause a pause in the interpretation of the application program. Therefore, some JIT compilers perform a runtime analysis of the application program. A block of bytecode is dynamically translated into native machine code only if it is advantageous to do so, such as if that block is executed more than once. Some JIT compilers provide command-line options that allow the developer to specify how many times a block of bytecode must execute before it is translated into native code.

A JIT compiler may be able to perform code optimizations that are not possible by a traditional AOT compiler. Because dynamic translation occurs during the application program's run time, it has the added context of the current state of the underlying actual machine, plus any runtime analysis of the application program. For example, it can generate native code optimized for the how many cores are currently available. Runtime analysis can determine that the native code for a function should be inlined rather than invoked. (See e.g., <http://java.sun.com/developer/onlineTraining/Programming/JDCBook/perf2.html> for the JVM and <http://blogs.msdn.com/b/davidnotario/archive/2004/10/28/248953.aspx> for Microsoft.NET.)

To be effective, a JIT compiler must make the tradeoff between time lost by the interpreter to dynamic translation and time gained by faster execution of native code. An application program that does not contain many loops or function calls may not benefit much from a JIT compiler (Li, 2004).

68.6 Compilation for Parallel Execution

An important aspect of modern compiler design is to ensure that the code generated by a compiler makes good use of opportunities provided by hardware for parallel execution. This has become even more important with the recent advent of so-called multicore architectures (see the chapter on Multicore Architectures), where two or more functionally distinct processors are built into the same chip. Virtually all personal computers sold today contain such chips, with the expectation that most programs running on these machines will actually use the hardware to improve execution speeds. Note, however, that the responsibility for assigning execution tasks to different processors is shared between the operating system and the compiler; an operating system can already assign independently running programs to different processors without any compiler intervention. Additionally, the operating system must provide an appropriate set of primitives to the compiler for it to be able to schedule parallel execution effectively. In this section, we will only briefly survey the issues and the current state of the art of compiling for parallel execution.

First, we should note that compiler writers have struggled to find ways for compilers to automatically discover opportunities for parallel execution of code within programs. Reasons for this include the unpredictable interaction of program features with data paths within the hardware, such as bus and cache operations, as well as the difficulty in predicting data dependencies within a program in the presence of control flow and aliasing. As a result, compilers do not usually generate code for multiple processors without programmer intervention, in that the programmer must write source code that explicitly states what code should be executed in parallel and how that code will communicate with the rest of the program. Thus, compilers must not only rely on the operating system to provide adequate mechanisms for parallelism but also the compiler must also rely on the programmer to provide source-level instructions on how to use the operating system mechanisms in a particular program. Further complicating this issue is the fact that many popular programming languages such as C/C++ do not include parallel mechanisms in their standard definitions; Java is a major exception, having included parallel mechanisms in the form of threads (see subsequent section) since its inception. This situation has been partially ameliorated by several widely accepted parallel interface standards, such as POSIX Pthreads (<http://www.opengroup.org/onlinepubs/007904975/basedefs/pthread.h.html>) and OpenMP (<http://openmp.org>, supported by GNU, Microsoft, and Intel C/C++ compilers).

One area of parallel execution where compilers play a role without user intervention is in the scheduling of consecutive machine instructions to take advantage of parallel execution within a single processor. Most modern processors have several ways of executing instructions in parallel. Usually, this is expressed as an instruction pipeline that splits the processing of a computer instruction into a series of independent steps. A standard pipeline (called the classic RISC pipeline) consists of five stages: fetch, decode, execute, store, and register writeback; each stage is executed in a single clock cycle, and new instructions are fed at each cycle into the pipeline, so that while one instruction is decoded, the next instruction is simultaneously fetched. In the ideal case, this can result in throughput of one instruction per cycle, even though a typical instruction takes several cycles to complete. Dependencies between successive instructions can inhibit this ideal situation from being achieved, as can jumps, interrupts, and cache misses, which may all stall the pipeline, causing the processor to wait one or more cycles for an action to complete. By constructing a dependency graph, typically during code optimization, a compiler can rearrange target code to substantially reduce pipeline stalls. An additional situation occurs in some architectures (e.g., RISC and SPARC computers) where an explicit delay slot is required in the code immediately after a jump that must either be filled by a *nop* (no operation) or a legal instruction (thus avoiding a pipeline stall caused by a jump). This can cause control flow in a target program to become very counterintuitive (and can lead to debugging and interrupt problems). For example, the simple C function

```
int absdiff(int x, int y)
{ if (x > y) return x - y;
  else return y - x;
}
```

is translated by the GNU C compiler on a SPARC machine as follows:

```
    mov %o0, %g1
    cmp %g1, %o1
    bg .LL1
    sub %o0, %o1, %o0
    sub %o1, %g1, %o0
.LL1:
    retl
    nop
```

In this code, the first subtraction (in the delay slot after the conditional branch) will always be performed, whether or not the jump is taken, and the second subtraction will overwrite the first only if the jump is not taken. (Note also the *nop* after the return; there is no available instruction to fill this delay slot.) Pipelining and instruction scheduling are discussed in more detail in the Chapter 22 (Performance Enhancements).

A further important situation where parallel execution is frequently scheduled by the compiler (with hints from the programmer) is that of loop optimizations (see Section 68.3.7). Computationally intensive programs, such as those involving matrices, typically spend a lot of execution time within loops, often nested two or three deep. Executing loop iterations in parallel can result in significant speedups. Most Fortran compilers therefore have special instructions for the programmer to mark loops for parallel execution: a *DOALL* Fortran statement indicates that each iteration of a loop is independent of the others, so that each iteration can be executed in parallel with the others. In situations where there are dependencies across iterations, the programmer can still mark a loop for parallel execution with a *DOACROSS* statement, but for this to be useful a compiler must be able to determine how to group successive iterations in ways that admit effective parallel execution. Often, this is combined with loop unrolling operations to achieve speedups.

In order to schedule more general program segments to run concurrently, possibly on multiple cores, the most common mechanism used at present is the *thread*: a program section encapsulated for concurrent execution that does not run as an independent process but shares resources, particularly memory, with the program as a whole. Most modern operating systems, including the latest versions of Linux and Windows, guarantee that code written using thread packages provided by the operating system will use available cores or other parallel hardware when executing a program. In this regard, the Java programming language has a significant advantage, since Java has included threads in its definition from the start. Indeed, a Java compiler transparently generates code that can make use of the latest multicore technology, since a JVM that executes the bytecode programs generated by the compiler encapsulates the required operating system calls, and all modern JVM implementations have been updated to use multicore facilities.

68.7 Research Issues and Summary

Language translators can be decomposed into the phases of scanning (lexical analysis), parsing (syntactic analysis), semantic analysis, optimization, and code generation. A scanner breaks the input program into tokens using the theory of regular expressions and finite automata. A parser constructs, implicitly or explicitly, a representation for the syntactic structure of the program, using the theory of context-free grammars. The construction of both a scanner and a parser can be easily automated, using tools such as Lex/Flex and Yacc/Bison or JavaCC. Yacc/Bison constructs a LALR(1) bottom-up parser; JavaCC constructs a recursive-descent top-down parser. Bottom-up parsers are generally too complex to construct by hand, but recursive-descent can be used to hand-construct a parser. Implementations of scanners as finite automata are also relatively easy to construct by hand.

The semantic analysis and code generation steps of a compiler can be modeled theoretically by an attribute grammar, which expresses in equational form the relationships among the various attributes of language entities. In fact, attribute grammars can be used as a basis for automating the construction of an entire compiler, but this has not become common, possibly because of the complexity of representing the entire semantics of a language as an attribute grammar, and possibly because of the difficulty of producing optimized target code. It may be that other semantic definition mechanisms, such as denotational semantics, will result in better automation techniques, but this remains for future study. Current methods typically construct hand-generated semantic analyzers, which operate during parsing using auxiliary data structures, such as the symbol table, or analyzers that perform recursive traversals of a syntax tree.

Some success has been achieved in automating the code-generation step, with easy retargeting as the primary goal. These methods include the syntax-based approach of Glanville and Graham (1978) and the semantic approach of Ganapathi and Fischer (1985). An alternative is to use a symbolic machine description language to describe the target machine, which is then used by the code generator to produce target code. Effective use of this method has been made in the widely retargeted GNU compiler collection.

An important aspect of the automation and retargetability of a compiler is the choice of an appropriate intermediate code representation for the source code. The best choice appears to be a symbolic code for a hypothetical abstract machine. One may then choose either to interpret the intermediate code using a simulator or to perform code generation based on a static simulation of this machine. The primary requirements of such an intermediate code are flexibility, security, and the availability of enough information to provide good optimization over a wide variety of target architectures. A significant challenge for future translator technology is to develop a standard intermediate code that can be generated by many different language front ends, and which can also be efficiently and safely interpreted and compiled on many different architectures under many different operating systems. Optimized versions of the JVM, such as the Jikes research virtual machine (<http://jikesrvm.org>), hold the promise that this may happen in the not-too-distant future.

Key Terms

- Attribute grammar:** A set of equations associated to the grammar rules of a context-free grammar that define a collection of attributes associated to the terminals and nonterminals of the grammar. Attribute equations are written in purely functional form (i.e., without side effects) and may be “solved” for the actual attribute values by different kinds of traversals of the parse or syntax tree. Alternatively, attribute values may be computed by replacing the attribute equations with equivalent side effect-generating code using separate data structures such as the symbol table.
- Back end:** The part of a compiler that depends only on the target language and is independent of the source language. The back-end receives the intermediate code produced by the front end and translates it into the target language.
- BNF:** Backus normal form or Backus–Naur form. A notation for context-free grammar rules first used in the Algol60 report to describe syntax. It comprises only two metasympols, usually written \rightarrow or $::=$ and $|$.
- Bottom-up:** A parsing algorithm that constructs the parse tree from the leaves to the root. Bottom-up algorithms include LR and LALR parsers, such as those produced by Yacc/Bison.
- Bytecode:** Numerically encoded intermediate code generated by a compiler that can be executed by an easily retargeted virtual machine.
- Disambiguating rule:** A rule stated separately from the rules of a context-free grammar, which specifies the correct choice of syntax tree structure when more than one structure is possible.
- EBNF:** Extended BNF. Adds bracketing metasympols [...] and {...} to BNF to indicate optional and repeated structures, respectively. (These can also be written as (...)? and (...)*) to remain consistent with standard regular expression notation.)
- Front end:** The part of a compiler that depends only on the source language and is independent of the target language. The front end translates and analyzes the source program.
- Incremental compilation:** Compilation or recompilation that occurs in small steps based on incremental changes made during the editing of a program and which encompasses only those parts of the program affected by the changes.
- Inherited attribute:** An attribute whose value depends on attribute values at syntax tree nodes, which are not descendants. A nonsynthesized attribute.
- Intermediate code or representation:** An internal data structure or sequence of abstract instructions representing a program as produced by the parser or other phase inside a compiler.
- Item:** A grammar rule choice with a distinguished position (often indicated by a period), indicating that a parse has reached that position in attempting to recognize the rule. Sets of items are used by a bottom-up parser to record a state reached during a parse. Items may have 0 or more tokens of lookahead attached to them. LR(0) items contain no lookahead, whereas LR(1) items contain one token of lookahead.
- Just-in-time (JIT) compiler:** A compiler that dynamically translates blocks of bytecode “on the fly” into native machine code during execution in a virtual machine, usually just before the virtual machine would execute the code.
- L-attributed grammar:** An attribute grammar whose attributes may be computed by a left-to-right traversal of the source program. An attribute grammar must be L-attributed for the attributes to be computable during a parse that processes the input from left to right (as most parsers do). Synthesized attributes are always L-attributed.
- LALR(1):** The lookahead LR(1) algorithm invented by DeRemer (1971). The algorithm is used in many bottom-up parser generators, including Yacc/Bison. A language is also called LALR(1) if it can be parsed unambiguously by the LALR(1) algorithm.
- Lexeme:** The actual character string read from the input when recognizing a token. The lexeme of an identifier token is the identifier name.

- LL(k):** A top-down parsing algorithm that processes the input from left to right, producing a leftmost derivation using k tokens of lookahead. The term can also be applied to a language that can be unambiguously parsed using this algorithm.
- LR(k):** A bottom-up parsing algorithm that processes the input from left to right, producing a rightmost derivation (in reverse) using k tokens of lookahead. The term can also be applied to a language that can be unambiguously parsed using this algorithm.
- Nonterminal:** A name for a structure defined by a context-free grammar rule. Interior nodes of parse trees are labeled by nonterminals.
- Phase:** A logical unit of a compiler. Typical phases include scanning, parsing, semantic analysis, and code generation. Phases are distinct from passes, which comprise a complete sequential processing of the input program. Phases may or may not correspond to physical code units within the compiler.
- Production:** Another term for a context-free grammar rule or grammar rule choice.
- Recursive-descent:** A top-down parsing algorithm that translates context-free grammar rules into a set of mutually recursive procedures, with each procedure corresponding to a nonterminal. Recursive-descent parsing is usually the method of choice when writing a parser by hand.
- Reduce-reduce conflict:** In bottom-up parsers, a property of a state in which a parser has a choice of two productions that can be used to reduce the parsing stack, and both are legal for the amount of lookahead allowed. Reduce-reduce conflicts have no natural disambiguating rule.
- Retargeting:** The process of changing a compiler to produce target code (assembly or machine code) for a different machine. This may involve rewriting the compiler back end or creating a machine definition file for the new machine.
- Shift-reduce conflict:** In bottom-up parsers, a property of a state in which a parser has a choice of either reducing the parsing stack using a production or shifting a token from the input, and both are legal for the amount of lookahead allowed. A natural disambiguating rule is to prefer the shift, thus allowing the parser to match the longest possible input string at each point.
- Synthesized attribute:** An attribute whose value depends only on the attribute values of descendants in the parse or syntax tree. Synthesized attributes are the easiest to compute during a parse, requiring no special data structures or techniques. The syntax tree itself is the most important example of a synthesized attribute.
- Terminal:** Another term for a token in a context-free grammar. Leaf nodes of parse trees are labeled by terminals.
- Thread:** A program section encapsulated for concurrent execution that does not run as an independent process but shares resources, particularly memory, with the program as a whole.
- Top-down:** A parsing algorithm that constructs the parse tree from the root to the leaves. Top-down algorithms include LL parsers and recursive-descent parsers, such as those produced by JavaCC.
- Virtual machine:** An interpreter for intermediate code, such as the Java virtual machine, which executes Java bytecode. A virtual machine provides transparent cross-platform retargetability for compilers and other software.

69.1 Introduction

A programming language possesses *syntax* and *semantics*. Syntax refers to the spelling of the language's programs, and semantics refers to the meanings of the programs. A language's syntax is formalized by a grammar or syntax chart; such formalizations are found in the back of language manuals. A language's semantics should be formalized, too, and this is the topic of this chapter.

Before we begin, we might ask, "What do we gain by formalizing the semantics of a programming language?" Consider the related question, "What was gained when language syntax was formalized with BNF?"

- A language's syntax definition standardizes the official syntax. This is crucial to users, who require a guide to writing syntactically correct programs, and to implementors, who must write a correct parser for the language's compiler.
- The syntax definition permits a formal analysis of its properties, such as whether the definition is $LL(k)$, $LR(k)$, or ambiguous.
- The syntax definition can be used as input to a compiler front-end generating tool, such as YACC; it becomes, in effect, the implementation.

We derive similar benefits from a formal semantics definition:

- The semantics definition standardizes the official semantics of the language. This is crucial to users, who require a guide to understanding the programs that they write, and to implementors, who must write a correct code generator for the language's compiler.
- The semantics definition permits a formal analysis of its properties, such as whether the definition is strongly typed, block structured, uses single-threaded data structures, is parallelizable, etc.
- The semantics definition can be used as input to a compiler back-end generating tool [26,31]; it becomes, in effect, the implementation.

Programming-language syntax was studied intensively in the 1960s and 1970s, and programming language semantics is undergoing similar intensive study. Unlike the acceptance of BNF as the standard for syntax definition, it is unlikely that a single definition method will take hold for semantics—semantics is harder to formalize than syntax, and it has a wider variety of applications.

Semantics-definition methods fall roughly into three groups:

- *Operational*: The meaning of a well-formed program is the trace of computation steps that results from processing the program's input. Operational semantics is also called *intensional* semantics, because the sequence of internal computation steps (the “intension”) is most important. For example, two differently coded programs that both compute factorial have different operational semantics.
- *Denotational*: The meaning of a well-formed program is a mathematical function from input data to output data. The steps taken to calculate the output are unimportant; it is the relation of input to output that matters. Denotational semantics is also called *extensional* semantics, because only the “extension”—the visible relation between input and output—matters. Thus, two differently coded versions of factorial have the same denotational semantics.
- *Axiomatic*: A meaning of a well-formed program is a logical proposition (a “specification”) that states some property about the input and output. For example, the proposition $\forall x. x \geq 0 \supset \exists y. y = x!$ is an axiomatic semantics of a factorial program.

69.2 Underlying Principles of Semantics Methods

We survey the three semantic methods by applying each in turn to the world's oldest and simplest programming language, arithmetic. The syntax of our arithmetic language is

$$E ::= N \mid E_1 + E_2$$

where N stands for the set of numerals $\{0, 1, 2, \dots\}$. Although this language has no notion of input and output, it is computational.

69.2.1 Operational Semantics

There are several versions of operational semantics for arithmetic. The one that you learned as a child is called a *term rewriting system* [6,25]. It uses rule schemes that generate computation steps. There is just one rule scheme for arithmetic:

$$N_1 + N_2 \Rightarrow N' \quad \text{where } N' \text{ is the sum of the numerals } N_1 \text{ and } N_2$$

The rule scheme states that adding two numerals is a computation step, for example, $1 + 2 \Rightarrow 3$ is one computation step. An operational semantics of a program is a sequence of such computation steps. For example, an operational semantics of $(1 + 2) + (4 + 5)$ goes as follows:

$$(1+2)+(4+5) \quad 3+(4+5) \quad 3+9 \quad 12$$

Three computation steps led to the answer, 12. An intermediate expression like $3 + (4 + 5)$ is a “state,” so this operational semantics traces the states of the computation.

Another semantics for the example is $(1 + 2) + (4 + 5) \Rightarrow (1 + 2) + 9 \Rightarrow 3 + 9 \Rightarrow 12$. The outcome is the same, and a set of rules that has this property is called *confluent* [25].

A *structural operational semantics* is a term-rewriting system plus a set of inference rules that state precisely the context in which a computation step can be undertaken. (A structural operational semantics is sometimes called a “small-step semantics,” because each computation step is a small step towards the final answer.) Say that we demand left-to-right computation of arithmetic expressions. This is encoded as follows:

$$N_1 + N_2 \Rightarrow N' \quad \text{where } N' \text{ is the sum of } N_1 \text{ and } N_2$$

$$\frac{E_1 \Rightarrow E'_1}{E_1 + E_2 \Rightarrow E'_1 + E_2} \quad \frac{E_2 \Rightarrow E'_2}{N + E_2 \Rightarrow N + E'_2}$$

The first rule goes as before; the second rule states, if the left operand of an addition expression can be rewritten, then do this. The third rule is the crucial one: if the right operand of an addition expression can be rewritten *and* the left operand is already a numeral (completely evaluated), then rewrite the right operand. Working together, the three rules force left-to-right evaluation.

Each computation step must be deduced by the rules. For $(1 + 2) + (4 + 5)$, we deduce this initial computation step:

$$\frac{1 + 2 \Rightarrow 3}{(1 + 2) + (4 + 5) \Rightarrow 3 + (4 + 5)}$$

Thus, the first step is $(1 + 2) + (4 + 5) \Rightarrow 3 + (4 + 5)$; note that we *cannot* deduce that $(1 + 2) + (4 + 5) \Rightarrow (1 + 2) + 9$. The next computation step is justified by this deduction:

$$\frac{4 + 5 \Rightarrow 9}{3 + (4 + 5) \Rightarrow 3 + 9}$$

The last deduction is simply $3 + 9 \Rightarrow 12$, and we are finished. The example shows why the semantics is “structural”: each computation step is explicitly embedded into the structure of the overall program.

Operational semantics is often used to expose implementation concepts, like instruction counters, storage vectors, and stacks. For example, say our semantics of arithmetic must show how a stack holds intermediate results. We use a *state* of form $\langle s, c \rangle$, where s is the stack and c is the arithmetic expression to evaluate. A stack containing n items is written $v_1 :: v_2 :: \dots :: v_n :: \text{nil}$, where v_1 is the topmost item and *nil* marks the bottom of the stack. The c component will be written as a stack as well. The initial state for an arithmetic expression, p , is written $\langle \text{nil}, p :: \text{nil} \rangle$, and computation proceeds until the state appears as $\langle v :: \text{nil}, \text{nil} \rangle$; we say that the result is v .

The semantics uses three rewriting rules:

$$\begin{aligned} \langle s, N :: c \rangle &\Rightarrow \langle N :: s, c \rangle \\ \langle s, E_1 + E_2 :: c \rangle &\Rightarrow \langle s, E_1 :: E_2 :: \text{add} :: c \rangle \\ \langle N_2 :: N_1 :: s, \text{add} :: c \rangle &\Rightarrow \langle N' :: s, c \rangle \quad \text{where } N' \text{ is the sum of } N_1 \text{ and } N_2 \end{aligned}$$

The first rule says that a numeral is evaluated by pushing it on the top of the stack. The second rule decomposes an addition into its operands and operator, which must be computed individually. The third rule removes the top two items from the stack and adds them. Here is the previous example, repeated:

$$\begin{aligned} &\langle nil, (1+2)+(4+5) :: nil \rangle \\ &\Rightarrow \langle nil, 1+2 :: 4+5 :: add :: nil \rangle \\ &\Rightarrow \langle nil, 1 :: 2 :: add :: 4+5 :: add :: nil \rangle \\ &\Rightarrow \langle 1 :: nil, 2 :: add :: 4+5 :: add :: nil \rangle \\ &\Rightarrow \langle 2 :: 1 :: nil, add :: 4+5 :: add :: nil \rangle \\ &\Rightarrow \langle 3 :: nil, : 4+5 :: add :: nil \rangle \Rightarrow \dots \Rightarrow \langle 12 :: nil, nil \rangle \end{aligned}$$

This form of operational semantics is sometimes called a *state-transition semantics* because each rewriting rule operates upon the entire state. A state-transition semantics has no need for structural operational-semantics rules.

The formulations presented here are typical of operational semantics. When one wishes to prove properties of an operational-semantics definition, the standard proof technique is *induction on the length of the computation*. That is, to prove that a property, P , holds for an operational semantics, one must show that P holds for all possible computation sequences that can be generated from the rewriting rules. For an arbitrary computation sequence, it suffices to show that P holds no matter how long the computation runs. Therefore, one shows (1) P holds after zero computation steps, that is, at the outset, and (2) if P holds after n computation steps, it holds after $n + 1$ steps. See Nielson and Nielson [34] for examples.

Operational semantics lies close to implementation, and early forms of operational semantics were *definitional interpreters*—implementations that generated the state-transition steps [13,44]. Figure 69.1 displays a Python-coded definitional interpreter that generates the computation steps of the stack-based arithmetic semantics, modeling the stack with a list argument and modeling subexpression evaluation with recursive-function calls. (As an exercise, you should prove the interpreter prints a sequence of stacks that matches the one computed by the state-transition rules.) A definitional interpreter is a powerful, practical tool for language definition and prototyping.

```
def eval (t, stack):
    """eval computes the meaning of t using stack.
       parameters: t - an arithmetic term, parsed into a nested list of form:
                   term ::= N | ["+", term, term], where N is a string of digits
                   stack - a list of integers
       returns: stack with the integer meaning of t pushed on its top.
    """
    print "Evaluate", t, "with stack =", stack
    if isinstance(t, str) and t.isdigit(): # is t a string of digits?
        newstack = [int(t)] + stack # push the int onto the stack
    else: # t is a list, ["+", t1, t2]
        stack1 = eval(t[1], stack)
        stack2 = eval(t[2], stack1)
        answer = stack2[1] + stack2[0] # add top two stack values
        newstack = [answer] + stack2[2:] # push answer onto popped stack
    print "Evaluated", t, "Updated stack =", newstack
    return newstack
```

69.2.2 Denotational Semantics

Operational semantics emphasizes internal state transitions. For the arithmetic language, we were distracted by questions about order of evaluation of subphrases, even though this issue is not at all important to arithmetic. Further, the key property that the meaning of an expression is built from the meanings of its subexpressions was obscured.

We use denotational semantics to establish that a program has an underlying *mathematical meaning* that is independent of the computation strategy used to compute it. In the case of arithmetic, an expression like $(1 + 2) + (4 + 5)$ has the meaning, 12. The implementation that computes the 12 is a separate issue, perhaps addressed by an operational semantics.

The assignment of meaning to programs is performed *compositionally*: the meaning of a phrase is built from the meanings of its subphrases. We now see this in the denotational semantics of the arithmetic language. First, we assert that meanings of arithmetic expressions must be taken from the *domain* (“set”) of natural numbers, $Nat = \{0, 1, 2, \dots\}$, and there is a binary, mathematical function, *plus* : $Nat \times Nat \rightarrow Nat$, which maps a pair of natural numbers to their sum.

The denotational semantics definition of arithmetic is simple and elegant:

$$\begin{aligned} \mathcal{E} : Expression &\rightarrow Nat \\ \mathcal{E}[\mathbf{N}] &= N \\ \mathcal{E}[E_1 + E_2] &= plus(\mathcal{E}[E_1]; \mathcal{E}[E_2]) \end{aligned}$$

The first line states that \mathcal{E} is the name of the function that maps arithmetic expressions to their meanings. Since there are two BNF constructions for expressions, \mathcal{E} is completely defined by the two equational clauses. (This is a Tarski-style interpretation, as used in symbolic logic to give meaning to logical propositions [49].) The interesting clause is the one for $E_1 + E_2$; it says that the meanings of E_1 and E_2 are combined compositionally by *plus*. Here is the denotational semantics of our example program:

$$\begin{aligned} \mathcal{E}[(1+2) + (4+5)] &= plus(\mathcal{E}[1+2], \mathcal{E}[4+5]) \\ &= plus(plus(\mathcal{E}[1], \mathcal{E}[2]), plus(\mathcal{E}[4], \mathcal{E}[5])) \\ &= plus(plus(1, 2), plus(4, 5)) = plus(3, 9) = 12 \end{aligned}$$

Read the aforementioned equation as follows: the meaning of $(1 + 2) + (4 + 5)$ equals the meanings of $1 + 2$ and $4 + 5$ added together. Since the meaning of $1 + 2$ is 3, and the meaning of $4 + 5$ is 9, the meaning of the overall expression is 12. This reading says nothing about order of evaluation or run-time data structures—it states only mathematical meaning.

Here is an alternative way of understanding the semantics; write a set of simultaneous equations based on the denotational definition:

$$\begin{aligned} \mathcal{E}[(1+2) + (4+5)] &= plus(\mathcal{E}[1+2], \mathcal{E}[4+5]) \\ \mathcal{E}[1+2] &= plus(\mathcal{E}[1], \mathcal{E}[2]) \\ \mathcal{E}[4+5] &= plus(\mathcal{E}[4], \mathcal{E}[5]) \\ \mathcal{E}[1] &= 1 & \mathcal{E}[2] &= 2 \\ \mathcal{E}[4] &= 4 & \mathcal{E}[5] &= 5 \end{aligned}$$

Now, solve the equation set to discover that $\mathcal{E}[(1+2) + (4+5)]$ is 12.

Since denotational semantics states the meaning of a phrase in terms of the meanings of its subphrases, its associated proof technique is structural induction. That is, to prove that a property, P , holds for all programs in the language, one must show that the meaning of each construction in the language has property P . Therefore, one must show that each equational clause in the semantic definition produces a meaning with property P . In the case that a clause refers to subphrases (e.g., $\mathcal{E}[\llbracket E_1 + E_2 \rrbracket]$), one may assume that the meanings of the subphrases have property P . Again, see Nielson and Nielson [34] for examples.

69.2.3 Natural Semantics

A semantics method has been proposed that is halfway between operational semantics and denotational semantics; it is called *natural semantics*. Like structural operational semantics, natural semantics shows the context in which a computation step occurs, and like denotational semantics, natural semantics emphasizes that the computation of a phrase is built from the computations of its subphrases.

A natural semantics is a set of inference rules, and a complete computation in natural semantics is a single, large derivation. The natural semantics rules for the arithmetic language are

$$\begin{array}{c}
 N \quad N \\
 \hline
 \frac{E_1 \Rightarrow n_1 \quad E_2 \Rightarrow n_2}{E_1 + E_2 \Rightarrow m} \quad \text{where } m \text{ is the sum of } n_1 \text{ and } n_2
 \end{array}$$

Read a configuration of the form $E \Rightarrow n$ as “ E evaluates to n .” The rules resemble a denotational semantics written in inference rule form; this is no accident—natural semantics can be viewed as a denotational-semantics variant where the internal calculations of meaning are made explicit and the domains are left implicit. The internal calculations are seen in the natural semantics of our example expression:

$$\frac{\frac{1 \Rightarrow 1 \quad 2 \Rightarrow 2}{(1+2) \Rightarrow 3} \quad \frac{4 \Rightarrow 4 \quad 5 \Rightarrow 5}{(4+5) \Rightarrow 9}}{(1+2) + (4+5) \Rightarrow 12}$$

Unlike denotational semantics, natural semantics does not claim that the meaning of a program is necessarily “mathematical.” And unlike structural operational semantics, where a configuration $e \Rightarrow e'$ says that e transits to an intermediate state, e' , in natural semantics $e \Rightarrow v$ asserts that the final answer for e is v . For this reason, a natural semantics is sometimes called a “big-step semantics.” An interesting drawback of natural semantics is that semantics derivations can be drawn only for terminating programs.

The usual proof technique for proving properties of a natural semantics definition is induction on the height of the derivation trees that are generated from the semantics. Once again, see Nielson and Nielson [34].

69.2.4 Axiomatic Semantics

An axiomatic semantics produces *properties* of programs rather than meanings. The derivation of these properties is done by an inference rule set that looks somewhat like a natural semantics.

As an example, say that we wish to prove even-odd properties of programs in arithmetic and our set of properties is simply $\{is_even, is_odd\}$. For example, $2 : is_even$ and $(2 + 3) : is_odd$ both hold true. We can define an axiomatic semantics to do this:

$$N : is_even \text{ if } N \bmod 2 = 0 \quad N : is_odd \text{ if } N \bmod 2 = 1$$

$$\frac{E_1 : p_1 \quad E_2 : p_2}{E_1 + E_2 : p_3} \quad \text{where } p_3 = \begin{cases} is_even & \text{if } p_1 = p_2 \\ is_odd & \text{otherwise} \end{cases}$$

The derivation of the even-odd property of our example program is

$$\frac{\frac{1:is_odd \quad 2:is_even}{1+2:is_odd} \quad \frac{4:is_even \quad 5:is_odd}{4+5:is_odd}}{(1+2)+(4+5):is_even}$$

In the usual case, the properties to be proved of programs are expressed in the language of predicate logic; see Section 69.3.7. Also, axiomatic semantics has strong ties to the *abstract interpretation* of denotational and natural semantics definitions; see Section 69.4.

69.3 Semantical Principles of Programming Languages

The semantics methods shine when they are applied to programming languages—primary features of a language are made prominent, and subtle features receive proper mention. Ambiguities and anomalies stand out like the proverbial sore thumb. In this section, we use a classic block-structured imperative language to demonstrate. Denotational semantics will be emphasized, but excerpts from the other semantics formalisms will be provided for comparison.

69.3.1 Language Syntax and Informal Semantics

The syntax of the programming language is presented in Figure 69.2. As stated in the figure, there are four “levels” of syntax constructions in the language, and the topmost level, Program, is the primary one. The language is a while-loop language with local, nonrecursive procedure definitions. For simplicity, variables are predeclared and there are just three of them—X, Y, and Z. A program, C., operates as follows: an input number is read and assigned to X’s location. Then the body, C, of the program is evaluated, and upon completion, the storage vector holds the results. For example, this program computes n^2 for a positive input n ; the result is found in Z’s location:

```
begin proc INCR = Z:= Z+X; Y:= Y+1
  in Y:= 0; Z:= 0; while Y not= X do call INCR od end.
```

It is possible to write nonsense programs in the language; an example is: A:=0; call B. Such programs have no meaning, and we will not attempt to give semantics to them.

69.3.2 Domains for Denotational Semantics

To give a denotational semantics to the sample language, we must state the sets of meanings, called *domains*, that we use. Our imperative, block-structured language has two primary domains:

P ∈ Program	I ∈ Identifier = alphabetic strings
D ∈ Declaration	V ∈ Variable = {X, Y, Z} ⊆ Identifier
C ∈ Command	N ∈ Numeral = {0, 1, 2, ...}
E ∈ Expression	
P ::= C.	
D ::= proc I=C	
C ::= V:=E C ₁ ; C ₂ begin D in C end call I while E do C od	
E ::= N E ₁ + E ₂ E ₁ not=E ₂ V

FIGURE 69.3 Semantic domains.

(1) the domain of storage vectors, called *Store*, and (2) the domain of symbol tables, called *Environment*. There are also secondary domains of booleans and natural numbers. The primary domains and their operations are displayed in Figure 69.3.

The domains and operations deserve study. First, the *Store* domain states that a storage vector is a triple. (Recall that programs have exactly three variables.) The operation *lookup* extracts a value from the store, for example, $lookup(2, \langle 1, 3, 5 \rangle) = 3$, and *update* updates the store, for example, $update(2, 6, \langle 1, 3, 5 \rangle) = \langle 1, 6, 5 \rangle$. Operation *init_store* creates a starting store. We examine *check* momentarily.

The environment domain states that a symbol table is a list of identifier-value pairs. For example, if variable *X* is the name of location 1, and *P* is the name of a procedure that is a “no-op,” then the environment that holds this information would appear $(X, 1) :: (P, id) :: nil$, where $id(s) = s$. (Procedures will be discussed momentarily.) Operation *find* locates the binding for an identifier in the environment, for example, $find(X, (X, 1) :: (P, id) :: nil) = 1$, and *bind* adds a new binding, e.g., $bind(Y, 2, (X, 1) :: (P, id) :: nil) = (Y, 2) :: (X, 1) :: (P, id) :: nil$. Operation *init_env* creates an environment to start the program.

In the next section, we will see that the job of a command, for example, an assignment, is to update the store—the meaning of a command is a function that maps the current store to the updated one. (That’s why a “no-op” command is the identity function, $id(s) = s$, where $s \in Store$.) But sometimes commands “loop,” and no updated store appears. We use the symbol, \perp , read “bottom,” to stand for a looping store, and we use $Store_{\perp} = Store \cup \{\perp\}$ as the possible outputs from commands. Therefore, the meaning of a command is a function of form $Store \rightarrow Store_{\perp}$.

It is impossible to recover from looping, so if there is a command sequence, C_1 ; C_2 , and C_1 is looping, then C_2 cannot proceed. The *check* operation is used to watch for this situation.

Finally, here are two commonly used notations. First, functions like $id(s) = s$ are often reformatted to read $id = \lambda s.s$; in general, for $f(a) = e$, we write $f = \lambda a.e$, that is, we write the argument to the function to the right of the equals sign. This is called *lambda notation*, and stems from the *lambda calculus*, an elegant formal system for functions [4]. The notation $f = \lambda a.e$ emphasizes that (1) the function $\lambda a.e$ is a value in its own right, and (2) the function’s name is *f*.

Second, it is common to revise a function that takes multiple arguments, for example, $f(a,b) = e$, so that it takes the arguments one at a time: $f = \lambda a.\lambda b.e$. So, if the arity of f was $A \times B \rightarrow C$, its new arity is $A \rightarrow (B \rightarrow C)$. This reformatting trick is named *currying*, after Haskell Curry, one of the developers of the lambda calculus.

69.3.3 Denotational Semantics of Programs

Figure 69.4 gives the denotational semantics of the programming language. Since the syntax of the language has four levels, the semantics is organized into four levels of meaning. For each level, we define a *valuation function*, which produces the meanings of constructions at that level. For example, at the Expression level, the constructions are mapped to their meanings by \mathcal{E} .

What is the meaning of the expression, say, $X + 5$? This would be $\mathcal{E}\llbracket X + 5 \rrbracket$, and the meaning depends on which location is named by X and what number is stored in that location. Therefore, the meaning is dependent on the current value of the environment and the current value of the store. So, if the current environment is $e_0 = (\mathbb{P}, \lambda s.s) :: (X, 1) :: (Y, 2) :: (Z, 3) :: \text{nil}$ and the current store is $s_0 = \langle 2, 0, 0 \rangle$, then the meaning of $X + 5$ is 7:

$$\begin{aligned} \mathcal{E}\llbracket X + 5 \rrbracket e_0 s_0 &= \text{plus}(\mathcal{E}\llbracket X \rrbracket e_0 s_0, \mathcal{E}\llbracket 5 \rrbracket e_0 s_0) \\ &= \text{plus}(\text{lookup}(\text{find}(X, e_0), s_0), 5) \\ &= \text{plus}(\text{lookup}(1, s_0), 5) = \text{plus}(2, 5) = 7 \end{aligned}$$

As this simple derivation shows, data structures like the symbol table and storage vector are modelled by the environment and store arguments. This pattern is used throughout the semantics definition.

$$\begin{aligned} \mathcal{P} &: \text{Program} \rightarrow \text{Nat} \rightarrow \text{Nat}_\perp \\ \mathcal{P}\llbracket C \rrbracket &= \lambda n.C\llbracket C \rrbracket \text{init_env}(\text{init_store } n) \\ \mathcal{D} &: \text{Declaration} \rightarrow \text{Environment} \rightarrow \text{Environment} \\ \mathcal{D}\llbracket \text{Proc } I = C \rrbracket &= \lambda e.\text{bind}(I, C\llbracket C \rrbracket e, e) \\ \mathcal{C} &: \text{Command} \rightarrow \text{Environment} \rightarrow \text{Store} \rightarrow \text{Store}_\perp \\ \mathcal{C}\llbracket V := E \rrbracket &= \lambda e.\lambda s.\text{update}(\text{find}(V, e), \mathcal{E}\llbracket E \rrbracket e s, s) \\ \mathcal{C}\llbracket C_1; C_2 \rrbracket &= \lambda e.\lambda s.\text{check}(\mathcal{C}\llbracket C_2 \rrbracket e, \mathcal{C}\llbracket C_1 \rrbracket e s) \\ \mathcal{C}\llbracket \text{begin } D \text{ in } C \text{ end} \rrbracket &= \lambda e.\lambda s.C\llbracket C \rrbracket (\mathcal{D}\llbracket D \rrbracket e) s \\ \mathcal{C}\llbracket \text{call } I \rrbracket &= \lambda e.\text{find}(I, e) \\ \mathcal{C}\llbracket \text{while } E \text{ do } C \text{ od} \rrbracket &= \lambda e.\bigcup_{i \geq 0} w_i \\ &\quad \text{where } w_0 = \lambda s.\perp \\ &\quad \quad w_{i+1} = \lambda s.\text{if } \mathcal{E}\llbracket E \rrbracket e s \text{ then } \text{check}(w_i, \mathcal{C}\llbracket C \rrbracket e s) \text{ else } s \\ \mathcal{E} &: \text{Expression} \rightarrow \text{Environment} \rightarrow \text{Store} \rightarrow (\text{Nat} \cup \text{Bool}) \\ \mathcal{E}\llbracket N \rrbracket &= \lambda e.\lambda s.N \\ \mathcal{E}\llbracket E_1 + E_2 \rrbracket &= \lambda e.\lambda s.\text{plus}(\mathcal{E}\llbracket E_1 \rrbracket e s, \mathcal{E}\llbracket E_2 \rrbracket e s) \\ \mathcal{E}\llbracket E_1 \text{ not } = E_2 \rrbracket &= \lambda e.\lambda s.\text{notequals}(\mathcal{E}\llbracket E_1 \rrbracket e s, \mathcal{E}\llbracket E_2 \rrbracket e s) \\ \mathcal{E}\llbracket V \rrbracket &= \lambda e.\lambda s.\text{lookup}(\text{find}(V, e), s) \end{aligned}$$

FIGURE 69.4 Denotational semantics.

As noted in the previous section, a command updates the store. Precisely stated, the valuation function for commands is: $C: \text{Command} \rightarrow \text{Environment} \rightarrow \text{Store} \rightarrow \text{Store}_\perp$. For example, for e_0 and s_0 given above, we see that

$$C[Z := X + 5]e_0 s_0 = \text{update}(\text{find}(Z, e_0), \mathcal{E}[X + 5]e_0 s_0, s_0) = \text{update}(3, 7, s_0) = \langle 2, 0, 7 \rangle$$

But a crucial point about the meaning of the assignment is that it is a function upon stores. That is, if we are uncertain of the current value of store, but we know that the environment for the assignment is e_0 , then we can conclude

$$C[Z := X + 5]e_0 = \lambda s. \text{update}(3, \text{plus}(\text{lookup}(1, s), 5), s)$$

That is, the assignment with environment e_0 is a function that updates a store at location 3.

Next, consider this example of a command sequence:

$$\begin{aligned} C[Z : X + 5 ; \text{call } P]e_0 s_0 &= \text{check}(C[\text{call } P]e_0, C[Z : X + 5]e_0 s_0) \\ &= \text{check}(\text{find}(P, e_0), \langle 2, 0, 7 \rangle) = \text{check}(\lambda s.s, \langle 2, 0, 7 \rangle) \\ &= (\lambda s.s)\langle 2, 0, 7 \rangle = \langle 2, 0, 7 \rangle \end{aligned}$$

As noted in the earlier section, the *check* operation verifies that the first command in the sequence produces a proper output store; if so, the store is handed to the second command in the sequence. Also, we see that the meaning of *call P* is the store updating function bound to *P* in the environment.

Procedures are placed in the environment by declarations, as we see in this example: let e_1 denote $(X, 1)::(Y, 2)::(Z, 3)::\text{nil}$:

$$\begin{aligned} C[\text{begin proc } P = Y := Y \text{ in } Z := X + 5, \text{call } P \text{ end}]e_1 s_0 & \\ = C[Z := X + 5, \text{call } P](\mathcal{D}[\text{proc } P = Y := Y] e_1) s_0 & \\ = C[Z := X + 5, \text{call } P](\text{bind}(P, C[Y := Y]e_1, e_1))s_0 & \\ = C[Z := X + 5, \text{call } P](\text{bind}(P, \lambda s. \text{update}(2, \text{lookup}(2, s), s), e_1))s_0 & \\ = C[Z := X + 5, \text{call } P]((P, \text{id}) :: e_1) s_0 & \\ \text{where } \text{id} = \lambda s. \text{update}(2, \text{lookup}(2, s), s) = \lambda s.s & \quad (*) \\ = C[Z := X + 5, \text{call } P]e_0 s_0 = \langle 2, 0, 7 \rangle & \end{aligned}$$

The equality marked by (*) is significant; we can assert that the function $\lambda s. \text{update}(2, \text{lookup}(2, s), s)$ is identical to $\lambda s.s$ by appealing to the *extensionality* law of mathematics: if two functions map identical arguments to identical answers, then the functions are themselves identical. The extensionality law can be used here because in denotational semantics the meanings of program phrases are mathematical—functions. In contrast, the extensionality law cannot be used in operational semantics calculations.

Finally, we can combine our series of little examples into the semantics of a complete program:

$$\begin{aligned}
 & \mathcal{P}[\text{begin proc } P=Y:=Y \text{ in } Z:=X+5; \text{ call } P \text{ end.}]2 \\
 &= \mathcal{C}[\text{begin proc } P=Y:=Y \text{ in } Z:=X+5; \text{ call } P \text{ end}]_{\text{init_env}(\text{init_store } 2)} \\
 &= \mathcal{C}[\text{begin proc } P=Y:=Y \text{ in } Z:=X+5; \text{ call } P \text{ end}]_{e, s_0} \\
 &= \langle 2, 0, 7 \rangle
 \end{aligned}$$

69.3.4 Semantics of the While Loop

The most difficult clause in the semantics definition is the one for the while-loop. Here is some intuition: to produce an output store, the loop `while E do C od` must terminate after some finite number of iterations. To measure this behavior, let `whilei E do C od` be a loop that can iterate at most *i* times—if the loop runs more than *i* iterations, it becomes exhausted, and its output is \perp . For example, for input store $\langle 4, 0, 0 \rangle$, the loop `whilek Y not= X do Y:=Y+1 od` can produce the output store $\langle 4, 4, 0 \rangle$ only when *k* is greater than 4. (Otherwise, the output is \perp .)

It is easy to conclude that the family, `whilei E do C od`, for $i \geq 0$, can be written equivalently as

$$\begin{aligned}
 \text{while}_{e_0} E \text{ do } C \text{ od} &= \text{"exhausted"} \text{ (that is, its meaning is } \lambda s. \perp) \\
 \text{while}_{e_{i+1}} E \text{ do } C \text{ od} &= \text{if } E \text{ then } C; \text{ while}_{e_i} E \text{ do } C \text{ od else skip fi}
 \end{aligned}$$

When we refer back to Figure 69.3, we draw these conclusions:

$$\begin{aligned}
 \mathcal{C}[\text{while}_{e_0} E \text{ do } C \text{ od}]e &= w_0 \\
 \mathcal{C}[\text{while}_{e_{i+1}} E \text{ do } C \text{ od}]e &= w_{i+1}
 \end{aligned}$$

Since the behavior of a while loop must be the “union” of the behaviors of the `whilei E do C od`-loops, we conclude that $\mathcal{C}[\text{while } E \text{ do } C \text{ od}]e = \bigcup_{i \geq 0} w_i$. The semantic union operation is well defined because each w_i is a function from the set $\text{Store} \rightarrow \text{Store}_{\perp}$, and a function can be represented as a set of argument-answer pairs. (This is called the *graph of the function*.) So, $\bigcup_{i \geq 0} w_i$ is the union of the graphs of the w_i functions*.

The definition of $\mathcal{C}[\text{while } E \text{ do } C \text{ od}]$ is succinct, but it is awkward to use in practice. An intuitive way of defining the semantics is

$$\begin{aligned}
 \mathcal{C}[\text{while } E \text{ do } C \text{ od}]e &= w \\
 \text{where } w &= \lambda s. \text{ if } \mathcal{E}[E]e \text{ s then } \text{check}(w, \mathcal{C}[C]e \text{ s}) \text{ else } s
 \end{aligned}$$

The problem here is that the definition of w is circular, and circular definitions can be malformed. Fortunately, this definition of w can be claimed to denote the function $\bigcup_{i \geq 0} w_i$ because the following equality holds:

$$\bigcup_{i \geq 0} w_i = \lambda s. \text{ if } \mathcal{E}[E]e \text{ s then } \text{check}\left(\bigcup_{i \geq 0} w_i, \mathcal{C}[C]e \text{ s} \text{ else } s\right)$$

So, $\bigcup_{i \geq 0} w_i$ is a solution—a *fixed point*—of the circular definition, and in fact it is the smallest function that makes the equality hold. Therefore, it is the *least fixed point*.

* Several important technical details have been glossed over. First, pairs of the form (s, \perp) are ignored when the union of the graphs is performed. Second, for all $i \geq 0$, the graph of w_i is a subset of the graph of w_{i+1} ; this ensures the union of the graphs is a function.

Typically, the denotational semantics of the while-loop is presented by the circular definition, and the claim is then made that the circular definition stands for the least fixed point. This is called *fixed-point semantics*. We have omitted many technical details regarding fixed-point semantics; these are available in several texts [15,45,47,51].

69.3.5 Natural Semantics of the Language

We can compare the denotational semantics of the imperative language with a natural semantics formulation. The semantics of several constructions appear in Figure 69.5.

A command configuration has the form $e, s \vdash C \Rightarrow s'$, where e and s are the “inputs” to command C and s' is the “output.” To understand the inference rules, read them “bottom up.” For example, the rule for $I:=E$ says, given the inputs e and s , one must first find the location, l , bound to I and then calculate the output, n , for E . Finally, l and n are used to update s , producing the output.

The rules are denotational-like, but differences arise in several key constructions. First, the semantics of a procedure declaration binds I not to a function but to an environment-command pair called a *closure*. When procedure I is called, the closure is disassembled, and its text and environment are executed. Since a natural semantics does not use function arguments, it is called a *first-order semantics*. (Denotational semantics is sometimes called a *higher-order semantics*.)

Second, the while-loop rules are circular. The second rule states, in order to derive a while-loop computation that terminates in s'' , one must derive (1) the test, E is true, (2) the body, C , outputs s' , and (3) using e and s' , one can derive a terminating while-loop computation that outputs s'' . The rule makes one feel that the while-loop is “running backwards” from its termination to its starting point, but a complete derivation, like the one shown in Figure 69.6, shows that the iterations of the loop can be read from the root to the leaves of the derivation tree.

$$\begin{array}{c}
 \frac{e \vdash \text{proc } I = C \Rightarrow \text{bind}(I, (e, C), e) \quad \frac{e \vdash D \Rightarrow e' \quad e', s \vdash C \Rightarrow s'}{e, s \vdash \text{begin } D \text{ in } C \text{ end} \Rightarrow s'}}{e, s \vdash \text{begin } D \text{ in } C \text{ end} \Rightarrow s'} \\
 \frac{l = \text{find}(V, e) \quad e, s \vdash E \Rightarrow n \quad \frac{e, s \vdash C_1 \Rightarrow s' \quad e, s' \vdash C_2 \Rightarrow s''}{e, s \vdash C_1; C_2 \Rightarrow s''}}{e, s \vdash V : E \Rightarrow \text{update}(l, n, s)} \\
 \frac{(e', C') = \text{find}(I, e) \quad e', s \vdash C' \Rightarrow s' \quad \frac{e, s \vdash E \Rightarrow \text{false}}{e, s \vdash \text{while } E \text{ do } C \text{ od} \Rightarrow s}}{e, s \vdash \text{call } I \Rightarrow s'} \\
 \frac{e, s \vdash E \Rightarrow \text{true} \quad e, s \vdash C \Rightarrow s' \quad e, s' \vdash \text{while } E \text{ do } C \text{ od} \Rightarrow s''}{e, s \vdash \text{while } E \text{ do } C \text{ od} \Rightarrow s''}

 \end{array}$$

FIGURE 69.6 Natural semantics derivation.

One important aspect of the natural semantics definition is that derivations can be drawn only for terminating computations. A nonterminating computation is equated with no computation at all.

69.3.6 Operational Semantics of the Language

A fragment of the structural operational semantics of the imperative language is presented in Figure 69.7. For expressions, a computation step takes the form $e \vdash \langle E, s \rangle \Rightarrow E'$, where e is the environment, E is the expression that is evaluated, s is the current store, and E' is E rewritten. In the case of a command, C , a step appears $e \vdash \langle C, s \rangle \Rightarrow \langle C', s' \rangle$, because computation on C might also update the store. If the computation step on C “uses up” the command, the step appears $e \vdash \langle C, s \rangle \Rightarrow s'$.

The rules in the figure are more tedious than those for a natural semantics, because the individual computation steps must be defined, and the order in which the steps are undertaken must also be defined. This complicates the rules for command composition, for example. On the other hand, the rewriting rule for the while-loop merely decodes the loop as a conditional command.

The rules for procedure call are awkward; as with the natural semantics, a procedure, I , is represented as a closure of the form (e', C') . Since C' must execute with environment, e' , which is different from the environment that exists where procedure I is called, the rewriting step for `call I` must retain *two* environments; a new construct, `use e' in C'` , remembers that C' must use e' (and not e). A similar trick is used in `begin D in C end`.

Unlike a natural semantics definition, a computation can be written for a nonterminating program; the computation is a state sequence of countably infinite length.

69.3.7 Axiomatic Semantics of the Language

An axiomatic semantics computes upon *properties* of stores because programs are understood as “knowledge transformers.” For example, the property $X = 3 \wedge Y > X$ asserts knowledge about the values of X and Y (namely, the store holds 3 at X ’s location and a number in Y ’s location that is even larger). The meaning of a command, C , is stated in terms of configurations of form, $\{P\} C \{Q\}$, stating that, if predicate (knowledge) P holds true then C generates knowledge Q upon termination (if C does indeed terminate). For example, all of these configurations are true assertions of the command, `$X := X + 1$` : (1) $\{X > 2\} X := X + 1 \{X > 3\}$; (2) $\{Y > X\} X := X + 1 \{Y > X - 1\}$; (3) $\{X = 3 \wedge Y > X\} X := X + 1 \{X = 4 \wedge Y > X - 1\}$.

Figure 69.8 displays the rules for the primary command constructions. The rule for `$I := E$` states that an assignment transforms knowledge about E into knowledge about E ’s “new name,” I . (To understand

 \frac{\frac{P \supset P' \quad \{P'\} C \quad \{Q\} \quad Q' \supset Q \quad \{P\} C_1 \quad \{Q\} C_2 \quad \{R\}}{\{P\} C \quad \{Q\}} \quad \frac{\{E/I\} P \quad I := E \quad \{P\}}{\{P\} C_1; C_2 \quad \{R\}}}{\{P \wedge E\} C_1 \quad \{Q\} \quad \{P \wedge \neg E\} C_2 \quad \{Q\}} \quad \frac{\{P \wedge E\} C \quad \{P\}}{\{P\} \text{ if } E \text{ then } C_1 \text{ else } C_2 \text{ fi } \{Q\}} \quad \frac{\{P\} \text{ while } E \text{ do } C \text{ od } \{P \wedge \neg E\}}
 \end{array}$$

FIGURE 69.8 Axiomatic semantics inference rules.

this, recall that $[E/I]P$ stands for the substitution of E for all free occurrences of I in P . For example, $[Y + 1/X](X > 3)$ is $Y + 1 > 3$. We can use the rule to prove that $X := X + 1$ transforms $X + 1 > 3$ into $X > 3$, that is, $\{X + 1 > 3\} X := X + 1 \{X > 3\}$. Again, $I := E$ transforms knowledge about E into knowledge about E 's "new name," I .

The second rule in the figure uses logical implication to deduce new knowledge; we deduce that $\{X > 2\} X := X + 1 \{X > 3\}$, because $X + 1 > 3$ implies $X > 2$. The properties of command composition are defined by the third rule: knowledge generated by command C_1 passes to command C_2 .

The fourth rule, for the if-command, shows how to make a property hold upon termination regardless of which arm of the conditional is evaluated. For example, the rule proves $\{X \neq 0\} \text{ if } X < 0 \text{ then } Y := -X \text{ else } Y := X \text{ fi } \{Y > 0\}$, because knowledge from the test, $X < 0$, lets us prove both $\{X < 0 \wedge X \neq 0\} Y := -X \{Y > 0\}$ and also $\{\neg(X < 0) \wedge X \neq 0\} Y := X \{Y > 0\}$.

The most fascinating rule is the last one, for $\text{while } E \text{ do } C \text{ od}$. The loop's body, C , is "repeatable code," which means whatever knowledge, I , is required to *use* C must be regenerated to *reuse* C — $\{E \wedge I\} C \{I\}$! I is called an *invariant* because it remains true for all the repetitions of the loop. We conclude that I holds true if and when the loop terminates.

Another viewpoint is that a loop is kind of "game" played in rounds. If C lists the moves taken in one round, then the invariant, I , is the strategy one uses to "keep the lead" and eventually win. The game ends when the loop's test, E , goes false.

Here is an example: We play a pebble game, where pebbles can be moved only one at a time. There are two boxes of pebbles, named X and Y . To win the game, all the pebbles must be moved into Y 's box without losing any. Here is how we might play one round of the game: $X := X - 1; Y := Y + 1$. Our strategy is encoded by the invariant, $\text{TOTAL} = X + Y$, which says that we do not lose any pebbles when we move them:

$$\{ \text{TOTAL} = X + Y \} X := X - 1; Y := Y + 1 \{ \text{TOTAL} = X + Y \}$$

The completed game is this loop program, $\text{while } X \text{ not} = 0 \text{ do } X := X - 1; Y := Y + 1 \text{ od}$, and the proof that the loop generates a victory is listed in Figure 69.9, which shows at the end that $\text{TOTAL} = Y$, that is, all the pebbles rest in Y 's box. The derivation is difficult to read, but when reformatted vertically, as seen in the right half of the figure, it shows clearly how the input knowledge, $\text{TOTAL} = X + Y$, is transformed into the output knowledge, $\text{TOTAL} = Y$.

The key to building the proof is determining a loop invariant. Since the goal was to prove $\text{TOTAL} = Y$, this made $\text{TOTAL} = X + Y$ useful, because $X := X - 1$ eventually lowers X to zero.* With the invariant in hand, it is easy to work backwards, from the end of the loop body, to the top, to calculate that the loop body is indeed "repeatable code": The rule for assignment proves both $\{ \text{TOTAL} = X + (Y + 1) \} Y := Y + 1 \{ \text{TOTAL} = X + Y \}$, and also $\{ \text{TOTAL} = (X - 1) + (Y + 1) \} X := X - 1 \{ \text{TOTAL} = X + (Y + 1) \}$. Finally, $\text{TOTAL} = (X - 1) + (Y + 1)$ implies $\text{TOTAL} = X + Y$.

* The loop terminates only if X 's value begins as a nonnegative. The laws in Figure 69.8 *do not guarantee termination*. This requires additional logical machinery.

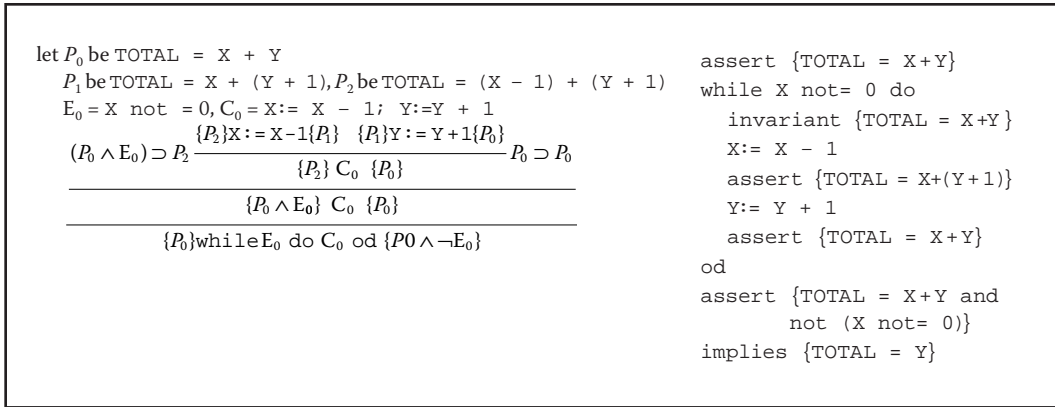

FIGURE 69.9 Axiomatic semantics derivation.

There are three ways of stating the semantics of a command in an axiomatic semantics:

1. Relational semantics: The meaning of C is the set of P, Q pairs for which $\{P\} C \{Q\}$ holds. Termination is not demanded of C. (This is called “partial correctness.”)
2. Postcondition semantics: The meaning of C is a function from an input predicate to an output predicate. We write $slp(P, C)=Q$; this means that $\{P\} C \{Q\}$ holds, and for all Q' such that $\{P\} C \{Q'\}$ holds, it is the case that Q implies Q'. This is also called *strongest liberal postcondition semantics*. When termination (“total correctness”) is demanded also of C, the name becomes *strongest postcondition semantics*.
3. Precondition semantics: The meaning of C is a function from an output predicate to an input predicate. We write $wlp(C, Q)=P$; this means that $\{P\} C \{Q\}$ holds, and for all P' such that $\{P'\} C \{Q\}$ holds, it is the case that P' implies P. This is also called *weakest liberal precondition semantics*. When termination is demanded also of C, the name becomes *weakest precondition semantics*.

69.4 Practical Impact

Research on programming-language semantics showed how a language can be defined precisely, its correctness properties proved, and its implementation realized. Indeed, the area of *formal methods* (cf. Chapter 116) is an adaptation of the semantics methods from computer languages to computer programs—how a program can be specified precisely, its correctness properties proved, and its specification implemented.

Operational semantics, having the longest life of the semantic approaches, is most entrenched within software development. From operational semantics came virtual machines to which languages can be translated. Definitional interpreters are now the norm for prototyping new languages, especially “little” or “domain-specific” languages, which are designed for problem solving in a limited application domain, for example, file-linking (Make), web-page layout (HTML), spreadsheet layout (Excel), or linear algebra (MATLAB). Scripting languages (see Chapter 110) are also implemented in definitional-interpreter style.

Axiomatic semantics has undergone a significant revival, not only as the starting point for specification writing and verification in formal-methods work, but as the language for description and analysis of secure and safety-critical software systems, where correctness properties, above all, must be stated so that there can validation or justification, whether by testing, monitoring, or theorem proving. Indeed, the object control language (OCL) used in the Unified Modelling Language for software blueprinting is a derivative of the classic axiomatic semantics notation. (See Volume 2 of this handbook.) A wide variety of *proof assistants* and *logical frameworks* are available for helping a designer state and validate crucial properties of software, for example, ACL2 [24], PVS [38], Isabelle/HOL [35], and Coq [41].

The primary impact of denotational semantics has been to the design of modern programming languages. The modelling of programming constructions as functions that operate on storage motivated many designers to add such functions as primitive constructions to the programming language itself—the results are (1) *higher-order* constructions, such as the anonymous functions in ML and Java; (2) generic and *polymorphic* constructions, such as class templates in C++ and Scala; and (3) *reflective constructions*, like that found in JavaBeans and 3-Lisp. The importance of polymorphic constructions to modern-day software assembly has stimulated extensions of denotational semantics into “higher-order” formats that are expressed within *type theory* [39,36].

Within the subarea of programming-languages research, the semantics methods play a central role. Language designers use semantics definitions to formalize their creations, as was done during the development of Ada [10] and after development for Scheme [43] and Standard ML [27]. Software tools are readily available to prototype a syntax-plus-semantics definition into an implementation [5,8,26,31].

A major success of formal semantics is the analysis and synthesis of data-flow analysis and type-inference algorithms from semantics definitions. This subject area, called *abstract interpretation* [3,7,33], uses algebra techniques to map semantic definitions from their “concrete” (execution) definition to their “abstract” (homomorphic property) definition. The technique can be used to extract properties from the definitions, generate data flow and type inference, and prove program correctness or code-improvement transformations. Most automated methods for program validation use abstract interpretation.

69.5 Research Issues

The techniques in this chapter have proved successful for defining, improving, and implementing sequential programming languages. But new language and software paradigms present new challenges to the semantics methods.

Challenging issues arise in the object-oriented programming paradigm. Not only can objects be arguments (“messages”) to other objects’ procedures (“methods”), but coercion laws based on *inheritance* allow controlled mismatches between arguments and parameters. For example, an object argument that contains methods for addition, subtraction, and multiplication is bound to a method’s parameter that expects an object with just addition and subtraction methods. Carelessly defined coercions lead to unsound programs, so semantics definitions must be extended with inheritance hierarchies [16,40]. See Chapter 107 for details.

Yet another challenging topic is defining communication as it arises in distributed programming, where multiple processes (threads of execution) synchronize through communication. Structural operational semantics has been adapted to formalize such systems. More importantly, the protocol used by a system lies at the center of the system’s semantics; semantics approaches based on *process algebra* [12,20,28] have been developed that express a protocol as a family of simultaneous algebra equations that must be “solved” to yield a convergent solution. See Chapter 12.

A current challenge is applying semantics methods to define and explain programs that exploit the architecture of multicore processors, where subcomputations and their storage requirements must be allocated to processor cores and their associated cache hierarchy [18]. See Chapter 34 for background.

Finally, a longstanding crucial topic is the relationship between different forms of semantic definitions: If one has, say, both a denotational semantics and an axiomatic semantics for the same programming language, in what sense do the semantics agree? Agreement is crucial, since a programmer might use the axiomatic semantics to reason about the properties of programs, whereas a compiler writer might use the denotational semantics to implement the language. This question generalizes to the problem of *refinement* of software specifications—see Chapter 116. In mathematical logic, one uses the concepts of *soundness* and *completeness* to relate a logic’s proof system to its interpretation, and in semantics there are similar notions of *soundness* and *adequacy* to relate one semantics to another [15,37]. Important as these properties are, they are quite difficult to realize in practice [1].

Key Terms

Axiomatic semantics: The meaning of a program as a property or specification in logic.

Denotational semantics: The meaning of a program as a compositional definition of a mathematical function from the program's input data to its output data.

Fixed-point semantics: A denotational semantics where the meaning of a repetitive structure, like a loop or recursive procedure, is expressed as the smallest mathematical function that satisfies a recursively defined equation.

Loop invariant: In axiomatic semantics, a logical property of a while-loop that holds true no matter how many iterations the loop executes.

Natural semantics: A hybrid of operational and denotational semantics that shows computation steps performed in a compositional manner. Also known as a "big-step semantics."

Operational semantics: The meaning of a program as calculation of a trace of its computation steps on input data.

Strongest postcondition semantics: A variant of axiomatic semantics where a program and an input property are mapped to the strongest proposition that holds true of the program's output.

Structural operational semantics: A variant of operational semantics where computation steps are performed only within prespecified contexts. Also known as a "small-step semantics."

Weakest precondition semantics: A variant of axiomatic semantics where a program and an output property are mapped to the weakest proposition that is necessary of the program's input to make the output property hold true.

Further Information

The best starting point for further reading is the comparative semantics text of Nielson and Nielson [34], which thoroughly develops the topics in this chapter. See also the texts by Slonneger and Kurtz [46] and Watt [50].

Operational semantics has a long history; modern introductions are Hennessey's text [17] and Plotkin's report on structural operational semantics [42]. The principles of natural semantics are documented by Kahn [23]. A good example of the interpreter-based approach to semantics is the text by Friedman et al. [13].

Mosses's paper [32] is a useful introduction to denotational semantics; textbook-length treatments include those by Schmidt [45], Stoy [47], Tennent [48], and Winskel [51]. Gunter's text [15] uses denotational-semantics-based mathematics to compare several of the semantics approaches. Pierce [39] and Mitchell [29] provide foundational supporting material.

Of the many textbooks on axiomatic semantics, one might start with books by Dromey [11] or Gries [14]; both emphasize precondition semantics, which is most effective at deriving correct code. Apt's paper [2] is an excellent description of the formal properties of relational semantics, and Dijkstra's text [9] is the standard reference on precondition semantics. Hoare's landmark papers on relational semantics [19,21] are worth reading as well. Many texts have been written on the application of axiomatic semantics to systems development; two samples are by Jones [22] and Morgan [30].

70.1 Introduction

Many modern programming languages come equipped with *type systems*, which ensure that programs are free from certain classes of execution errors. For example, type systems prevent buffer overruns, invalid code execution, and memory accesses to protected data. In general, type systems describe invariants that all programs must satisfy. They are a valuable component for program development, assisting in the creation of correct, secure, and robust systems.

In this chapter, we introduce research in the design of *safe* programming languages with *static type systems*. In such languages, a tool known as a *type checker* verifies that a program *type checks* before it may be compiled or interpreted. Languages are *safe* when they ensure that no untrapped errors are possible at runtime. Safety is guaranteed in statically typed languages by a *type soundness* theorem that ensures that all *well-typed* programs do not “go wrong.” Languages can be statically typed but unsafe when this theorem does not hold, that is, when the process of type checking does not provide firm guarantees about execution. Languages can be safe but dynamically typed when they rule out errors by runtime monitoring instead of compiletime type checking.

The development of safe, statically typed languages is an area of active research. There are many different ways to type programs. The analysis required to claim type soundness requires precision and

close attention to detail. Language designers must balance the expressiveness of the type system (which allows it to certify more safe programs) with the complexity of the type soundness proof (any flaw in which could invalidate the entire enterprise).

This chapter provides an overview of that field and examines the following questions: Why do languages check types during compilation? What are the components of a type system? How do language researchers describe and formalize type systems? What are their important properties? What are the limitations of static type checking? What are some of the current areas of type systems research?

This chapter is intended for *students* and *researchers* as an entry point to the study of type systems. Because of the richness of this field and the variety in the design of languages, the goal of this chapter is breadth, not depth. As a result, only the most basic type systems receive the most rigorous mathematical treatment—many topics are covered at an overview level, leaving full discussion to referenced sources.

This chapter is also aimed at *programmers* and *language designers*. Type systems are powerful tools for software development, providing assistance in the challenging task of developing and maintaining correct systems. A secondary goal of this chapter is an appreciation of this power and an understanding of how it may be put to use.

Because the mathematical models that we present here are most similar to the type systems of functional programming languages, this chapter assumes basic experience with languages such as Haskell and ML and draws on examples from those languages. Furthermore, it requires some background in mathematical reasoning, including the knowledge of functions, sets and relations, bound and free variables, the presentation of programming language abstract syntax, and the principle of mathematical induction.

The remainder of this section introduces static type systems by motivating their inclusion in the definitions of programming languages. It is followed by a discussion of what makes a good static type system through a listing of evaluation properties for their design. This description of the concepts and ideas behind static typing is deliberately kept at an informal level.

Section 70.2 introduces the formal notation and mathematical concepts necessary for working with and analyzing type systems. The key components of a type system definition are *judgments*, which assert relationships such as “this program has that type,” *derivations*, which provide evidence for the truth of those assertions, and *typing rules*, which are the building blocks of derivations. We introduce the components of modern type systems gradually, building up the vocabulary of structures and relationships piece-by-piece. Section 70.3 uses a core type system, called System F, to demonstrate mathematical reasoning about type systems. This section walks through the type soundness theorem and also discusses the principle of parametricity. Section 70.4 concludes the technical discussion with an overview of type inference, the problem of determining whether a program should type check given limited type annotations. Section 70.5 concludes with references for future study and a list of defining terms.

70.1.1 What Are Type Systems Good For?

A *safe* language is one that does not admit untrapped errors. For example, a buffer overrun in C might not be detected at runtime. If one occurs, the behavior of the program is unspecified. Untrapped errors are an insidious form of execution error because they go unnoticed. As a result, they are a significant source of security vulnerabilities in computer systems. In contrast, trapped errors are permitted in safe languages. For example, most safe languages check that array accesses are in bounds at run time and stop the current computation immediately if the check fails.

A *dynamically typed language* is one that uses only runtime checks to ensure safety. These languages are safe even though they do not have a type system or employ a type checker. The advantage of these

languages is simplicity and expressiveness. They have a gentle learning curve because there is no type system that new programmers must learn. Furthermore, they allow some programming patterns that statically typed languages reject because static type checking must approximate program execution and sometimes rules out code that does not trigger run-time failures.

There has been much debate over whether languages should be safe, and if they are, whether they should be dynamically or statically typed. Ultimately, these debates balance trade-offs between expressiveness, performance, development time, maintenance time, and security. Although the choice of implementation language is often determined by economic and social factors, the technical arguments in favor of statically typed languages include the following points.

- *Eliminating bugs and execution errors at compile time*

The primary purpose of static type systems is compile-time certified safety. Type systems rule out unsafe code by assigning a type to every form of data value and operation in the language, and then ensuring that operations are only applied to the right types of values. In this sense, types are interfaces. They specify the capabilities of data values, and restrict their use to compatible operations.

For example, boolean values should not be the arguments to numeric operations. A program containing the expression `true + 3` is sure to be buggy. Furthermore, this bug may not be detected at runtime if after compilation boolean and numeric values have the same machine representation. A sound, static type system can ensure that only numbers are ever added together during the course of execution and detect such bugs when the program is compiled.

- *Making distinctions between values*

The distinction between boolean and numeric values given earlier is part of the language definition. However, experienced programmers use static type systems to make application-specific data distinctions. For example, a programmer may use integer values as error codes to indicate run-time failures in a system.

0	SUCCESS
1	INVALID_FUNCTION
2	FILE_NOT_FOUND
3	PATH_NOT_FOUND
4	TOO_MANY_OPEN_FILES

However, not all integer values may have an associated error code. What does error code-41 mean?* What does it mean to add error codes together? When a function or method returns an integer, when should that integer be interpreted as an error code?

Languages that support enumerations or algebraic datatypes permit users to define new types containing only specified values. That way the type system can prevent error codes from being the argument to arithmetic operations. Functions that return error codes have different types from those that return integers, maintaining this distinction.

- *Information hiding and modularity*

Static types also provide information hiding through type abstraction. Because types specify the interfaces of data structures, they govern how client code must interact with that data. If that interface includes an abstract type, library implementors are free to make changes in the representation of a data structure as long as the interface is still satisfied.

* See <http://xkcd.com/1024/>.

For example, a data structure library might export an abstract type of sets of integers, as well as operations to construct and manipulate values of that type. In the OCaml language, this interface could be defined as follows:

```
module type SET =
  type set
  val empty : set
  val insert : int -> int set -> int set
  val contains : int set -> boolean
end
```

This interface does not specify how sets are represented. As a result, the library implementor is free to choose ordered lists, balanced trees, or any other implementation. Furthermore, this implementation can be replaced without invalidating code that uses this interface.

This interface also allows modular reasoning about the correctness of the implementation. Because the type of sets is abstract, the implementor knows that any set that is passed to the `contains` function must have been created by this module. Therefore, preserving invariants about the set implementation requires reasoning only about a single module, not the entire program.

- *Expressive code reuse*

Although code in dynamically typed languages is often naturally applicable to many situations, *polymorphism* provides a strong mechanism for statically typed languages to create and mark reusable code. A polymorphic function or method is one that works on many different types of arguments—this behavior is safe because the function is required to use those arguments only in ways that do not violate the capabilities specified by their types.

For example, *subtype polymorphism* allows functions to specify minimum requirements about the capabilities of their arguments. Any argument that provides at least the required functionality may be passed to such a function. Subtyping is common in object-oriented languages, where one object type is a subtype of another if it supports at least the same methods. For example, an object that has both a `reset` and a `move` method may be passed to a function that only calls the `move` method of its argument.

Similarly, *parametric polymorphism* (also called *generics*) allows the interfaces to functions to include type parameters. For example, the filter function, which preserves only the elements of a list that satisfy a given predicate, can be given a parametric type:

```
val filter : ('a -> bool) -> 'a list -> 'a list
```

This type indicates that the function can be used with any type of list—the parameter `'a` can be instantiated with any type. However, this type must be instantiated consistently, the supplied predicate must be compatible with the input list, and the type of the resulting list must be same as the input.

Finally, *ad hoc polymorphism* or *type-directed programming* uses types as metadata to define reusable code. This feature is a form of reflection where execution is determined by type information. A simple, powerful form of type-directed programming is *overloading*—where the types of the arguments to a function determine how the function executes. For example, the Haskell language supports overloading through the use of *type classes*, providing uniform access to operations for serialization, equality, and traversals, as well as algebraic structures such as monoids, functors and monads. Furthermore, Haskell also supports many flavors of *datatype-generic programming* [24], which automates the creation of these overloaded functions by analyzing the structure of datatypes.

- *Code documentation and maintenance*

Types and interfaces provide documentation for software artifacts. As opposed to comments, they are mechanically checked for correctness, so they can never become out-of-date. Furthermore, in languages that support *type inference*, this documentation can automatically be generated for each program fragment. As such, it is documentation that does not need to be maintained or written, but is available on demand.

Furthermore, static types assist with code maintenance and refactoring. For example, when programmers change the representation of some data structure, the type system identifies all parts of the program that must be updated with respect to this modification. The programmer need not search by hand nor worry about missing modification sites. Each site will produce a type error when the structure of the data does not match what was provided. Tools such as IDEs can take advantage of type information to support code development and refactoring.

70.1.2 What Are Good Type Systems?

How can we ensure that static type systems live up to their promises? To ensure that type systems provide the benefits discussed earlier, researchers evaluate the quality of type system designs using the following criteria. The following list includes a brief description of each desirable property as well as forward references to discussion of how it may be formally evaluated.

1. Type systems should *eliminate program errors* by ruling out executions that are not consistent with the semantics of the programming language. Formally, the type soundness theorem (Section 70.3.2) provides this assurance.
2. Type systems should be *expressive*, capable of statically describing common data structures and the relationships between program values. Programmers should have a rich vocabulary with which to express the invariants of their code. Type systems should have minimal reliance on runtime checks to ensure safety. Section 70.2 provides an overview of the components of expressive type systems.
3. Type systems should be *modular*. The definitions of values should be checkable independent of their uses and types should provide precise interfaces that govern interaction between different parts of the program. Modular type checking is primitively enabled through the use of typing environments, introduced in Section 70.2.2. Type abstraction, described in Section 70.2.6 enhances this interface by hiding implementation details.
4. Type systems should be *informative* about the semantics of programs. The type soundness property gives some of this information—an expression of type τ evaluates to a value of the same type τ . Going further, Section 70.3.3 uses types as the basis for an equivalence relation between programs, especially in the presence of type abstraction.
5. Type systems should be *effectively checkable* and *predictable*. There should be an algorithm that determines whether a program type checks. Developers should be able to understand why their programs type check and know what program transformations preserve typability. Section 70.2.3 describes the design of annotations that derive simple type checking algorithms. Section 70.4 discusses more sophisticated algorithms that use constraint solving to infer type information that is not explicitly present.

Although we have discussed these properties informally, we can evaluate them rigorously. Such treatment requires a mathematical model of programming languages and their type systems. In the next section, we introduce the notation and tools that are commonly used for this analysis.

70.2 Formal Type Systems

Programming languages are large, complicated artifacts, so it is difficult to design and analyze their type systems wholesale. As a result, programming language researchers have developed tractable mathematical models of languages, and it is the type systems of these formal models that is the

topic of study. By defining a model that captures the essence of computation, we can carefully understand its semantics and evaluate its properties.

The language of the formal model of type systems derives from *formal proof systems*. A proof system is a system of *inference rules* that can be used to show that a program has a specific type by constructing a typing *derivation* for a particular typing *judgment*. Learning to understand this language means that type systems can be understood as mathematical specifications, without the need to read the source code of a particular compiler.

Additionally, many type systems specified in this manner are *declarative*, in that they define valid programs without determining a particular type checking algorithm. Having a declarative specification means that formal type systems are part of the language definition: they state what good programs are, in the simplest terms possible, leaving compilers the freedom to implement these specifications in the most appropriate manner.

Furthermore, these formal models provide the basis for the *metatheory* of a programming language—the properties that can be mathematically proven about the language and all its programs. Section 70.3 discusses a few of these properties in detail and describes the mathematical techniques that researchers use for these proofs.

However, the rest of this section discusses what type systems *are* before going into depth about their mathematical properties. It starts with the simplest of languages—arithmetic expressions only—and then introduces new features and type system capabilities incrementally. Understanding these individual features provides insight into their semantics as they occur in the context of full languages.

70.2.1 Arithmetic Expressions

We introduce this mathematical language of type systems with an extremely simple example, that of arithmetic expressions. An arithmetic expression is either a natural number value, such as 0, 1 or 2, a boolean value **true** or **false**, or a binary operator applied to two arguments. For further simplicity, this language only includes operators for addition, subtraction, and equality. Yet, even in this simple language there are expressions, such as $1 + \mathbf{true}$, that the type system should rule out.

The abstract syntax of this language can be described by the following table, presented in Backus-Naur Form (BNF). We use the metavariable n for numeric values, b for boolean values, op for operators, and e for expressions.* We use metavariables consistently—the variable n always stands for a number and e always stands for an expression. If we need to refer to more than one expression at a time, we use primes (e' or e'') and subscripts (e_1 or e_2) to indicate different metavariables.

Numeric values include all natural numbers (not shown in the table but indicated by ...). Boolean values only for equality testing include **true** and **false**. The operator symbols include $+$ for addition $-$ for subtraction and \equiv for equality testing. Finally, we combine these in expressions, which are literal values, an infix operator applied to two arguments, or an **if** expression:

$$\begin{aligned} n &\in \{0, 1, 2, \dots\} \\ b &::= \mathbf{false} \mid \mathbf{true} \\ op &::= + \mid - \mid \equiv \\ e &::= n \mid b \mid e_1 \ op \ e_2 \mid \mathbf{if} \ e_1 \ \mathbf{then} \ e_2 \ \mathbf{else} \ e_3 \end{aligned}$$

Note that this grammar does not specify how to parse arithmetic expressions, only how to represent them. In particular, the abstract syntax does not include parentheses, but we often use them in examples for disambiguation. For example, $(1 + 2) \equiv 3$ is an expression of this language.

* Expressions are also called *terms*.

The syntax of types is defined similarly, again using BNF. All valid expressions in this language have one of two types—they are either numbers or booleans:

$$\tau ::= \mathbf{nat} \mid \mathbf{bool}$$

We can capture the relationship between expressions and their types by defining a logical *judgement*, which asserts that “expression e has type τ .” This judgment has the following form, starting with a *typing context* Γ and a turnstile* and then putting a colon between the expression and its type:

$$\Gamma \vdash e : \tau$$

Typing contexts, also called *typing environments*, contain assumptions that can be used for type checking. In this simple language, the typing environment plays no role. We include it here to prepare for future extensions (see Section 70.2.2). For now, the syntax of typing contexts includes only the empty context:

$$\Gamma ::= \varepsilon$$

In general, typing judgments often have the form $\Gamma \vdash \mathfrak{J}$, where Γ is a typing environment and \mathfrak{J} is an assertion like “ $e:\tau$.”

Like propositions in logic, particular judgments can be valid or invalid. For example the judgment $\Gamma \vdash 1 + \mathbf{true}:\mathbf{bool}$ is invalid. The expression $1 + \mathbf{true}$ does not evaluate to a boolean value, so it should not have this (or any other) type. To tell whether a judgment is valid, type systems include *rules* that can be used to *derive* only valid judgments. When a judgment $\Gamma \vdash \mathfrak{J}$ is valid, we say that Γ *entails* \mathfrak{J} . The derivation is the justification or proof of the validity of the judgment (and implies the validity of the typing context Γ).

The type system of the arithmetic language includes six *inference rules*, as shown in Figure 70.1. The rules E_NV and E_BV assign the types **nat** and **bool** to natural number and boolean values, respectively. For operator expressions, the rules E_OP and E_EQ require that the two arguments have the appropriate

$$\begin{array}{c}
 \boxed{\Gamma \vdash e : \tau} \\
 \\

types for the operator. The rule E_IF requires the argument of an **if**-expression to be a boolean expression and the two branches to have equal types.

The last rule of the figure, rule C_EMP , is for an auxiliary judgment that determines only that the typing context itself is *well formed*. Because typing contexts are trivial in this language, this single rule merely states that the empty context is valid. As we extend the type system, we will extend this and other judgments with additional rules.

In general, an inference rule contains two parts divided by a horizontal line. To the right of the rule is its name, for easy reference. Often, a naming convention indicates the form of the judgment in the *conclusion* of the rule (below the line). For example, four rules in Figure 70.1 start with $E_$ to indicate that they derive judgments about the types of expressions, whereas the single rule for typing contexts starts with $C_$.

The *premises* of a typing rule appear above the line. These judgments must hold before the rule can be applied. A typing rule can have zero, one or many premises. All must be valid for the rule to apply. The premises of a rule need not have the same form as in the conclusion of the rule. For example, the rules E_NV and E_BV include premises for the judgment $\Gamma \vdash \diamond$ even though they derive the types of expressions. Other premises may be simple logical facts, such as the rule E_OP that explicitly declares the set of valid operators for that rule with the premise $op \in \{+, -\}$.

Rules are schematic templates that can be put together to form *typing derivations*, evidence that a particular program type checks. A derivation is a tree of judgments, where the root of the tree (at the bottom) is the final conclusion of the derivation. Each step of the derivation must be an instance of one of the typing rules, where the metavariables of the rule have been replaced with concrete types, expressions, operators, and contexts.

For example, we can construct the derivation that, using an empty typing context ε , the expression $(1 + 2) \equiv 3$ has type **bool**. We write this judgment as $\varepsilon \vdash (1 + 2) \equiv 3 : \mathbf{bool}$. The last step of the derivation concludes this judgment using the rule E_EQ by satisfying all of the premises of that rule. Each of those premises also satisfy their premises and so on, until in each case reaching the rule C_EMP , which has no premises:

$$\frac{\frac{\frac{\frac{}{C_EMP}}{\varepsilon \vdash \diamond}}{E_NV} \quad \frac{\frac{}{C_EMP}}{\varepsilon \vdash \diamond}}{E_NV} \quad \frac{\frac{}{C_EMP}}{\varepsilon \vdash \diamond}}{E_NV}}{\varepsilon \vdash 1 : \mathbf{nat} \quad \varepsilon \vdash 2 : \mathbf{nat}} \quad E_OP \quad \frac{\frac{}{C_EMP}}{\varepsilon \vdash \diamond}}{E_NV}}{\varepsilon \vdash 1 + 2 : \mathbf{nat} \quad \varepsilon \vdash 3 : \mathbf{nat}} \quad E_EQ$$

$$\frac{}{\varepsilon \vdash (1 + 2) \equiv 3 : \mathbf{bool}}$$

This derivation is complete because the rule used at the leaves (at the top of the tree) has no premises. Rules with no premises are called *axioms*. Each line in the tree corresponds to the usage of a rule. Note that the rules constrain how the derivation can be formed. The rule E_OP requires that the types of the subexpressions both be **nat**. Likewise, rule E_EQ requires that both subexpressions have the same type, but it does not fix what that type must be.

A *type system* is the entire set of rules necessary for creating derivations. In the arithmetic language, it includes all of the rules that conclude $\Gamma \vdash e : \tau$ as well as all of those for $\Gamma \vdash \diamond$.

Programs that have typing derivations are considered *typeable*, or *well formed*. Those that do not are *untypeable*. There may be multiple derivations that assign a type to an expression and an expression may be typeable with more than one type. The rules of a *syntax-directed* type system directly specify an algorithm for determining whether an expression should type check (see Section 70.2.3). In such a type system, each expression has at most one typing derivation.

70.2.2 Assumptions and Functions

The language above does not include many of the most important features of programming languages. In this and the next few subsections, we gradually extend our vocabulary of type systems to develop a more convincing model of computation.

The syntax of the language of this subsection is the same as before, extended with three new expression forms. These forms are variables x , anonymous functions $\lambda x.e$, and applications $e_1 e_2$. These three forms are listed in the last line of the following syntax table:

$$\begin{aligned}
 n & ::= 0, 1, 2, \dots \\
 b & ::= \mathbf{false} \mid \mathbf{true} \\
 op & ::= + \mid - \mid \equiv \\
 e & ::= n \mid b \mid e_1 op e_2 \mid \mathbf{if } e_1 \mathbf{ then } e_2 \mathbf{ else } e_3 \\
 & \quad \mid x \mid \lambda x.e \mid e_1 e_2
 \end{aligned}$$

These new additions are taken from the λ -calculus, a simple model of computation developed by the logician Alonzo Church in the 1930s to investigate the foundations of mathematics. Because of its foundational nature, researchers often use it for the basis of formal study of programming languages. Here we study a typed version of the λ -calculus, called the *simply-typed lambda calculus* or STLC.

The definition of STLC relies on a number of standard definitions from the theory of the λ -calculus, which appear in many textbooks on programming languages and logic [2]. These definitions include the definition of free and bound variables, the definition of capture-avoiding substitution (where $[e'/x]e$ stands for the replacement of the free variable x with the expression e' in the expression e) and the definition of α -equivalence (where functions are identified up to renaming of their parameters, so that $\lambda x.x$ and $\lambda y.y$ are considered to be the same expressions).

To define a type system for the λ -calculus, we must add a type for functions to the syntax of types.

$$\tau ::= \mathbf{nat} \mid \mathbf{bool} \mid \tau_1 \rightarrow \tau_2$$

The type $\tau_1 \rightarrow \tau_2$ classifies a function with argument of type τ_1 and result of type τ_2 . Using currying, we can define functions that take multiple arguments. The \rightarrow operator associates to the right, so $\mathbf{nat} \rightarrow \mathbf{bool} \rightarrow \mathbf{nat}$ means $\mathbf{nat} \rightarrow (\mathbf{bool} \rightarrow \mathbf{nat})$.

The STLC type system uses typing contexts to record assertions about the types of free variables. Therefore, we extend the syntax of typing contexts with assumptions.

$$\Gamma ::= \varepsilon \mid \Gamma, x:\tau$$

Typing contexts can be viewed as ordered lists. If a context is nonempty, we often omit parentheses and elide the ε at the beginning, writing a context such as $(\varepsilon, x:\mathbf{nat}), y:\mathbf{nat}$ more simply as $x:\mathbf{nat}, y:\mathbf{nat}$.

An important condition for typing contexts is *uniqueness*, which means that there is at most one assumption about the type of a particular variable. For example,

$$x:\mathbf{nat}, y:\mathbf{nat}$$

is a valid context but the following are not*:

$$x:\mathbf{nat}, x:\mathbf{bool} \quad x:\mathbf{nat}, x:\mathbf{nat}$$

* Although it is possible in some situations to allow later bindings to *shadow* earlier ones, shadowing does not make sense in every type system.

$$\boxed{\Gamma \vdash \tau : \star}$$

$$\frac{\Gamma \vdash \diamond}{\Gamma \vdash \mathbf{nat} : \star} \text{ T_NAT} \quad \frac{\Gamma \vdash \diamond}{\Gamma \vdash \mathbf{bool} : \star} \text{ T_BOOL}$$

$$\frac{\Gamma \vdash \tau_1 : \star \quad \Gamma \vdash \tau_2 : \star}{\Gamma \vdash \tau_1 \rightarrow \tau_2 : \star} \text{ T_ARROW}$$

FIGURE 70.2 Well formed types.

When this uniqueness condition holds, we can treat typing contexts as finite maps. In particular, it is straightforward to define a number of operations and predicates on these structures, such as calculating all of the variables with typing assumptions in the context (written $\text{dom}(\Gamma)$), stating whether a particular assumption is in the context, written $(x:\tau) \in \Gamma$, and appending the assumptions in one context after those in another, written Γ_1, Γ_2 .

We ensure uniqueness with a new rule for well formed contexts. An assumption can only be added when the variable does not already appear in the typing context:

$$\frac{\Gamma \vdash \diamond \quad x \notin \text{dom}(\Gamma) \quad \Gamma \vdash \tau : \star}{\Gamma, x : \tau \vdash \diamond} \text{ C_EVAR}$$

This rule includes a premise for yet another auxiliary judgment, $\Gamma \vdash \tau : \star$, which asserts that the type τ is a valid type. (The notation “ $: \star$ ” can be read as “is a type.”) The rules that derive this judgment appear in Figure 70.2. In this system, the judgment is trivial, as all syntactically well formed types are valid. Again, we introduce this judgment now to prepare for future extension (see Section 70.2.6).

To type check the new expression forms, we need three new rules as shown in Figure 70.3. The first states that variables have the types that the context assumes for them. Next, functions introduce assumptions about the types of their parameters to the typing context when their bodies are checked. There is an implicit requirement that the name of the variable not appear already in the domain of the context. This requirement is enforced when the context is checked for well formedness. The last rule, for function applications, constrains the type of e_1 to be a function type and the type of its argument e_2 to match the domain of the function.

Typing contexts serve several purposes in formal type systems besides typing functions. First, they provide a simple way to add new primitive operations. For example, we can add a primitive boolean negation operation, *not*, to the type system merely by adding an assumption $\text{not}:\mathbf{bool} \rightarrow \mathbf{bool}$ to the initial typing context.

Furthermore, the ability to type check in the presence of assumptions means that type checking is *modular* and is scalable to large programs. Instead of typing an entire program at once, a program can be broken into smaller parts that can be checked individually. The definitions in a module define an interface that can be described by a typing context. Other modules that use the definitions can be checked using that context. Therefore we do not need to recheck the entire program after each modification, as long as the interfaces are unchanged.

70.2.3 Syntax-Directed Type Systems

For any type system, it is important that there is an algorithm that decides whether any program type checks. Some type systems are *syntax directed*, meaning that an algorithm can be derived directly from the typing rules. This algorithm works by structural recursion over the form of expressions.

For example, the typing rules of the simple arithmetic language of Section 70.2.1 are syntax directed. For any expression in this language, there is a straightforward algorithm to determine its type. We define this algorithm using the partial function $Type(\Gamma, e)$ shown in Figure 70.4, which is taken almost directly by “reading” the typing rules from bottom to top. The arguments to this function are the typing context Γ and an expression e . If this function returns a type τ , then we know that there is some derivation of the judgment $\Gamma \vdash e : \tau$. The definition of this function pattern matches the syntax of its argument. It then calls itself recursively on any subexpressions of that argument. If the type of any subexpression is undefined, then there is no such typing derivation and the whole expression does not type check. In the base cases, this function uses the auxiliary function $Wf(\Gamma)$ to ensure that the context is well formed.

We can see that this function terminates by noting that each recursive call is to a subterm—a smaller expression. Therefore, this function is partial only when the conditions fail, such as when the types of the arguments to the equality operation do not match. Therefore, for any expression in the arithmetic language, we can use this partial function to either determine its type or determine that it does not type check.

In contrast, STLC is not syntax directed. Although we can extend these partial functions to infer the types of variables and function applications and check the well formedness of contexts with assumptions

(E_VAR)	$Type(\Gamma, x) = \tau$ when $(x:\tau) \in \Gamma$ and $Wf(\Gamma)$
(E_APP)	$Type(\Gamma, e_1 e_2) = \tau_2$ when $Type(\Gamma, e_1) = \tau_1 \rightarrow \tau_2$ and $Type(\Gamma, e_2) = \tau_1$
(C_EVAR)	$Wf(\Gamma, x:\tau) = Wf(\Gamma)$ when $x \notin dom(\Gamma)$

we run into trouble with anonymous functions. What should the type of $\lambda x.e$ be?

$$(E_{\text{ABS}}) \quad \text{Type}(\Gamma, \lambda x.e) = ?$$

The problem is that the syntax of functions does not indicate what type should be added to the context when checking the body of the function. Even worse, some functions have many types. For example, $\lambda x.x$ can be typed with $\mathbf{nat} \rightarrow \mathbf{nat}$ and $\mathbf{bool} \rightarrow \mathbf{bool}$ (and many more). In other words, STLC does not have the *uniqueness of types* property, where each expression can be typed with exactly one type.

One way to make this language syntax directed is to annotate functions with the types of their arguments. In other words, we replace $\lambda x.e$ with $\lambda x:\tau.e$ and replace the typing rule E_{ABS} with one for annotated functions:

$$\frac{\Gamma, x:\tau_1 \vdash e : \tau_2}{\Gamma \vdash \lambda x:\tau_1.e : \tau_1 \rightarrow \tau_2} E_{\text{AABS}}$$

After these modifications, we can finish the last line of the type checking function as follows:

$$(E_{\text{AABS}}) \quad \text{Type}(\Gamma, \lambda x:\tau.e) = \text{Type}(\Gamma, x:\tau, e)$$

when $x \notin \text{dom}(\Gamma)$

Type checking could fail if the variable x already appears in the domain of the typing context. However, the type checking function is allowed to rename the bound variable in the expression to ensure uniqueness.

Note that this algorithm is not the most efficient way to determine whether an expression is typeable. In particular, it checks that the context is well formed many times. We could replace this algorithm with a more efficient version that checks assumptions as they enter the typing context. This version of the type system is convenient for reasoning about the type system, but even though it derives *an* algorithm for type checking, it does not derive the best algorithm.

In general, the simply-typed λ -calculus without annotations on functions is called a *Curry-style* type system. The system with annotated functions is known as a *Church-style* system [3]. We will also use the words *implicitly typed* and *explicitly typed* to distinguish between the two versions. Even though the Curry-style type system is not syntax directed, there is still an algorithm for type checking it. That algorithm is just not directly determined by the syntax (see Section 70.4).

Many forms besides functions have implicitly-typed and explicitly-typed versions. In the sections that follow, we introduce each new form in its implicit version and then discuss how typing annotations may be added to it afterwards. We order the discussion in this manner to simplify the syntax of each form, draw connections to existing programming languages that often feature these forms without annotation, and focus attention to the important parts of the semantics.

70.2.4 Structured Types

In this section, we extend STLC with unit, product and sum types. These new forms are only the first of many additions that make formal type systems closer to that of actual programming languages such as Haskell and ML.

For each new type construction, we introduce the necessary syntax for the addition and describe the associated rules. In each case, the set of rules follows a basic pattern. These rules declare when the type is well formed, how to *introduce* elements of the type and how to *eliminate* elements of that type.

$$\begin{aligned}
\tau & ::= \dots | \mathbf{unit} \\
e & ::= \dots | () \\

\end{aligned}$$

\end{aligned}$$

FIGURE 70.6 Product types.

For example, in STLC we extended the grammar with variables, functions, and applications. The rule E_ARROW defines when function types are well formed, the introduction rule is T_ABS , and the elimination rule is T_APP .

The **unit** type (Figure 70.5) is a trivial type for an uninteresting value. It is called *void* in some languages. There are no primitive operations available for the single value of this type, written $()$, so there are only two rules: one for checking that the type is well formed and an introduction rule for showing that the unit value has the unit type.

Product types (Figure 70.6) are the types of composite values. These values contain two components which may be of differing types. The pair expression $\langle e_1, e_2 \rangle$ introduces a product; they are eliminated with $\mathbf{fst} e$ and $\mathbf{snd} e$, which extract the first and second components of e , respectively.

Sum types (Figure 70.7), also called disjoint union types, represent alternatives. A value of type $\tau_1 + \tau_2$, could either be a value of type τ_1 or a value of type τ_2 . In either case, the value is tagged so that its type can be determined. The expressions $\mathbf{inl} e$ and $\mathbf{inr} e$ introduce sum types tagged as either the left or the right type of the sum. The elimination form for sum types is case analysis (a simplified form of pattern matching found in functional programming languages). This construct evaluates one of two branches, depending on the tag of the *scrutinee*, the argument of case analysis. Inside each branch, the value that was tagged is available with either the left or the right type depending on the branch.

Note that the inclusion of **unit** and sum types makes the **bool** type unnecessary. We could replace all uses of **bool** with the type **unit** + **unit**, representing **true** as $\mathbf{inl} ()$ and **false** as $\mathbf{inr} ()$. An **if**-expression,

$$\begin{aligned}
\tau & ::= \dots | \tau_1 + \tau_2 \\
e & ::= \dots | \mathbf{inl} e | \mathbf{inr} e | \mathbf{case} e \mathbf{ of} \{ \mathbf{inl} x_1 \rightarrow e_1; \mathbf{inr} x_2 \rightarrow e_2 \} \\
\frac{\Gamma \vdash \tau_1 : \star \quad \Gamma \vdash \tau_2 : \star}{\Gamma \vdash \tau_1 + \tau_2 : \star} \quad T_SUM & \\
\frac{\Gamma \vdash e : \tau_1}{\Gamma \vdash \mathbf{inl} e : \tau_1 + \tau_2} \quad E_INL & \quad \frac{\Gamma \vdash e : \tau_2}{\Gamma \vdash \mathbf{inr} e : \tau_1 + \tau_2} \quad E_INR \\
\frac{\Gamma \vdash e : \tau_1 + \tau_2 \quad \Gamma, x : \tau_1 \vdash e_1 : \tau \quad \Gamma, y : \tau_2 \vdash e_2 : \tau}{\Gamma \vdash \mathbf{case} e \mathbf{ of} \{ \mathbf{inl} x_1 \rightarrow e_1; \mathbf{inr} x_2 \rightarrow e_2 \} : \tau} \quad E_CASE
\end{aligned}$$

FIGURE 70.7 Sum types.

which eliminates the boolean type, can be implemented with case analysis, ignoring the unit values carried by the tags. We formalize this encoding with the following table:

bool	\triangleq	unit + unit
true	\triangleq	inl()
false	\triangleq	inr()
if e_1 then e_2 else e_3	\triangleq	case e_1 of { inl $y \rightarrow e_2$; inr $y \rightarrow e_3$ }
		where $y \notin fv(e_2) \cup fv(e_3)$

The additions of this section are intended to give an idea of composite type structure—complex types can be formed from simple components. Programming languages typically generalize products and sums to more convenient versions. For example, n -ary tuple types $\tau_1 \times \tau_2 \times \dots \tau_n$, generalize products from two components to n components for any $n \geq 2$.

Another generalization is to identify tuple components by name instead of by number—this produces record types, written $\{l_1:\tau_1, \dots, l_n:\tau_n\}$, where each component of the aggregate data structure is named by some label l . The components of record types can often be accessed using dot notation, $e.l$ accesses the component named l in the record e . Likewise, sums can be generalized from two options to more, and from numbered options to labels. Labelled n -ary sums are called *variant* types.

Although a typing algorithm for unit and product types can be read directly from the rules, the introduction rules for sum types are not syntax directed. To make this language explicitly typed, we replace **inl** e with **inl** $_{\tau}$ e and **inr** e with **inr** $_{\tau}$ e , where the annotation τ indicates the type of the other alternative:

$$\frac{\Gamma \vdash e : \tau_1 \quad \Gamma \vdash \tau_2 : \star}{\Gamma \vdash \mathbf{inl}_{\tau_2} e : \tau_1 + \tau_2} \text{E_AINL} \quad \frac{\Gamma \vdash \tau_1 : \star \quad \Gamma \vdash e : \tau_2}{\Gamma \vdash \mathbf{inr}_{\tau_1} e : \tau_1 + \tau_2} \text{E_AINR}$$

70.2.5 Recursive Types

Recursive data structures, such as lists and trees, can be typed by recursive types, written $\mu\alpha : \star.\tau$. Similar to a λ term, a μ type binds the *type variable* α in the type τ . We use greek letters from the beginning of the alphabet for type variables. As with terms, we can calculate the free type variables that appear in a type with the syntax $fv(\tau)$, substitute types for free type variables (while avoiding capture) with the syntax $[\tau/\alpha]\tau'$, and identify types up to renaming of bound variables. For example, the types $\mu\alpha : \star.\alpha \rightarrow \alpha$ and $\mu\beta : \star.\beta \rightarrow \beta$ are considered equal.

The new syntax and typing rules are in Figure 70.8. Not only do we add the new forms for variables and recursive type definitions, but we also extend the syntax for typing contexts. Assumptions of the form $\alpha : \star$ record the type variables that may appear in types. As with term variables, type variable

$$\begin{aligned} \tau &::= \dots | \alpha | \mu\alpha : \star.\tau \\ \Gamma &::= \dots | \Gamma, \alpha : \star \\ \frac{\Gamma \vdash \diamond \quad \alpha \notin \text{dom}(\Gamma)}{\Gamma, \alpha : \star \vdash \diamond} &\text{C_TVAR} \\ \frac{\Gamma \vdash \diamond \quad (\alpha : \star) \in \Gamma}{\Gamma \vdash \alpha : \star} &\text{T_VAR} \quad \frac{\Gamma, \alpha : \star \vdash \tau : \star}{\Gamma \vdash \mu\alpha : \star.\tau : \star} &\text{T_MU} \\ \frac{\Gamma \vdash e : [\mu\alpha : \star.\tau/\alpha]\tau}{\Gamma \vdash e : \mu\alpha : \star.\tau} &\text{E_ROLL} \quad \frac{\Gamma \vdash e : \mu\alpha : \star.\tau}{\Gamma \vdash e : [\mu\alpha : \star.\tau/\alpha]\tau} &\text{E_UNROLL} \end{aligned}$$

\frac{\Gamma \vdash e : [\mu\alpha : \star.\tau/\alpha]\tau}{\Gamma \vdash \mathbf{roll}_{\mu\alpha:\star.\tau} e : \mu\alpha : \star.\tau} \text{E_RLA} \qquad \frac{\Gamma \vdash e : \mu\alpha : \star.\tau}{\Gamma \vdash \mathbf{unroll} e : [\mu\alpha : \star.\tau/\alpha]\tau} \text{E_URLA}
\end{array}$$

assumptions in the context must be unique. The rule C_TVAR restricts type variables from occurring multiple times. Rule T_VAR makes the judgment form $\Gamma \vdash \tau : \star$ nontrivial. It says that type variables are valid only when they are declared in the context. The formation rule for recursive types (T_MU) adds the bound type variable to the context when it checks the body of the recursive type.

Because the context now contains both type and term variables, the order of assumptions in a typing context matters. Rule C_EVAR (from Section 70.2.2) ensures that the types of assumed term variables are well formed using the prior context. If the context is reordered, these types may no longer be valid.

The last two rules implicitly introduce and eliminate recursive types. In a recursive type $\mu\alpha : \star.\tau$, the type variable α stands for the whole type. Therefore these rules equate recursive types $\mu\alpha : \star.\tau$ with their unrolling $[\mu\alpha : \star.\tau/\alpha]\tau$, allowing terms to have either type as necessary. These type conversions are implicit, so this type system is not syntax directed.

To define a syntax-directed system, we explicitly mark the locations where the type should be “rolled” and “unrolled” in expressions, using the constructs in Figure 70.9. The forms **roll** and **unroll** are explicit coercions between values of type $\mu\alpha : \star.\tau$ and $[\mu\alpha : \star.\tau/\alpha]\tau$. These forms are witnesses to an isomorphism between a recursive type and its unfolding. Recursive types with implicit conversions are called *quirecursive*; those with **roll** and **unroll** are called *isorecursive types*.

Regular algebraic datatypes, as found in ML and Haskell, can be encoded by recursive types. For example, in Haskell, one might define a tree structure as follows:

```
data Tree = Empty | Node Tree Tree
```

This structure declares the existence of a new data type, called `Tree` and two *data constructors* for the datatype. The data constructor `Empty` constructs a leaf with no children and the data constructor `Node` constructs a tree with left and right children. Recursive functions that work over datatypes use pattern matching, such the case expression in the following function definition:

```
height :: Tree -> Int
height = \ x -> case x of
  Empty -> 0
  Node x y -> 1 + height x + height y
```

We can encode trees with products, sums, unit, and recursive types. The tree type is a recursive type, which is either unit (for the empty tree) or a product of two occurrences of the recursive variable. The constructors `Empty` and `Node` construct values of this type, using the introduction forms for unit, sums, products and (iso)recursion. Finally, case analysis on `Trees` is implemented with the corresponding elimination forms:

$$\begin{array}{l}
\text{Tree} \quad \triangleq \quad \mu\beta : \star. \mathbf{unit} + (\beta \times \beta) \\
\text{Empty} \quad \triangleq \quad \mathbf{roll}_{\mu\beta : \star. \mathbf{unit} + (\beta \times \beta)} (\mathbf{inl}()) \\
\text{Node } e_1 e_2 \quad \triangleq \quad \mathbf{roll}_{\mu\beta : \star. \mathbf{unit} + (\beta \times \beta)} (\mathbf{inr} \langle e_1, e_2 \rangle) \\
\text{case } e \text{ of } \{\text{Empty} \rightarrow e_1; \text{Node } x y \rightarrow e_2\} \triangleq \\
\quad \text{case } (\mathbf{unroll} e) \text{ of } \{\mathbf{inl} x_1 \rightarrow e_1; \mathbf{inr} x_2 \rightarrow [\mathbf{fst} x_2/x][\mathbf{snd} x_2/y]e_2\} \\
\quad \text{where } x_1 \notin \text{fv}(e_2), \quad x_2 \notin \text{fv}(e_2)
\end{array}$$

Furthermore, type-level recursion can be used to add value-level recursion to typed languages. Recursive definitions, such as the height function above, are possible in the λ -calculus with the Y -combinator. The Y -combinator computes the fixed point of its argument, allowing the definition of recursive, anonymous functions. For example, the height function is defined using the Y -combinator as

$$\begin{aligned} \text{height} &\triangleq \\ &Y(\lambda h. \lambda x. \text{case}(\text{unroll } x) \text{ of } \{ \\ &\quad \text{inl } y \rightarrow 1; \\ &\quad \text{inr } y \rightarrow 1 + h(\text{fst } y) + h(\text{snd } y)\}) \end{aligned}$$

For call-by-name languages, the Y -combinator is defined as follows:

$$Y \triangleq \lambda f. (\lambda x. f(x \ x)) (\lambda x. f(x \ x))$$

The Y -combinator can be type checked using recursive types. Below, we give the definition of Y in the explicitly-typed language, marking where coercions to and from the recursive type must occur:

$$\begin{aligned} Y_{\tau} &\triangleq \lambda f : \tau \rightarrow \tau. \\ &(\lambda x : (\mu\alpha : \star. \alpha \rightarrow \tau). f ((\text{unroll } x)x)) \\ &(\text{roll}_{\mu\alpha : \star. \alpha \rightarrow \tau} (\lambda x : (\mu\alpha : \star. \alpha \rightarrow \tau). f ((\text{unroll } x)x))) \end{aligned}$$

The implicitly-typed language with equirecursive types can type the definition of Y directly. However, the Y -combinator, like any potentially nonterminating expression, cannot be type checked in STLC [52]. The addition of recursive types is enough to make this language Turing complete.

70.2.6 Parametric Polymorphism

Parametric polymorphism, or type abstraction, enables programs to be generic in the types of data that they work with. This feature increases the flexibility of statically typed languages such as ML, Haskell, Java and Scala. Parametric polymorphism was first studied (independently) by the logician Jean-Yves Girard [17] and the computer scientist John Reynolds [48].

In this subsection, we extend our small language with two different forms of type abstraction: *universally quantified types*, written $\forall\alpha : \star. \tau$ and *existentially quantified types*, written $\exists\alpha : \star. \tau$. In both cases, the type variable α is bound within the body of the type τ . This type variable α stands for an abstract type, one that is unknown when the term is compiled. Type systems that include quantified types are called *second-order*.

70.2.6.1 Universal Polymorphism

We add universally quantified types to the language with the three rules in Figure 70.10. The introduction form generalizes the type of an expression. If we can type check an expression while treating one part of its type abstractly (i.e., while knowing nothing but its name α), then we can generalize that part

$$\begin{array}{c}
\tau ::= \dots | \forall \alpha : \star . \tau \\
\frac{\Gamma, \alpha : \star \vdash \tau : \star}{\Gamma \vdash \forall \alpha : \star . \tau : \star} \text{ T_ALL} \\
\frac{\Gamma, \alpha : \star \vdash e : \tau}{\Gamma \vdash e : \forall \alpha : \star . \tau} \text{ E_TABS} \qquad \frac{\Gamma \vdash e : \forall \alpha : \star . \tau \quad \Gamma \vdash \tau' : \star}{\Gamma \vdash e : [\tau'/\alpha]\tau} \text{ E_TAPP}
\end{array}$$

FIGURE 70.10 Universally quantified types (implicit rules).

of the type. For example, generalization shows that the identity function $\lambda x.x$ can be given type $\forall \alpha : \star. \alpha \rightarrow \alpha$ because the type of the argument is unconstrained:

$$\begin{array}{c}
\frac{\frac{\frac{\frac{}{\varepsilon \vdash \diamond} \text{C_EMP}}{\varepsilon, \alpha : \star \vdash \diamond} \text{C_TVAR}}{\varepsilon, \alpha : \star, x : \alpha \vdash \diamond} \text{E_VAR}}{\varepsilon, \alpha : \star, x : \alpha \vdash x : \alpha} \text{E_ABS}}{\varepsilon \vdash \lambda x.x : \forall \alpha : \star . \alpha \rightarrow \alpha} \text{E_TABS} \qquad \frac{\frac{\frac{}{\varepsilon \vdash \diamond} \text{C_EMP}}{\varepsilon, \alpha : \star \vdash \alpha : \star} \text{T_VAR}}{\varepsilon, \alpha : \star, x : \alpha \vdash \diamond} \text{C_EVAR}}{\varepsilon \vdash \lambda x.x : \forall \alpha : \star . \alpha \rightarrow \alpha} \text{E_TABS}
\end{array}$$

The elimination form allows us to use an expression with a polymorphic type at any instance. Any well formed type can be substituted for the variable. For example, we can apply the identity function to itself by instantiating it with its own type. Part of this derivation is shown as follows:

$$\frac{\frac{\dots}{\varepsilon \vdash \lambda x.x : \forall \alpha : \star . \alpha \rightarrow \alpha} \qquad \frac{\dots}{\varepsilon \vdash \forall \alpha : \star . \alpha \rightarrow \alpha : \star}}{\varepsilon \vdash \lambda x.x : (\forall \alpha : \star . \alpha \rightarrow \alpha) \rightarrow (\forall \alpha : \star . \alpha \rightarrow \alpha)} \qquad \frac{\dots}{\varepsilon \vdash \lambda x.x : \forall \alpha : \star . \alpha \rightarrow \alpha}}{\varepsilon \vdash \lambda x.x (\lambda x.x) : \forall \alpha : \star . \alpha \rightarrow \alpha}$$

Languages with parametric polymorphism distinguish between *predicative* and *impredicative* variants. The rules in Figure 70.10 are impredicative. The difference between the two is the meaning of the quantifier. In a type such as $\forall \alpha : \star . \alpha \rightarrow \alpha$, can the type variable α really be instantiated by itself as shown in the derivation above? This behavior causes difficulty—if we think of these types as the set of all of their instances, then the meaning of impredicative quantification is circular.

Predicative type systems stratify quantification to escape this circularity. Instantiation is only allowed by “smaller” types. One way to enforce predicativity is to mark each type by a level and allow quantifiers to range only over types from a lower level.

Type systems with predicative polymorphism can be easier to reason about and model semantically because of this stratification. However, impredicative polymorphism is more expressive. It can encode a number of other type forms such as products, sums, existentials (see next section), and some recursive types [5]. Thus, someone studying the semantics of a language with impredicative polymorphism need not include these type forms in the model—they are already available.

Once again, the rules presented in Figure 70.10 are not syntax directed. Explicit universal polymorphism (shown in Figure 70.15) marks the introduction of polymorphic types with the type abstraction form $\Lambda \alpha : \star . e$ and the elimination with a type application form $e(\tau)$.

70.2.6.2 Existential Polymorphism

Existentially quantified types, written $\exists \alpha : \star . \tau$, model *abstract data types* (ADT). An ADT is a type that is defined solely by its interface—how it may be used—without revealing its representation.

$$\begin{aligned}
\tau & ::= \dots \mid \exists \alpha : \star. \tau \\
e & ::= \dots \mid \mathbf{pack} \langle \tau, e \rangle \mathbf{as} \exists \alpha : \star. \tau' \mid \mathbf{let} \langle \alpha, x \rangle = e_1 \mathbf{in} e_2 \\
& \frac{\Gamma, \alpha : \star \vdash \tau : \star}{\Gamma \vdash \exists \alpha : \star. \tau : \star} \quad T_EX \\
& \frac{\Gamma \vdash \tau : \star \quad \Gamma \vdash e : [\tau/\alpha]\tau'}{\Gamma \vdash \mathbf{pack} \langle \tau, e \rangle \mathbf{as} \exists \alpha : \star. \tau' : \exists \alpha : \star. \tau'} \quad E_PACK \\
& \frac{\Gamma \vdash e : \exists \alpha : \star. \tau \quad \Gamma, \alpha : \star, x : \tau \vdash e' : \tau' \quad \Gamma \vdash \tau' : \star}{\Gamma \vdash \mathbf{let} \langle \alpha, x \rangle = e \mathbf{in} e' : \tau'} \quad E_UNPACK
\end{aligned}$$

FIGURE 70.11 Existentially quantified types.

Abstract data types are important because they provide encapsulation, localization of change, and flexibility to programmers.

Figure 70.11 contains the necessary definitions and rules for this form of type. Because these types rarely appear in implicitly-typed systems, we describe only the explicitly-typed version. The introduction form $\mathbf{pack} \langle \tau, e \rangle \mathbf{as} \exists \alpha : \star. \tau'$ creates an “existential package” that hides part of the structure of a type. The elimination form $\mathbf{let} \langle \alpha, x \rangle = e \mathbf{in} e'$ provides access to this value but requires that the hidden type be used abstractly.

For example, we can implement a stack of numbers using an encoding of lists as a recursive sum of products. The *empty* stack is just an empty list. The *push* operation adds a new number to the top of the stack. The *peek* operation returns either unit, when the stack is empty, or the top value on the stack. Finally, the *pop* operation returns the stack without its top value:

$$\begin{aligned}
stack & \triangleq \mu \alpha : \star. \mathbf{unit} + (\mathbf{nat} \times \alpha) \\
empty & \triangleq \mathbf{roll}_{stack}(\mathbf{inl}()) \\
push & \triangleq \lambda x : \mathbf{nat}. \lambda y : stack. \mathbf{roll}_{stack}(\mathbf{inr} \langle x, y \rangle) \\
peek & \triangleq \lambda y : stack. \mathbf{case}(\mathbf{unroll} y) \mathbf{of} \{ \mathbf{inl} x \rightarrow \mathbf{inl}(); \mathbf{inr} x \rightarrow \mathbf{inr}(\mathbf{fst} x) \} \\
pop & \triangleq \lambda y : stack. \mathbf{case}(\mathbf{unroll} y) \mathbf{of} \{ \mathbf{inl} x \rightarrow y; \mathbf{inr} x \rightarrow \mathbf{snd} x \}
\end{aligned}$$

Putting these four operations together in a record allows the implementation of the stack type to be hidden. In other words, we can use \mathbf{pack} to give a record of these operations the following type, where the type *stack* has been hidden by the variable α :

$$\begin{aligned}
stkmod & \triangleq \exists \alpha. \{ \\
& \quad empty \quad : \alpha; \\
& \quad push \quad : \mathbf{nat} \rightarrow \alpha \rightarrow \alpha; \\
& \quad peek \quad : \alpha \rightarrow \mathbf{unit} + \mathbf{nat}; \\
& \quad pop \quad : \alpha \rightarrow \alpha; \\
& \}
\end{aligned}$$

Clients of the stack module use the elimination form for existential types, $\mathbf{let} \langle \alpha, x \rangle = e_1 \mathbf{in} e_2$. This form introduces the type variable α and expression variable x with type that mentions α into the context. Clients cannot know the actual type that was used for α when the module was constructed. Instead, they must use this type abstractly, according to the interface specified by the type of x .

For example, once the stack module has been unpacked, the stack operations can be accessed from the record and used with each other. If y is a variable with type as given earlier, then it can be used as follows:

$$\Gamma, y : \text{stkmod} \vdash \text{let } (\alpha, x) = y \text{ in } x.\text{peek } (x.\text{push } 1 \ x.\text{empty}) : \text{unit} + \text{nat}$$

The third premise of the typing rule for the elimination form for existentials implies that the result type τ' cannot contain the abstract variable α . Because of this premise, the type variable α cannot escape the scope of the **let**-expression.

70.2.7 Parameterized Types and Higher-Order Polymorphism

Parameterized types are those that abstract part of their structure. For example, in Haskell we can define a type of polymorphic lists that can be used with many different types of elements:

```
data List a = Nil | Cons a (List a)
```

This single definition can conveniently be used to construct both lists of integers and lists of boolean values.

```
x :: List Int
x = Cons 1 (Cons 2 (Cons 3 Nil))

y :: List Bool
y = Cons True (Cons False (Cons True Nil))
```

These lists are not heterogeneous; a single list can contain either integers or booleans, but not both. Yet the power of type parameterization means that we can write polymorphic functions that work for all lists, no matter what type of elements they contain. For example, the `map` function applies its argument to each element in a list in turn, constructing a new list from the results:

```
map :: forall a b. (a -> b) -> List a -> List b
map f Nil = Nil
map f (Cons x xs) = Cons (f x) (map f xs)
```

What exactly is `List` in these definitions? We call it a *parameterized type*. By itself, it does not make sense as a type—it needs a type argument like `Int` and `Bool` to be complete. `List` must be applied to another type to become a type.

Formally, we model parameterized types by adding *type application*, written $\tau_1 \tau_2$, to the syntax of types as shown in Figure 70.12. That way we can express the application of type constants like `List` to their parameters.

However, with this addition, we must worry about ill-formed types of the form **nat nat**, or **list list**. These types are syntactically correct but meaningless. Allowing them in the type system does not jeopardize type soundness, but they could lead to buggy interfaces as they do not contain any values. We rule such types out using *kinds*, that is, a “type of types.” Kind checking ensures that parameterized types are applied to the correct arguments.

There are two forms of kinds. The first, \star is the kind of normal types such as **nat**, **bool**, and **unit + unit**. Only types of this kind contain values. Arrow kinds, written $\kappa_1 \rightarrow \kappa_2$, describe parameterized types. For example, `List`, has kind $\star \rightarrow \star$ because it requires one type argument to be a complete type.

$$\begin{array}{l}
\tau ::= \dots \mid \tau_1 \tau_2 \mid \forall \alpha : \kappa. \tau \\
\kappa ::= * \mid \kappa_1 \rightarrow \kappa_2 \\
\boxed{\Gamma \vdash \tau : \kappa} \\
\frac{\Gamma \vdash \tau_1 : \kappa_1 \rightarrow \kappa_2 \quad \Gamma \vdash \tau_2 : \kappa_1}{\Gamma \vdash \tau_1 \tau_2 : \kappa_2} \text{ T_APP} \\
\frac{\Gamma \vdash \diamond \quad (\alpha : \kappa) \in \Gamma}{\Gamma \vdash \alpha : \kappa} \text{ T_VARK} \quad \frac{\Gamma, \alpha : \kappa \vdash \tau : *}{\Gamma \vdash \forall \alpha : \kappa. \tau : *} \text{ T_ALLK} \\
\boxed{\Gamma \vdash e : \tau} \\
\frac{\Gamma, \alpha : \kappa \vdash e : \tau}{\Gamma \vdash e : \forall \alpha : \kappa. \tau} \text{ E_TABSK} \quad \frac{\Gamma \vdash e : \forall \alpha : \kappa. \tau \quad \Gamma \vdash \tau' : \kappa}{\Gamma \vdash e : [\tau' / \alpha] \tau} \text{ E_TAPPK}
\end{array}$$

FIGURE 70.12 Higher-order polymorphism.

We also generalize the judgment we have been using to check that types are well formed so that it also tracks their kinds. The form of the judgment is now $\Gamma \vdash \tau : \kappa$. All previous rules are still valid. For a type application, the rule T_APP ensures that the parameterized type can be applied to its argument.

Higher-order polymorphism means that polymorphic functions can quantify over parameterized types. The Haskell programming language includes this feature [25], often using it for generic code that works for arbitrary functors, monads, arrows and idioms. We can add higher-order polymorphism to our formalism by relaxing the rules that introduce and use type variables in the context so that they apply to variables of any kind.

70.2.8 Type-Level Computation

The process of type checking a program is based on comparing types for equivalence. For example, when checking that function applications are well typed, a compiler must compare the type of the argument with the expected type of the formal parameter.

To this point, type equivalence has been unremarkable. In the preceding sections, types are equal only when they are α -equivalent, that is, syntactically equal up to renaming of bound variables. However, some type systems define a richer equality for types and allow them to be compared up to this equivalence. This subsection describes one example of a rich type equality, based on *type-level computation*.

Type-level computation turns the language of types τ into a programming language. However, “programs” in this language are never run, they are only compared for equivalence during type checking.

The simplest example of type-level computation is the addition of λ -calculus functions to the language of higher-order polymorphism:

$$\tau ::= \dots \mid \lambda \alpha : \kappa. \tau$$

Such type-level functions have function kinds:

$$\frac{\Gamma, \alpha : \kappa_1 \vdash \tau : \kappa_2}{\Gamma \vdash \lambda \alpha : \kappa_1. \tau : \kappa_1 \rightarrow \kappa_2} \text{ T_ABS}$$

This type system, which combines type-level abstractions with type variables, type application, and kinds (i.e., a simple “type system” for types), is called System F_\circ [17].

Languages that include type-level computation *define* what it means for types to be equivalent with the judgment form $\Gamma \vdash \tau_1 \simeq \tau_2 : \kappa$, as shown in Figure 70.13. Derivations of this judgment prove that the

$$\boxed{\Gamma \vdash \tau_1 \simeq \tau_2 : \kappa}$$

$$\frac{\Gamma \vdash (\lambda \alpha : \kappa. \tau) \tau' : \kappa}{\Gamma \vdash (\lambda \alpha : \kappa. \tau) \tau' \simeq [\tau'/\alpha] \tau : \kappa} \text{TE_BETA}$$

$$\frac{\Gamma \vdash \tau : \kappa_1 \rightarrow \kappa_2}{\Gamma \vdash \lambda \alpha : \kappa_1. (\tau \alpha) \simeq \tau : \kappa_1 \rightarrow \kappa_2} \text{TE_ETA}$$

$$\frac{\Gamma \vdash \tau : \kappa}{\Gamma \vdash \tau \simeq \tau : \kappa} \text{TE_REFL} \quad \frac{\Gamma \vdash \tau' \simeq \tau : \kappa}{\Gamma \vdash \tau \simeq \tau' : \kappa} \text{TE_SYM}$$

$$\frac{\Gamma \vdash \tau_1 \simeq \tau_2 : \kappa \quad \Gamma \vdash \tau_2 \simeq \tau_3 : \kappa}{\Gamma \vdash \tau_1 \simeq \tau_3 : \kappa} \text{TE_TRANS}$$

$$\frac{\Gamma \vdash \tau_1 \simeq \tau'_1 : \star \quad \Gamma \vdash \tau_2 \simeq \tau'_2 : \star}{\Gamma \vdash \tau_1 \rightarrow \tau_2 \simeq \tau'_1 \rightarrow \tau'_2 : \star} \text{TE_ARROW}$$

$$\frac{\Gamma, \alpha : \kappa \vdash \tau \simeq \tau' : \star}{\Gamma \vdash \forall \alpha : \kappa. \tau \simeq \forall \alpha : \kappa. \tau' : \star} \text{TE_ALL}$$

$$\frac{\Gamma, \alpha : \kappa_1 \vdash \tau \simeq \tau' : \kappa_2}{\Gamma \vdash \lambda \alpha : \kappa_1. \tau \simeq \lambda \alpha : \kappa_1. \tau' : \kappa_1 \rightarrow \kappa_2} \text{TE_ABS}$$

$$\frac{\Gamma \vdash \tau_1 \simeq \tau' : \kappa_1 \rightarrow \kappa_2 \quad \Gamma \vdash \tau_2 \simeq \tau'_2 : \kappa_1}{\Gamma \vdash \tau_1 \tau_2 \simeq \tau'_1 \tau'_2 : \kappa_2} \text{TE_APP}$$

FIGURE 70.13 Type equivalence.

type τ_1 is equal to the type τ_2 . The rules of this judgment capture equivalences derived from computation. For example, the β -equivalence rule (TE_BETA) identifies types such as $(\lambda \alpha : \star. \alpha \times \alpha)$ **nat** and **nat** \times **nat**. Type-level functions can also be identified using η -equivalence (TE_ETA). Other rules of the judgment assert that the relation is an equivalence relation (i.e., that it is reflexive, symmetric, and transitive) and that it is compatible with the structure of types.

Once type equality has been *defined*, it can be used with the *conversion* rule:

$$\frac{\Gamma \vdash e : \tau \quad \Gamma \vdash \tau \simeq \tau' : \star}{\Gamma \vdash e : \tau'} \text{E_CONV}$$

This rule permits the type of any expression to be replaced with any equivalent type at any point of a typing derivation. This rule is not syntax directed; it could apply at any point in a typing derivation to convert a type into an equivalent form.

Furthermore, the type equivalence relation $\Gamma \vdash \tau_1 \simeq \tau_2 : \kappa$ is itself not syntax directed because of rules like transitivity. There are several algorithms for determining whether types are equal. If type equivalence does not include η -equivalence, then it is possible to β -reduce both expressions to normal form and compare the results. Crary [8] describes a kind-directed algorithm for η -equivalence.

70.2.9 Subtyping

Subtype polymorphism also increases the expressiveness of type systems. If we view types as collections of values, then there is a natural relationship between them. If all values of a type τ_1 are also contained in the type τ_2 , then we consider τ_1 a *subtype* of τ_2 , and conversely that τ_2 is a *supertype* of τ_1 . This means that any interface that expects an argument of type τ_2 may be supplied a value of type τ_1 . Subtyping means that function interfaces can be flexible, specifying only the minimal requirements of their arguments, without fixing a particular representation.

Adding subtyping to a type system involves expressing the relationship between two types as a judgment form:

$$\Gamma \vdash \tau_1 <: \tau_2$$

that states that “in context Γ , the type τ_1 is a subtype of the type τ_2 .”

The type system uses this judgment in a single typing rule, called *subsumption*, that enables subtyping.

$$\frac{\Gamma \vdash e : \tau \quad \Gamma \vdash \tau <: \tau'}{\Gamma \vdash e : \tau'} \quad E_SUB$$

This rule states that an expression of one type can also be assigned any supertype. Note that this rule is also not syntax directed. It could appear anywhere in a typing derivation to change the type of an expression.

The rules defining the subtyping relation appear in Figure 70.14. The first two rules declare that the subtyping relation is reflexive and transitive. The other rules of the judgment are specific to the individual type forms.

Subtyping is prevalent in object-oriented languages. In such languages, there often is a maximal type that contains all values. For example, the type `Object` is maximal in the Java language and is the supertype of all reference types. Here we extend the syntax of types with a new type **top** as the maximal supertype,

$$\tau ::= \dots \mid \mathbf{top}$$

and declare that all types are subtypes of it with the rule `S_TOP`.

Products and sums are in the subtype relation when their components are, as in rules `S_PROD` and `S_SUM`. These rules are sometimes called *depth subtyping* as they allow subtyping to work deeply within the type. Languages that include records and variants, also permit *width subtyping* in their subtyping rules. With width subtyping, a record type with more components is a subtype of a type with fewer (but compatible) components and a variant type with fewer options is a subtype of one with more cases. For example, a point with a position and mass works in a context that only needs to query the position. Alternatively, a function that has cases for points, lines, and circles can be applied to a value that is known to be either a point or a line.

Function types provide the most confusion in reasoning about subtyping. Note that the rule `S_ARROW` declares $\tau_1 \rightarrow \tau_2$ a subtype of $\tau'_1 \rightarrow \tau'_2$ when τ'_1 is a subtype of τ_1 and τ_2 is a subtype of τ'_2 . For the domains, the relationship is inverted with respect to the whole relation: we call this property *contravariance*.

$$\frac{\Gamma \vdash \tau'_1 <: \tau_1 \quad \Gamma \vdash \tau_2 <: \tau'_2}{\Gamma \vdash \tau_1 \rightarrow \tau_2 <: \tau'_1 \rightarrow \tau'_2} \quad S_ARROW$$

FIGURE 70.14 Subtyping relation.

When the inclusion goes in the same direction, it is called *covariance*. In general, a type variable appears contravariantly within another type if it always occurs on the left of an odd number of arrows and covariantly if it always appears on right. If neither situation is true, then the variable appears invariantly. For example, α is covariant in the types $\mathbf{unit} \rightarrow \alpha$ and $(\alpha \rightarrow \mathbf{unit}) \rightarrow \alpha$ and contravariant in the types $\alpha \rightarrow \mathbf{unit}$ and $(\mathbf{unit} \rightarrow \alpha) \rightarrow \mathbf{unit}$. Finally, α is invariant in the type $\alpha \rightarrow \alpha$.

We can extend the notion of subtyping in many ways. Some languages include a minimal subtype, called *bottom*, as an analogue to the maximal supertype *top*. *Bounded polymorphism* combines subtyping with parametric polymorphism. In such systems, type variables are inserted into the typing context with supertype or subtype bounds that reveal partial information about the abstract type. The rules for subtyping quantified types differ in the treatment of these bounds. The combination of subtyping and parameterized types requires reasoning about *variance*.

Relationships like subtyping show up in many contexts, not just in the typing of objects. For example, in Haskell, type class constraints can be satisfied by any subclass [59]. In ML, modules can be given a variety of signatures in a subsignature relationship [31]. The Hindley–Milner type system (see later) orders polymorphic types by a “more-general” relation [10]. Languages with predicativity levels allow types of lower levels to be automatically promoted higher in the hierarchy [29].

As with the conversion rule of the previous section, the subsumption rule in this section is not syntax directed. Furthermore, the presence of a transitivity rule in the subtyping relation also makes it nonalgorithmic. Pierce [41] defines algorithms for subtyping and shows that they are equivalent to these rules.

70.2.10 Other Forms of Types and Type Systems

The preceding sections describe only a few of the many, many features of type systems that have been devised by language researchers. Next, we briefly give pointers to further reading.

Class and object types describe the essential features of object-oriented languages. A starting point is Featherweight Java [23], an essential formalization of classes, objects, methods, and subtyping.

Low-level types describe the structure of machines, including registers, heaps, stacks, and assembly language instructions. Morrisett [32,33] overviews this work.

Dependent types allow types to depend on values. A gentle introduction to dependent types in the context of the Agda programming language is by Bove and Dybjer [6]. Additional information is found in Aspinnall and Hofmann [1].

Linear, affine, and relevant types do not support all of the structural properties (see Section 70.3) found by most type systems. They are used to model resources that cannot be forged or forgotten. Walker gives an overview of this area [60].

Session types describe the protocols that govern how channels must be used in distributed systems [53]. Dezani-Ciancaglini and de’Liguoro [11] provide an introduction.

Security types track the flow of information and the integrity of data values through the execution of programs. These types include capabilities for various principals, and ensure, for example, that high-security data is not read by low-security principals [50].

Effect types talk about the properties of computations. Basic variants distinguish between pure and impure code; more precise systems can track memory usage, resource usage, potentially thrown exceptions, and running time. Henglein et al. [21] give an overview.

70.3 Reasoning about Type Systems

The preceding section individually describes the components of formal type systems piecemeal. After these pieces are assembled, it is natural to ask what properties are true of the system as a whole. Now that we have made the semantics of the type system formal, we can return to the properties discussed in Section 70.1.2 and examine them more rigorously.

Syntax

$$\Gamma ::= \varepsilon | \Gamma, x : \tau | \Gamma, \alpha : \star$$

$$\tau ::= \mathbf{bool} | \alpha | \tau \rightarrow \tau | \forall \alpha : \star. \tau$$

FIGURE 70.15 System F with boolean values.

The exact statement of these properties varies from system to system. Therefore, for concreteness, this section states and proves theorems about System F, the explicitly-typed polymorphic language with boolean values listed in Figure 70.15. Working with an explicitly-typed language simplifies some of the metatheory that follows. We discuss type inference, the process of producing explicit type annotations, in Section 70.4.

70.3.1 Structural Properties of Judgments

First, the typing judgments of System F satisfy a number of *structural* properties regarding the treatment of assumptions in the typing context. These properties are not that interesting in their own regard, but they provide the foundation for more significant theorems.

The first property, called *weakening*, states that irrelevant assumptions do not invalidate typing judgments. (Recall that the notation Γ, Γ' refers to the concatenation of two typing contexts.)

Lemma 70.1 (Weakening for typing)

If $\Gamma, \Gamma' \vdash e : \tau$ and $x \notin \text{dom}(\Gamma, \Gamma')$ and $\Gamma \vdash \tau' : \star$, then $\Gamma, x:\tau', \Gamma' \vdash e : \tau$.

The proof of this theorem, and all of the others in this subsection, is a simple induction on the typing derivation. We do not give the details here but refer readers to other sources [41].

In fact, there are several weakening lemmas that hold for this type system. Type variables may also be added to the context.

Lemma 70.2 (Type variable weakening for typing)

If $\Gamma, \Gamma' \vdash e : \tau$ and $\alpha \notin \text{dom}(\Gamma, \Gamma')$, then $\Gamma, \alpha:\star, \Gamma' \vdash e : \tau$.

Furthermore, weakening of both type and term variables holds for the other two judgments of the type system, type formation $\Gamma \vdash \tau : \star$ and context formation $\Gamma \vdash \diamond$. We can concisely cover all cases at once, including the two lemmas given earlier, by stating a general form of weakening for all judgments.

Lemma 70.3 (Weakening)

1. If $\Gamma, \Gamma' \vdash \mathfrak{J}$ and $\alpha \notin \text{dom}(\Gamma, \Gamma')$ then $\Gamma, \alpha:\star, \Gamma' \vdash \mathfrak{J}$
2. If $\Gamma, \Gamma' \vdash \mathfrak{J}$ and $x \notin \text{dom}(\Gamma, \Gamma')$ and $\Gamma \vdash \tau : \star$ then $\Gamma, x:\tau, \Gamma' \vdash \mathfrak{J}$

The inverse of weakening is *strengthening*, the ability to remove irrelevant assumptions from the context. Variables are irrelevant if they do not appear freely in contexts, expressions, or types. Strengthening is true for all judgments, for both type and term variables. The notation $\text{fv}(\Gamma)$ and $\text{fv}(\mathfrak{J})$ calculates the set of free variables appearing in the range of typing contexts Γ and in the components of assertions \mathfrak{J} , respectively.

Lemma 70.4 (Strengthening)

1. If $\Gamma, \alpha:\star, \Gamma' \vdash \tau : \star$ and $\alpha \notin \text{fv}(\Gamma') \cup \text{fv}(\mathfrak{J})$, then $\Gamma, \Gamma' \vdash \mathfrak{J}$.
2. If $\Gamma, x:\tau, \Gamma' \vdash \mathfrak{J}$ and $x \notin \text{fv}(\mathfrak{J})$, then $\Gamma, \Gamma' \vdash \mathfrak{J}$.

The next structural property, *exchange*, states that the order of assumptions does not matter. Again, this property holds for all orderings of term and type variables, in all judgments. There is one caveat: term variable assumptions can only move in front of type variable assumptions when the latter does not appear in the type of the former.

Lemma 70.5 (Exchange)

1. If $\Gamma, x:\tau_1, y:\tau_2, \Gamma' \vdash \mathfrak{J}$ then $\Gamma, y:\tau_2, x:\tau_1, \Gamma' \vdash \mathfrak{J}$.
2. If $\Gamma, \alpha:\star, \beta:\star, \Gamma' \vdash \mathfrak{J}$ then $\Gamma, \beta:\star, \alpha:\star, \Gamma' \vdash \mathfrak{J}$.

3. If $\Gamma, x:\tau_1, \alpha:\star, \Gamma' \vdash \mathfrak{J}$ then $\Gamma, \alpha:\star, x:\tau_1, \Gamma' \vdash \mathfrak{J}$.
4. If $\Gamma, \alpha:\star, y:\tau_2, \Gamma' \vdash \mathfrak{J}$ and $\Gamma \vdash \tau_2 : \star$ then $\Gamma, y:\tau_2, \alpha:\star, \Gamma' \vdash \mathfrak{J}$.

The *substitution* lemmas justify assumptions. Types can be substituted for type variables in any judgment.

Lemma 70.6 (Type variable substitution)

If $\Gamma, \alpha:\star, \Gamma' \vdash \mathfrak{J}$ and $\Gamma \vdash \tau : \star$ then $\Gamma, [\tau/\alpha]\Gamma' \vdash [\tau/\alpha]\mathfrak{J}$.

Furthermore, term variables can be replaced with a term of the same type in the typing judgment. (Term variables do not appear freely in types or contexts so there is no need for a general substitution lemma.)

Lemma 70.7 (Term variable substitution)

If $\Gamma, x:\tau, \Gamma' \vdash e : \tau'$ and $\Gamma \vdash e' : \tau$, then $\Gamma, \Gamma' \vdash [e'/x]e : \tau'$.

The final structural rule encodes an invariant that we maintain about the type system—all parts of a judgment are well formed. For example, if a term type checks, then the context and its type are also well formed.

Lemma 70.8 (Regularity/generation)

1. If $\Gamma \vdash \tau : \star$ then $\Gamma \vdash \diamond$.
2. If $\Gamma \vdash e : \tau$ then $\Gamma \vdash \diamond$ and $\Gamma \vdash \tau : \star$.

70.3.2 Syntactic Type Soundness

The most fundamental property of a type system is that of *type soundness*. This property captures the slogan (due to Milner [30]) that “well-typed programs don’t go wrong.” Said another way, a type system can be used to distinguish terms that have well-defined semantics from those that are syntactically correct but meaningless.

There are many ways to give a semantics to the expressions of a programming language. With *operational semantics*, the meaning of a program is given by its computational behavior or operation. A *small step* operational semantics (Figure 70.16) describes the meaning of an expression as a potentially infinite sequence of rewriting steps of the form $e \rightarrow e'$. The rules of this semantics come in two flavors: they either directly eliminate various data structures (rules BETA, TBETA, IFTRUE, and IFFALSE) or search through the term looking for a primitive reduction (rules IFCONG, APPCONG, and TCONG). This semantics is deterministic; any expression can step to at most one result. The reflexive transitive closure of this relation, written $e \rightarrow \star e'$, models any number of steps of evaluation. We say that an expression e *cannot step* if there is no e' such that $e \rightarrow e'$.

There are two sorts of expressions that cannot step. The first sort are the *values*, v , the desired results of a successfully concluded computation. In System F, values include boolean values, functions and type abstraction.

$$v ::= \mathbf{ture} + \mathbf{false} \mid \lambda x:\tau.e \mid \Lambda \alpha:\kappa.e$$

$$\begin{array}{c}
\frac{}{(\lambda x.e)e' \rightarrow [e'/x]e} \text{ BETA} \qquad \frac{}{\text{if true then } e_1 \text{ else } e_2 \rightarrow e_1} \text{ IFTRUE} \\
\frac{}{(\lambda \alpha:\kappa.e)\langle \tau \rangle \rightarrow [\tau/\alpha]e} \text{ TBETA} \qquad \frac{}{\text{if false then } e_1 \text{ else } e_2 \rightarrow e_2} \text{ IFFALSE} \\
\frac{e_1 \rightarrow e'_1}{\text{if } e_1 \text{ then } e_2 \text{ else } e_3 \rightarrow \text{if } e'_1 \text{ then } e_2 \text{ else } e_3} \text{ IFCONG} \\
\frac{e_1 \rightarrow e'_1}{e_1 e_2 \rightarrow e'_1 e_2} \text{ APPCONG} \qquad \frac{e \rightarrow e'}{e\langle \tau \rangle \rightarrow e'\langle \tau \rangle} \text{ TCONG}
\end{array}$$

FIGURE 70.16 Small-step operational semantics for System F.

All other expressions that cannot step are called *stuck* terms. For example, **true** ($\lambda x:\mathbf{bool}.x$) is stuck because no rule in Figure 70.16 applies.

The type soundness theorem asserts that well typed expressions must either diverge (i.e., reduce forever) or eventually produce values. This theorem is also called “Type Safety” [62]. They cannot get stuck. By ruling out stuck terms, this theorem asserts that well-typed expressions evaluate using only the behaviors described by the operational semantics.*

We can formally state this property with the following theorem:

Theorem 70.1 (Type soundness)

If $\varepsilon \vdash e : \tau$, then either e diverges or there exists some v such that $e \rightarrow \star v$.

The proof of type soundness derives from two separate results, *preservation* and *progress* [62]. Suppose the expression e does not diverge, but steps to some e' which cannot make any more steps. Preservation states that rewriting an expression does not change its type, so we know that e' is also well typed. Progress states that well typed expressions are either values or can step. However, we assumed that e' cannot make any more transitions, so it must be a value.

Theorem 70.2 (Preservation)

If $\Gamma \vdash e : \tau$ and $e \rightarrow e'$ then $\Gamma \vdash e' : \tau$

The proof of the preservation theorem is by induction on the typing derivation using the substitution and weakening lemmas. This theorem is sometimes called *Subject Reduction* after a similar result in proof theory.

Theorem 70.3 (Progress)

If $\varepsilon \vdash e : \tau$ then either e is a value, or there exists some e' such that $e \rightarrow e'$.

The proof of the progress theorem relies on the following canonical forms lemma. This lemma tells us that the type of a value is all we need to know to discern its form.

* There are no divergent terms in System F. However, this version of the type soundness theorem cannot derive that fact. Consequently, the same proof technique can be used for languages with nontermination.

Lemma 70.9 (Canonical forms)

1. If $\varepsilon \vdash v : \mathbf{bool}$ then v is **true** or **false**.
2. If $\varepsilon \vdash v : \tau_1 \rightarrow \tau_2$ then v is some function $\lambda x:\tau.e$.
3. If $\varepsilon \vdash v : \forall\alpha:\star.\tau$ then v is some type abstraction $\Lambda\alpha:\star.e$.

In System F, the proof of the canonical forms lemma is by mere inspection of the typing rules. For each appropriate form of value, there is only one type that it can be assigned. However, the proof of this lemma is not as straightforward in the presence of nontrivial type equality (Section 70.2.8) or subtyping (Section 70.2.9).

The appeal of small-step semantics is extensibility. The language can be extended with many sorts of structure, yet the proof of type soundness is still elementary. In particular, the techniques listed earlier are amenable to constructs such as tuples, disjoint unions, recursive functions, and data structures and objects. Furthermore, mutable state and exceptions require small revisions to the statements of the lemmas and theorems given earlier (e.g., allowing programs to throw exceptions as well as diverge or terminate with values). The reference *Types and Programming Languages* [41] gives the details of these extensions.

70.3.3 Equivalence and Parametricity

An important notion in the semantics of programming language is the definition of program equivalence. This relation is a prerequisite for arguing about the correctness of a compiler optimization, or even trying to prove that a program behaves as expected. But what does it mean for two λ -calculus terms to be equal? What about terms from System F?

The operational semantics presented in the last section gives a starting point for a definition of equivalence but it is not satisfactory. Consider the following naïve version of equivalence: two expressions are equal exactly when they both evaluate to the same value or when they both diverge. This definition makes sense for expressions of type **nat** or **bool**, but it fails to identify some “obviously equal” expressions. For example, $\lambda x:\mathbf{nat}.x + 1$ and $\lambda x:\mathbf{nat}.1 + x$ are not equal with this definition.

What is a better definition of equivalence? The gold standard is *contextual equivalence*, which identifies the most terms that can be done so in a manner consistent with the operational semantics. Informally, two expressions of type τ are *contextually equal*, written $e \simeq_\tau e'$, if there is no program context that can distinguish them. For base types such as booleans, contextual equivalence coincides with the naïve equivalence defined above—a program context can only observe whether the result of the computation is **true**, **false** or divergence. But for functions, contextual equivalence is much coarser. There is no program context that can distinguish between $\lambda x:\mathbf{nat}.x + 1$ and $\lambda x:\mathbf{nat}.1 + x$. Furthermore, abstract types can restrict the ability of the context to make distinctions. For example, the terms **pack** $\langle \mathbf{bool}, \mathbf{true} \rangle$ as $\exists\alpha:\star.\alpha$ and **pack** $\langle \mathbf{bool}, \mathbf{false} \rangle$ as $\exists\alpha:\star.\alpha$ are contextually equivalent because any context must use these terms with type $\exists\alpha:\star.\alpha$.

However, showing that two programs are contextually equivalent can be difficult. Given two expressions, how can we rigorously argue that there is no context that can tell them apart?

Fortunately, we can use types as the basis for a definition of equivalence for System F, written $e_1 \sim_\tau e_2 [\eta]$. We define this relation by recursion on the structure of the type τ .

This relation takes an argument η as part of its definition. This argument is a finite map from type variables to binary relations R . The empty map is written ε , and the notation $\eta, \alpha \mapsto R$ extends a map η with a new association from the type variable α to some relation $R:\tau_1 \Leftrightarrow \tau_2$ between closed expressions of types τ_1 and τ_2 . The notation $\eta(\alpha)$ looks up the binary relation associated with the type variable α .

Definition 70.1 (Logical equivalence)

Define the relation between closed expressions $e \sim_{\tau} e' [\eta]$ by induction on the structure of τ as follows:*

$$\begin{aligned}
 e \sim_{\mathbf{bool}} e' [\eta] &\triangleq e \simeq_{\mathbf{bool}} e' \\
 e \sim_{\tau_1 \rightarrow \tau_2} e' [\eta] &\triangleq e_1 \sim_{\tau_1} e'_1 [\eta] \text{ implies } e_1 \sim_{\tau_2} e_2 [\eta] \\
 e \sim_{\alpha} e' [\eta] &\triangleq \eta(\alpha)(e, e') \\
 e \sim_{\forall \alpha : \star. \tau} e' [\eta] &\triangleq \text{for every } \varepsilon \vdash \tau_1 : \star, \varepsilon \vdash \tau_2 : \star \text{ and admissible } R : \tau_1 \Leftrightarrow \tau_2, \\
 &\quad e\langle \tau_1 \rangle \sim_{\tau} e'\langle \tau_2 \rangle \quad [\eta, \alpha \mapsto R]
 \end{aligned}$$

For expressions of type **bool**, this relation coincides with contextual (and naïve) equivalence. Two expressions of type **bool** are related when they both evaluate to **true**, both evaluate to **false**, or both diverge. Expressions with function type are related *logically*: they are related when they take related arguments to related results. Therefore, we call this relation a *logical relation*.

The last two cases of the definition, for type variables and quantified types, involve the finite map η . This map directly specifies the relation that is used when the type is a variable. Finally, the relation for polymorphic types includes all expressions that, when given any pair of closed types and *any admissible* relation between those types, produces related results. A relation R is admissible if it is one that respects contextual equivalence (i.e., if two terms are related, then all terms contextually equivalent to the first are related to all terms contextually equivalent to the second).

For this relation to make sense as a definition of equivalence, it must be an equivalence relation. Symmetry and transitivity are easy to show by induction on the structure of τ . However, to show that the relation is reflexive, we must extend this definition to open terms—two open terms are equivalent if a closing substitution of related terms produces related results. We can then show reflexivity of the open logical equivalence for all well-typed expressions.

In fact, not only is logical equivalence an equivalence relation, but it is the *same* relation as contextual equivalence. Therefore, to show that two terms are contextually equivalent, we need only show that they are logically equivalent.

For System F, the reflexivity property also goes by the name *parametricity* and is valuable for reasoning about parametric polymorphism. For example, by looking at the definition of logical equivalence, we can derive that the behavior of a program is not affected by the types that are used to instantiate polymorphic functions. If there were such a dependence, then the definition would not be free to choose any pair of types in the last line. This property justifies the type erasure step in the compilation of ML and Haskell programs. Types cannot influence computation so they are not needed at run time.

Furthermore, if we extend the aforementioned definition to include existential types, parametricity means that we can reason about type abstraction. If the type of a data structure is hidden, then it could be anything. Abstract data structures provide *representation independence*—they can be arbitrarily replaced by any other implementation, as long as there is some relation between them.

Another consequence of parametricity is the derivation of “free theorems,” properties that can be concluded about polymorphic functions merely by looking at their types [58]. For example, we can use parametricity to show that there is only one expression of type $\forall \alpha : \star. \alpha \rightarrow \alpha$ up to contextual equivalence. All expressions of this type must behave like the polymorphic identity function $\Lambda \alpha : \star. \lambda x : \alpha. x$.

The structure of the parametricity theorem is similar to Girard’s proof that all well-typed System F expressions terminate [17]. In particular, the flexibility of quantifying over all admissible relations in the last case of the definition resembles “Girard’s trick” of quantifying over all “reducibility candidates” [15].

* This definition of logical equivalence is adapted from *Practical Foundations for Programming Languages* [19].

However, despite this similarity, parametricity is not limited to terminating languages. Techniques such as syntactic minimal invariance [4,9], top-top closure [45], and step-indexing [12], can be used to extend parametricity results to languages with features such as recursive functions, recursive types, and mutable state.

70.3.4 Machine Assistance for Formal Reasoning

Type systems for real languages are large and the proofs of their fundamental properties, such as preservation and progress, can be tedious. These proofs are not difficult. They often follow similar patterns and use similar lemmas in their development. What is difficult is managing the details to make sure that all interactions between various features are accounted for. Subtle flaws can lead to security holes, especially when type soundness guarantees are used to justify the security of software systems.

Fortunately, a number of reasoning tools exist to help language designers and type system researchers in their work.

One way to find bugs in type system designs is to test them. Tools such as the Twelf System [39] or PLT/Redex [13] assist in the creation of simple reference implementations. Automatic test case generation can help language designers find counterexamples to preservation or progress. The presence of an implementation also assists in the exploration of the expressiveness of the language—demonstrating that desirable programs actually do type check.

Some researchers use logical frameworks and proof assistants to develop and check their formal proofs. There are many suitable tools for this purpose; we mention only a few here. More information on this topic is available from the results of the POPLMARK challenge [55]. The Twelf System [20,39] supports syntactic reasoning. Through using higher-order abstract syntax and hypothetical judgments, many structural rules of the type system, such as substitution and weakening, are automatic. Nominal Isabelle [56] provides a first-order treatment of bound variables, allowing expressive binding patterns in the context of a general purpose logic. Although the Coq proof assistant [54] is a general purpose tool for formal mathematics and does not provide specific support for type system representation, many researchers have used it for this purpose [40,43].

The Ott tool [51] provides assistance for type setting the syntax of programming languages and judgments. It was used to produce this text. The same definitions can also be used to produce input for systems such as OCaml, Twelf, Coq, and Isabelle/HOL so that the paper, reference implementation, and formal system can be synchronized.

70.4 Type Inference

In Section 70.2, we used local annotations to ensure that that it is always possible to type check programs. For several constructs of the language, we introduced both implicit and explicit forms, pointing out sufficient information that ensures that type checking is syntax directed. Of course, the proposed annotations are not the only solution—there are many similar strategies that take advantage of local information during type checking [44].

However, type annotations are not the only way to define an algorithm for type checking. Sometimes ambiguities in the typing process can be resolved through static analysis. This process is called *type reconstruction* or *type inference*. The task is, when given an implicitly-typed program e and a typing environment Γ , to find an explicitly-typed program e' and type such that $\Gamma \vdash e:\tau$ if and only if $\Gamma \vdash e':\tau$.

70.4.1 Constraint-Based Type Inference

Constraint-based type inference breaks the problem of type reconstruction into two steps. First, traverse the program collecting constraints that must be satisfied in order for the program to type check. Next, determine if those constraints are indeed satisfiable.

Type reconstruction for implicitly-typed STLC requires the following simple system of constraints. Here, a constraint is an equality between types, the trivial constraint, or a conjunction of constraints:

$$C ::= \{\tau_1 = \tau_2\} \mid \mathbf{true} \mid C_1 \cup C_2$$

A constraint is satisfiable if there is some substitution for the type variables such that every equality is between syntactically equal types.

For example, given an expression $\lambda x.x\ 1$, we can elaborate it to an expression $\lambda x:\alpha.x\ 1$, with type $\alpha \rightarrow \beta$ under the constraint $\{\alpha = \mathbf{nat} \rightarrow \beta\}$. We can satisfy the constraint with a substitution that maps α to $\mathbf{nat} \rightarrow \beta$, so we know that $\lambda x.x\ 1$ type checks with type $(\mathbf{nat} \rightarrow \beta) \rightarrow \beta$.

On the other hand, the expression $\lambda x.x\ x$ produces the constraint $\{\alpha = \alpha \rightarrow \beta\}$. This constraint is not satisfiable by any substitution, so $\lambda x.x\ x$ does not type check.

For STLC (the language of Section 70.2.2), we can informally define constraint generation with the rules in Figure 70.17. These rules are syntax directed and specify an algorithm that, given a context Γ and expression e , produces a type τ and constraint C . If this constraint is satisfiable, then there is some valid typing derivation for the program e .

The rules in the figure are informal because they include “freshness assumptions,” written α **fresh**. This precondition asserts that the type variable α is freshly generated by the algorithm and distinct from all other variables. This new variable may appear in the output types and constraints. This informality can be resolved via bookkeeping, for example, threading a supply of fresh variables through the judgment.

The rules define a total algorithm by structural recursion over the input expression. For variables, this algorithm emits the type specified in the context and a trivial constraint. For functions, constraint generation for the body of the function uses a freshly generated type variable as the type of the argument. The generated constraints may constrain this variable depending on how that argument is used.

Constraint generation for application expressions uses a fresh type variable as the result type of the application. It determines the type of the function and arguments and then constrains the type of the function to have domain equal to the argument type. Likewise, for **if** expressions, the result constrains the type of the scrutinee of the **if** expression to be a boolean and constrains the two branches to have equal types.

FIGURE 70.17 Constraint generation for STLC.

For example, we can use these rules to calculate the constraint for the expression $\lambda x.x\ 1$. The produced type is $\alpha \rightarrow \beta$ under the constraint $\mathbf{true} \cup \mathbf{true} \cup \{\alpha = \mathbf{nat} \rightarrow \beta\}$.

$$\frac{\frac{\varepsilon, x : \alpha \mapsto x : \alpha, \mathbf{true} \quad \varepsilon, x : \alpha \mapsto 1 : \mathbf{nat}, \mathbf{true} \quad \beta \text{ fresh}}{\varepsilon, x : \alpha \mapsto x\ 1 : \beta, \mathbf{true} \cup \mathbf{true} \cup \{\alpha = \mathbf{nat} \rightarrow \beta\}} \quad \alpha \text{ fresh}}{\varepsilon \mapsto \lambda x.x\ 1 : \alpha \rightarrow \beta, \mathbf{true} \cup \mathbf{true} \cup \{\alpha = \mathbf{nat} \rightarrow \beta\}}$$

If the constraint is satisfiable, *unification* [49] can rewrite it into a “solved form,” θ . A constraint is in solved form if it can be viewed as a substitution. In other words, the constraint is *solved* when it is either \mathbf{true} or a sequence of the form $\{\alpha_1 = \tau_1\} \cup \dots \cup \{\alpha_i = \tau_i\}$, where the variables $\alpha_1 \dots \alpha_i$ are distinct and do not appear in $\tau_1 \dots \tau_i$.

Constraint generation is a total operation, but unification only succeeds if the constraint is satisfiable.

Type inference for STLC is sound and complete with respect to the Curry-style type system. Any program that produces a satisfiable constraint type checks without annotations. Likewise, all well-typed programs produce satisfiable constraints.

Theorem 70.4 (Soundness)

If $\Gamma \mapsto e : \tau$, C and $Unify(C) = \theta$ then $\theta(\Gamma) \vdash e : \theta(\tau)$

Theorem 70.5 (Completeness)

If $\Gamma \vdash e : \tau$ and $\Gamma \mapsto e : \tau_1$, C , then there is some θ such that $Unify(C) = \theta$ and $\theta(\tau_1) = \tau$

70.4.2 The Hindley–Milner Type System

The constraint generation process of the previous section directly extends to tuples, records, sums, and variants. We can also adapt the procedure to include recursive types. However, it does not extend to the polymorphic language in Section 70.2.6. In fact, type reconstruction for implicitly-typed System F is known to be undecidable [38,61].

How do languages like Haskell and ML accommodate polymorphism with type inference? The answer is that they restrict the uses of polymorphism to a tractable subset. This subset, called the Hindley–Milner (HM) (or Damas–Hindley–Milner) type system [10,22] restricts polymorphic types to *prenex quantification*. Instead of allowing quantification to appear anywhere in types, it must occur only at the top level.

The HM type system divides types into two sorts: *polytypes* that contain top-level quantification and *monotypes* that do not. Next we use σ for types that may start with a universal quantifier, and τ for types that contain no quantifiers whatsoever:

$$\begin{aligned} \text{polytypes } \sigma &::= \forall \alpha : \star . \sigma \mid \tau \\ \text{monotypes } \tau &::= \alpha \mid \tau \rightarrow \tau \mid \mathbf{nat} \mid \mathbf{bool} \end{aligned}$$

Monotypes are a subset of the polytypes and a polytype may or may not start with quantification. In other descriptions of this type system, monotypes are called “types” and polytypes are called “type schemes,” indicating that polytypes can be thought of as a family of types, parameterized by type variables.

$$\boxed{\sigma_1 \leq \tau_2}$$

$$\frac{}{\tau \leq \tau} \text{G_MONO} \quad \frac{[\tau'/\alpha]\sigma \leq \tau}{\forall \alpha : \star. \sigma \leq \tau} \text{G_INST}$$

$$\boxed{\sigma_1 \leq \sigma_2}$$

$$\frac{\sigma_1 \leq \sigma_2 \quad \alpha \quad fv(\sigma_1)}{\sigma_1 \leq \forall \alpha : \star. \sigma_2} \text{G_SKOL}$$

FIGURE 70.18 More-general relation.

A polytype σ *generalizes* a monotype τ , written $\sigma \leq \tau$, when τ is a substitution instance of the quantified variables of σ . This relation is defined at the top of Figure 70.18. Equivalently, if σ is of the form $\forall \alpha_1 : \star \dots \forall \alpha_i : \star. \tau'$ then τ must be equal to $[\tau_i/\alpha_i] \dots [\tau_i/\alpha_i] \tau'$. If this relation holds, then conversely, we say that τ is an *instance* or *specialization* of σ .

For example, the polytype $\forall \alpha : \star. \alpha \rightarrow \alpha$ generalizes the monotypes $\mathbf{nat} \rightarrow \mathbf{nat}$ and $\mathbf{bool} \rightarrow \mathbf{bool}$.

We can extend this relation to a judgment between polytypes. We say that σ_1 is *more general than* σ_2 when the judgment $\sigma_1 \leq \sigma_2$ is derivable using the last rule in Figure 70.18. If σ_1 is more general than σ_2 , then any instance of σ_2 is also an instance of σ_1 . For example, the polytype $\forall \alpha : \star. \alpha \rightarrow \alpha$ is more general than the polytype $\forall \alpha : \star. \forall \beta : \star. (\alpha \rightarrow \beta) \rightarrow (\alpha \rightarrow \beta)$ and the monotype $(\mathbf{nat} \rightarrow \mathbf{bool}) \rightarrow (\mathbf{nat} \rightarrow \mathbf{bool})$ is an instance of both polytypes.

The HM type system uses the distinction between monotypes and polytypes to restrict the typing rules of an implicit, polymorphic λ -calculus, as shown in Figure 70.19. The restrictions show up in two places: functions must take monotypes as arguments (rules HM_ABS and HM_APP) and polymorphism can only be instantiated with monotypes (rule HM_INST).

A nonessential difference between this system and the implicit system of Section 70.2.6 is that type variables are not recorded in the typing context. This bookkeeping is unnecessary because all polymorphism in this system is first order (i.e., all variables have kind \star). As a result, all types are well formed and there is no need for the $\Gamma \vdash \tau : \star$ judgment. This system ensures that generalized type variables in rule HM_GEN are unique and unconstrained by ensuring that they do not appear free in the typing environment.

If a program type checks using a derivation produced by these rules, then the Damas–Milner type inference *algorithm* will be able to infer its type. As in the previous section, this algorithm

$$\boxed{\Gamma \vdash_{HM} e : \tau}$$

$$\frac{(x : \sigma) \in \Gamma}{\Gamma \vdash_{HM} x : \sigma} \text{HM_VAR}$$

$$\frac{\Gamma, x : \tau_1 \vdash_{HM} e : \tau_2}{\Gamma \vdash_{HM} \lambda x. e : \tau_1 \rightarrow \tau_2} \text{HM_ABS}$$

$$\frac{\Gamma \vdash_{HM} e_1 : \tau_1 \rightarrow \tau_2 \quad \Gamma \vdash_{HM} e_2 : \tau_1}{\Gamma \vdash_{HM} e_1 e_2 : \tau_2} \text{HM_APP}$$

$$\frac{\Gamma \vdash_{HM} e_1 : \sigma \quad \Gamma, x : \sigma \vdash_{HM} e_2 : \sigma'}{\Gamma \vdash_{HM} \mathbf{let } x = e_1 \mathbf{ in } e_2 : \sigma'} \text{HM_LET}$$

$$\frac{\Gamma \vdash_{HM} e : \sigma \quad \alpha \notin fv(\Gamma)}{\Gamma \vdash_{HM} e : \forall \alpha : \star. \sigma} \text{HM_GEN}$$

$$\frac{\Gamma \vdash_{HM} e : \forall \alpha : \star. \sigma}{\Gamma \vdash_{HM} e : [\tau/\alpha]\sigma} \text{HM_INST}$$

FIGURE 70.19 Hindley–Milner polymorphism.

generates constraints by traversing an expression and solves them via unification to determine whether the expression is typeable.

Although the HM type system allows polytypes to be instantiated and generalized anywhere in the typing derivation, the algorithm uses instantiation and generalization only at specific points in the expression. Instantiation occurs only at the uses of variables—if a variable has a polymorphic type in the context, then all of its type arguments are immediately instantiated with fresh unification variables. Furthermore, generalization only occurs at **let**-binding. All free type variables in the type of the right-hand-side of a **let**-expression are generalized by the algorithm.

Even though the rules in Figure 70.19 do not have the uniqueness of types property, the Damas–Milner algorithm is able to type check the same programs as the rules. For example, according to the rules, the expression $\lambda x.x$ can be given the types $\mathbf{nat} \rightarrow \mathbf{nat}$ and $\forall\alpha:\star.\alpha \rightarrow \alpha$. The algorithm produces the type $\forall\alpha:\star.\alpha \rightarrow \alpha$ for this expression because that is the more general type according to the \leq relation. In fact, for any typeable expression, there is exactly one most general type for that expression, called the principal type. The algorithm works by always inferring this type.

Theorem 70.6 (Principal types)

If e is typeable, then there is some type σ , such that for all other types σ' that e could be typed with in the same context, $\sigma \leq \sigma'$.

The principal type theorem was first shown for a simple type system without let-expressions by Hindley [22] and was then extended to let polymorphism by Damas and Milner [10]. A modern treatment of this result and thorough discussion appears in Pottier and Rémy [46].

HM polymorphism is a “sweet spot” for implicitly-typed functional languages. It has been difficult to extend this type system with greater expressivity while retaining full type inference. One exception is rank two polymorphism, where functions may take polymorphic functions as arguments but restricts quantifiers from appearing to the left of two or more arrows [26].

However, by relaxing the requirement of complete inference, modern functional languages incorporate many extensions of HM polymorphism. Polymorphic recursion [34], higher-rank polymorphism [16,36], and existential types [27] can be adapted using annotations. Annotations also allow the MLF type system [28] to include first-class polymorphism as in System F. The HM(X) type system [37] formalizes an extension with quantification over arbitrary constraints drawn from arbitrary constraint systems. The OCaml compiler uses constraints for subtyping and row types [47], whereas the GHC compiler uses constraints for type classes, GADTs and type-level functions [57].

70.5 Conclusion

This chapter is intended as an entry point to the field of type systems research. It provides a foundation for the mathematical modeling of type systems, defining the prevalent notation, terminology and structures. The type systems featured in recent research papers use the same tools and methods that we have presented here and sometimes use similar notation. In particular, these papers employ inference rules and judgments for the definitions of the type system, base their model of computation on the λ -calculus, and prove preservation and progress theorems.

The study of type systems themselves frame a modern approach to programming language research. The precision that the study of type systems requires extends to a general study of programming language semantics. The formalisms that are the basis of type systems research give benefits to related endeavors, including language design, compiler construction, tool development, language learning, and program understanding. Furthermore, type systems provide several layers of understanding—computation can

be modeled not just in terms of what it does at run time, but also what can be known about it at compile time. Finally, type systems maintain the connection between programming languages and logic, continuing a long tradition of cross-fertilization.

Key Terms

Abstract type: A type whose representation is hidden, so that the only interactions that it supports are declared by its interface.

α -equivalence: An equivalence relation that identifies terms up to systematic renaming of bound variables.

Axiom: An inference rule with no premises.

Capture-avoiding substitution: The substitution of a term e_1 for a free variable in another term e_2 , where the bound variables of e_2 are renamed to avoid capturing the free variables in e_1 .

Church-style: An explicitly-typed language.

Compositional type checking: When the type of a compound construct is derived from the types of its subexpressions.

Contravariant: A component of a type where subtyping is defined inversely with respect to the entire type. The primary example is the domain of function types.

Covariant: A component of a type where subtyping is defined analogously with respect to the entire type.

Currying: Transforming a function that takes a tuple of arguments so that it can be partially applied to each argument in turn. For example, currying converts a function of type $(\tau_1 \times \tau_2) \rightarrow \tau$ into a function of type $\tau_1 \rightarrow \tau_2 \rightarrow \tau$.

Curry-Howard Isomorphism: A relationship between type systems and constructive logic, where types correspond to propositions and programs correspond to proofs.

Curry-style: An implicitly-typed language.

Derivation: A tree of judgments obtained by applying the rules of a type system.

First-order type system: A type system that does not include quantified types.

Ill-typed: An expression that cannot be assigned a type using any derivation of a given type system.

Impredicative polymorphism: Polymorphic types, such as $\forall\alpha : \star.\tau$ or $\exists\alpha : \star.\tau$, where the type variable ranges over polymorphic types, including themselves.

Inference rule: A schematic for a typing derivation, declaring the judgment that can be derived (below the line) from premises (the judgments above the line).

Judgment: A proposition about the relationship between the entities of a programming language, including typing context, terms, and types. A derivation is a proof of the validity of a judgment.

Lambda calculus: A foundational model of computation based on functions.

Metatheory: Logical properties that are proven about a type system or programming language.

Predicative polymorphism: Polymorphic types, such as $\forall\alpha : \star.\tau$ or $\exists\alpha : \star.\tau$, where the type variable does not range over all types, but only over some “smaller” collection of types that does not include the types themselves.

Second-order type system: A type system that includes quantified types, either universal or existential.

Static type system: A type system that supports type checking, an algorithm that determines whether a given program is well-typed just by looking at the text of the program at compile time.

Subsumption: A fundamental property of languages with subtyping: any expression of type τ may also be given any supertype of τ .

Subtype and supertype: In a valid judgment $\Gamma \vdash \sigma <: \tau$, σ is a subtype of τ and τ is a supertype of σ . Any context that requires a value of type τ can be safely provided with a value of type σ .

Syntax-directed type system: A set of typing rules that describe a simple algorithm that determines whether an expression is well typed by using the syntactic form of the expression.

Typeable expression: An expression that appears in a derivable typing judgment.

Type checker: The part of the compiler or interpreter that performs type checking.

Type checking: The process of checking a program to make sure that it complies with a given type system.

Type inference: The process of determining the type of a program when it is not directly specified.

Type rule: A component of a type system.

Type system: The collection of rules that describes the types of programs.

Typing environment or typing context: A list of assumptions about the types of variables.

Uniqueness of derivations: For any judgment $\Gamma \vdash e:\tau$, there is at most one derivation.

Uniqueness of types: For any expression e and typing context Γ , there is at most one type τ such that the judgment $\Gamma \vdash e:\tau$, is derivable.

Valid judgment: A judgment that can be derived by a given type system.

Value: A desired result of computation.

Well-typed: An expression that can be assigned a type and appears in a valid typing judgment.

Further Information

Further information about the study of type systems of programming languages is available from several recent textbooks. Pierce's textbook [41], *Types and Programming Languages* is a standard reference and provides an extensive introduction to type systems research and reference for many topics including subtyping, recursive types, and first-order and higher-order polymorphism. The sequel, *Advanced Topics in Types and Programming Languages*, edited by Pierce [42], contains in-depth articles about logical relations, type inference, and many other topics. Robert Harper's recent book, *Practical Foundations for Programming Languages* [19], provides a modern exposition on the technical issues in this chapter. Cardelli's article [7] in *The Computer Science and Engineering Handbook* is an inspiration for this work and provides additional introductory material.

Many ideas that find their way into programming languages have their roots in Type Theory, a foundational logic grounded in computation. Barendregt's article, "Lambda Calculi with Types" [3], discusses Curry and Church-style type systems as well as their relation to logics via the Curry–Howard isomorphism. Nordstrom, Petersson and Smith [35] summarizes Martin-Löf's work, which introduced the notation for judgments and typing rules. Girard, Lafont and Taylor [18] describe the connections between System F and computation.

The latest research papers about type systems appear in the ACM SIGPLAN conferences *Principles of Programming Languages (POPL)*, *International Conference on Functional Programming (ICFP)*, and *Object-Oriented Programming Languages, Systems and Applications (OOPSLA)*.

71.1 Introduction

Computers do not make mistakes, or so we are told. However, computer software is written by, and hardware systems are designed and assembled by, humans, who certainly *do* make mistakes.

Errors in a computer system may be as a result of misunderstood or contradictory requirements, unfamiliarity with the problem, or simply human error during design or coding of the system. Alarming, the costs of maintaining software—the costs of rectifying errors and adapting the system to meet changing requirements or changes in the environment of the system—greatly exceed the original implementation costs.

As computer systems are being used increasingly in safety-critical applications—that is, systems where a failure could result in the loss of human life, mass destruction of property, or significant financial loss—both the media and various regulatory bodies involved with standards, especially covering safety-critical applications (Bowen and Stavridou 1993, Gnesi and Margaria 2012) and security applications (Grumberg et al. 2008) have considered formal methods and their role in the specification and design phases of system development and software engineering for many years (Bjørner 2000).

71.2 Underlying Principles

There can be some confusion over what is meant by a “specification” and a “model.” David Parnas has differentiated between specification and descriptions or models as follows (Parnas 1995):

- A *description* is a statement of some of the actual attributes of a product, or a set of products.
- A *specification* is a statement of properties required of a product, or a set of products.
- A *model* is a product, neither a description nor a specification. Often it is a product that has some, but not all, of the properties of some “real product.”

Others use the terms *specification* and *model* more loosely; a model may sometimes be used as a specification. The process of developing a specification into a final product is one in which a model may be used along the way or even as a starting point.

71.2.1 Formal Methods

Over the last 50 years, computer systems have increased rapidly in terms of both size and complexity. As a result, it is both naive and dangerous to expect a development team to undertake a project without stating clearly and precisely what is required of the system. This is done as part of the *requirements specification* phase of the software life cycle, the aim of which is to describe *what* the system is to do, rather than *how* it will do it.

The use of natural language for the specification of system requirements tends to result in ambiguity and requirements that may be mutually exclusive. Formal methods have evolved as an attempt to overcome such problems by employing discrete mathematics to describe the function and architecture of a hardware or software system, and various forms of *logic* to reason about requirements, their interactions, and validity.

The term *formal methods* is itself misleading; it originates from formal logic but is now used in computing to refer to a plethora of mathematically based activities. For our purposes, a formal method consists of notations and tools with a mathematical basis that are used to unambiguously specify the requirements of a computer system and that support the *proof* of properties of this specification and proofs of correctness of an eventual implementation with respect to the specification.

Indeed, it is true to say that so-called formal methods are not so much methods as formal systems. Although the popular formal methods provide a *formal notation*, or formal specification language, they do not adequately incorporate many of the methodological aspects of traditional development methods.

Even the term *formal specification* is open to misinterpretation by different groups of people. Two alternative definitions for “formal specification” are given in a glossary issued by the IEEE (IEEE 1991):

1. A specification written and approved in accordance with established standards
2. A specification written in a formal notation, often for use in proof of correctness

In this chapter, we adopt the latter definition, which is the meaning assumed by most formal method users.

The notation employed as part of a formal method is “formal” in that it has a mathematical semantics so that it can be used to express specifications in a clear and unambiguous manner and allow us to abstract from actual implementations to consider only the salient issues. This is something that many programmers find difficult to do because they are used to thinking about implementation issues in a very concrete manner.

While programming languages are formal languages, they are generally not used in formal specification, as most languages do not have a full formal semantics, and they force us to address implementation issues before we have a clear description of what we want the system to do. Instead, we use the language of mathematics, which is universally understood, well established in notation, and most importantly enables the generalization of a problem so that it can apply to an unlimited number of different cases. Here we have the key to the success of formal specification—one must *abstract* away from the details of the implementation and consider only the essential relationships of the data, and we can model even the most complex systems using simple mathematical objects: for example, *sets*, *relations*, *functions*, etc.

At the specification phase, the emphasis is on clarity and precision, rather than efficiency. Eventually, however, one must consider how a system can be implemented in a programming language that,

in general, will not support abstract mathematical objects (functional programming languages are an exception) and will be efficient enough to meet agreed requirements and concrete enough to run on the available hardware configuration.

As in structured design methods, the formal specification must be translated to a design—a clear plan for implementation of the system specification—and eventually into its equivalent in a programming language. This approach is known as *refinement* (Back and von Wright 1998).

The process of *data refinement* involves the transition from abstract data types such as sets, sequences, and mappings to more concrete data types such as arrays, pointers, and record structures, and the subsequent verification that the concrete representation can adequately capture all of the data in the formal specification. Then, in a process known as *operation refinement*, each *operation* must be translated so that it operates on the concrete data types. In addition, a number of *proof obligations* must be satisfied, demonstrating that each concrete operation is indeed a “refinement” of the abstract operation—that is, performing at least the same functions as the abstract equivalent, but more concretely, more efficiently, involving less nondeterminism, etc.

Many specification languages have relatively simple underlying mathematical concepts involved. For example, the Z (pronounced “zed”) notation (Spivey 2001, ISO 2002) is based on (typed) set theory and first-order predicate logic, both of which *could* be taught at school level. The problem is that many software developers do not currently have the necessary education and training to understand these basic principles, although there have been attempts to integrate suitable courses into university curricula (Bowen and Reeves 2011).

It is important for students who intend to become software developers to learn how to abstract away from implementation detail when producing a system specification. Many find this process of *abstraction* a difficult skill to master. It can be useful for reverse engineering as part of the software maintenance process, to produce a specification of an existing system that requires restructuring. Equally important is the skill of refining an abstract specification toward a concrete implementation, in the form of a program for development purposes (Morgan 1998).

The process of refinement is often carried out informally because of the potentially high cost of fully formal refinement. Given an implementation, it is theoretically possible, although often intractable, to *verify* that it is correct with respect to a specification, if both are mathematically defined. More usefully, it is possible to *validate* a formal specification by formulating required or expected properties and formally proving, or at least informally demonstrating, that these hold. This can reveal omissions or unexpected consequences of a specification. *Verification* and *validation* are complementary techniques, both of which can expose errors.

71.3 Best Practices

Technology transfer (e.g., see Ball et al. 2004) has always been an issue with formal methods, largely because of the significant training and expertise that is necessary for their use. Most engineering disciplines accept mathematics as the underpinning foundations, to allow calculation of design parameters before the implementation of a product. However, software engineers have been somewhat slow to accept such principles in practice, despite the very mathematical nature of all software. This is partly because it is still possible to produce remarkably reliable systems without using formal methods. In any case, the use of mathematics for software engineering is a matter of continuing debate (Tremblay 2000, Hinchey et al. 2008, Parnas 2010).

There are well-documented and well-established industrial examples in which a formal approach has been taken to develop significant systems in a beneficial manner that are easily accessible by professionals (e.g., see Hinchey and Bowen 1999, Ball et al. 2004). Formal methods, including formal specification and modeling, should be considered as one of the possible techniques to improve software quality, where it can be demonstrated to do this cost-effectively.

In fact, just using formal specification within the software development process has been shown to have benefits in reducing the overall development cost (Bowen and Stavridou 1993). Costs tend to be increased early in the life cycle, but reduced later on at the programming, testing, and maintenance stages, where correction of errors is far more expensive. A formal specification can be especially useful in generating test cases rigorously and cost-effectively (Hierons et al. 2009).

An early and widely publicized successful example of the use of formal methods in industry was the IBM CICS (Customer Information Control System) project, where Z was used to specify a portion of this large transaction processing system with an estimated 9% reduction in development costs. There were approximately half the usual number of errors discovered in the software, leading to increased software quality.

Writing a good specification is something that comes only with practice, despite the existence of guidelines. However, there are some good reasons why a mathematical approach may be beneficial in producing a specification:

Precision: Natural language and diagrams can be very ambiguous. A mathematical notation allows the specifier to be very exact about what is specified. It also allows the reader of a specification to identify properties, problems, etc., which may not be obvious otherwise.

Conciseness: A formal specification, although precise, is also very concise compared with an equivalent high-level language program, which is often the first formalization of a system produced if formal methods are not used. Such a specification can be an order of magnitude smaller than the program that implements it, and hence is that much easier to comprehend.

Abstraction: It is all too easy to become mired in detail when producing a specification, making it very confusing and obscure to the reader. A formal notation allows the writer to concentrate on the essential features of a system, ignoring those that are implementation details. However, this is perhaps one of the most difficult skills in producing a specification.

Reasoning: Once a formal specification is available, mathematical reasoning is possible to aid in its validation. This is also useful for discussing implications of features, especially within a team of designers.

A design team that understands a particular formal specification notation can benefit from the above improvements in the specification process. It should be noted that much of the benefit of a formal specification derives from the process of producing the specification, as well as the existence of the formal specification after this (Hall 1990).

71.3.1 Specification Languages

The choice of specification language is likely to be influenced by many factors: previous experience, availability of tools, standards imposed by various regulatory bodies, and the particular aspects that must be addressed by the system in question. Another consideration is the degree to which a specification language is executable. This is the subject of some dispute, and the reader is directed elsewhere for a discussion of this topic (Hayes and Jones 1989, Fuchs 1992, Bowen and Hinchey 1999). Indeed, the development of any complex system is likely to require the use of multiple notations at different stages in the process and to describe different aspects of a system at various levels of abstraction. As a result, over the last several decades, the vast majority of the mainstream formal methods have been extended and re-interpreted to address issues of concurrency (Milner 1999, Abdallah et al. 2005), real-time behavior (Zhou and Hansen 2003), and object orientation (Duke and Rose 2000, Smith 2000).

There is always, necessarily, a certain degree of trade-off between the expressiveness of a specification language and the levels of abstraction that it supports. While certain languages may have wider “vocabularies” and constructs to support the particular situations that need to be handled, they are likely to force us toward particular implementations; while they will shorten a specification, they will make it less abstract and more difficult for reasoning (Bowen and Hinchey, 1995a).

Formal specification languages can be divided into essentially three classes:

Model-oriented approaches as exemplified by ASM (Abstract State Machines) (Börger and Stärk 2003), B-Method (Schneider 2001), Event-B (Abrial 2010), RAISE (Rigorous Approach to Industrial Software Engineering) (Dang Van et al. 2002), VDM (Vienna Development Method) (ISO 1996), and the Z notation (Spivey 2001, ISO 2002). These approaches involve the derivation of an explicit model of the system's desired behavior in terms of abstract mathematical objects.

Property-oriented approaches using *axiomatic semantics* (such as Larch Gutttag 1993), which use first-order predicate logic to express *preconditions* and *postconditions* of operations over abstract data types, and *algebraic semantics* (such as the OBJ family of languages including CafeOBJ [Futatsugi et al. 2000]), which are based on multisorted algebras and relate properties of the system in question to equations over the entities of the system.

Process algebras such as CSP (Communicating Sequential Processes) (Abdallah et al. 2005) and the π -calculus (Milner 1999), which have evolved to meet the needs of concurrent, distributed, and real-time systems, and which describe the behavior of such systems by describing their algebras of communicating processes.

It is not always possible to classify a formal specification language in just one of the categories above. LOTOS (Language Of Temporal Ordering Specifications) (ISO 1989, Turner 1993), for example, is a combination of ACT ONE and CCS (Calculus of Communicating Systems); while it can be classified as an algebraic approach, it exhibits many properties of a process algebra too. Similarly, the RAISE development method is based on extending a model-based specification language (specifically, VDM-SL) with concurrent and temporal aspects.

As well as the basic mathematics, a specification language should also include facilities for structuring large specifications. Mathematics alone is all very well in the small, but if a specification is a thousand pages long (and formal specifications of this length exist), there must be aids to organize the inevitable complexity. Z provides the *schema notation* for this purpose, which packages up the mathematics so that it can be reused subsequently in the specification. A number of schema operators, many matching logical connectives, allow recombination in a flexible manner.

A formal specification should also include an informal explanation to put the mathematical description into context and help the reader understand the mathematics. Ideally, the natural language description should be understandable on its own, although the formal text is the final arbiter as to the meaning of the specification. As a rough guide, the formal and informal descriptions should normally be of approximately the same length. The use of mathematical terms should be minimized, unless explanations are being included for didactic purposes.

Formal methods have proved useful in embedded systems and control systems (e.g., see Tretmans et al. 2001, Tiwari et al. 2003, Kordon and Lemoine 2010). Synchronous languages, such as Esterel, Lustre and Signal, have also been developed for *reactive systems* requiring continuous interaction with their environment (Benveniste et al. 2003). Specialist and combined languages may be needed for some systems. *Hybrid systems* (Jones et al. 2007) extend the concept of *real-time systems*. In the latter, time must be considered, possibly as a continuous variable. In hybrid systems, the number of continuous variables may be increased. This is useful in control systems where a digital computer is responding to real-world analog signals.

More visual formalisms, such as the well-established Statecharts approach, are available and are appealing for industrial use, with the associated STATEMENT tool support (Harel and Politi 1998) that has been incorporated into the widely used Unified Modeling Language (UML). However, the reasoning aspects and the exact semantics are less well defined. Some specification languages, such as SDL (Specification and Design Language) (Turner 1993), have provided particularly good commercial tool support, which is very important for industrial use.

There have been many attempts to improve the formality of the various structural design notations in widespread use (Bowen and Hinchey 1999). UML includes the Object Constraint Language (OCL) (Warmer and Kleppe 2003) developed by IBM, an expression language that allows constraints to be formalized, but this part of UML is under-utilized with a lack of tool support and is only a small part of UML in any case.

Object orientation is an important development in programming languages that has also been reflected in specification languages. For example, Object-Z is an object-oriented version of the Z notation that has gained some acceptance (Duke and Rose 2000, Smith 2000, Derrick and Boiten 2001). The Perfect Developer tool has been developed by Escher Technologies to refine formal specifications to object-oriented programming languages such as Java.

71.3.2 Modeling Systems

As previously discussed, the difference between specification and modeling is open to some debate. Different specification languages emphasize and allow modeling to different extents. Algebraic specification eschews the modeling approach, but other specification languages such as Z and VDM actively encourage it.

Some styles of modeling have been formulated for specific purposes. For example, Petri nets may be applied in the modeling of concurrent systems using a specific diagrammatic notation that is quite easily formalizable. The approach is appealing, but the complexity can become overwhelming. Features such as deadlock are detectable, but full analysis can be intractable in practice, since the problem of scaling is not well addressed.

Mathematical modeling allows reasoning about (some parts of) a system of interest. Here, aspects of the system are defined mathematically, allowing the behavior of the system to be predicted. If the prediction is correct this reinforces confidence in the model. This approach is familiar to many scientists and engineers.

Executable models allow rapid prototyping of systems (Fuchs 1992). A very high-level programming language such as a functional program or a logic program (which have mathematical foundations) may be used to check the behavior of the system. Rapid prototyping can be useful in demonstrating a system to a customer before the expensive business of building the actual system is undertaken. Again, scientists and engineers are used to carrying out experiments by using such models.

A branch of formal methods known as *model checking* allows systems to be tested exhaustively (Grumberg et al. 2000, Bérard et al. 2001). Most computer-based systems are far too complicated to test completely because the number of ways the system could be used is far too large. However, a number of techniques, *Binary Decision Diagrams* (BDDs) for example, allow relatively efficient checking of significant systems, especially for hardware (Kropf 2000). An extension of this technique, known as *symbolic model checking*, allows even more generality to be introduced.

Mechanical tools exist to handle BDDs and other model-checking approaches efficiently. SPIN is one of the leading general model-checking tools that is widely used (Holzmann 2003). A more specialist tool based on CSP (Abdallah et al. 2005) known as FDR (Failure Divergence Refinement) allows model checking to be applied to concurrent systems that can be specified in CSP.

71.3.3 Conclusion

Driving forces for best practice include standards, education, training, tools, available staff, certification, accreditation, legal issues, etc. A full discussion of these is out of the scope of this chapter. Aspects of best practice for specification and modeling depend significantly on the selected specification notation. One of the more popular formal notations that has been used in industry is Z. To illustrate the way in which this notation is typically used, a case study using Z is presented in the

next section. This demonstrates both some of the underlying principles, and best practice, when employing Z for specification and modeling.

71.4 Case Study

The Z notation (Spivey 2001, ISO 2002) is one of the most widely used formal specification languages and is normally used in a modeling style. An abstract state is first formulated, and then operations on that state are specified. In this section, we present a case study using Z to illustrate this style of specification. The example does not exhaustively present the features of Z, but gives a flavor of the style of presentation of a typical Z specification, with extra informal explanation on the notation and conventions where required. Z constructs are introduced as the example is presented and a glossary of Z notation is provided at the end of the chapter for the convenience of the reader. A basic understanding of set theory and logic will help in understanding the specification.

Window management systems are used extensively for user interfaces to computer systems. The specification given here is of a (fictitious) window system. For more realistic examples of some implemented windows systems presented in Z (see Bowen 2003).

71.4.1 Basic Types

Z is a typed language, which allows a certain amount of consistency checking by a mechanical type-checker. However, the only predefined type is the set of integers, denoted Z . Further types must be defined for a particular specification. These *basic types* (also known as *given sets*) may be introduced as follows:

$$[Position, Value]$$

This provides a set of pixel (picture element) positions (e.g., coordinates on a screen), together with possible pixel values (e.g., colors). Note that we are no more specific than this in the specification presented here. It is important not to introduce irrelevant implementation details into a specification, since this restricts the eventual implementer of the system and clutters the specification with information that is not required at a high level of abstraction.

71.4.2 Abbreviation Definitions

It is often useful to include definitions in a specification for commonly used concepts. This helps to reduce the size of the specification and introduces important concepts to the reader in one place, allowing them to be used later within the specification. Pixel maps, relating pixels to their associated values, are an integral part of most window systems. In fact, each pixel has at most one value (assuming it is defined), so we can model a pixel map as a *partial function* from pixel positions to their values:

$$Pixmap == Position \mapsto Value$$

71.4.3 Generic Definitions

Z has its own library of “tool-kit” operators, formally defined in terms of more basic mathematical concepts, as presented in Spivey (2001). Sometimes it is helpful to extend this library with further *generic definitions* which may be used to define a family of generic constants, applicable to a variety of basic types. Such definitions may be useful for other specifications as well as the one being constructed, allowing reuse of specification components.

For example, a *sequence* of pixel maps may be overlaid in the order given by the sequence to produce a new pixel map. An operator to do this could equally well apply to other partial functions as well as pixel maps, so we can define it generically, using a “distributed overriding” operator:

$$\begin{array}{l} \hline \hline = [P, V] \hline \hline \oplus / : \text{seq } (P \rightarrow V) \rightarrow (P \rightarrow V) \\ \hline \oplus / \langle \rangle = \emptyset \\ \forall p : P \rightarrow V \cdot \oplus / \langle p \rangle = p \\ \forall s, t : \text{seq } (P \rightarrow V) \cdot \oplus / (s \frown t) = (\oplus / s) \oplus (\oplus / t) \\ \hline \hline \end{array}$$

Here, the base cases for the empty sequence $\langle \rangle$ and a singleton sequence $\langle p \rangle$ are considered, followed by the more general case of two arbitrary sequences concatenated together $s \frown t$. Distributed overriding is particularly useful for the specification presented here in specifying the view on a screen of a display, given a sequence of possibly overlapping pixel maps.

Z tool-kit operators normally have a number of laws associated with them, which are helpful in reasoning about specifications. For example, the following law applies for the distributed overriding operator:

$$p_1, p_2 : \text{Pixmap} \vdash \oplus / \langle p_1, p_2 \rangle = p_1 \oplus p_2$$

Such laws must be proved from the original definition. For example, in this case:

$$\begin{aligned} & \oplus / \langle p_1, p_2 \rangle \\ &= \oplus / (\langle p_1 \rangle \frown \langle p_2 \rangle) && \text{(property of } \frown \text{)} \\ &= (\oplus / \langle p_1 \rangle) \oplus (\oplus / \langle p_2 \rangle) && \text{(by the general case definition)} \\ &= p_1 \oplus p_2 && \text{(by the second base case definition, substituting twice)} \end{aligned}$$

If the windows in a sequence overlap, it is useful to be able to move selected windows so that their contents may be viewed (or hidden). This is analogous to stuffing a pile of sheets of paper (windows) on a desk (screen). Note that the sheets of paper may be of different sizes and in different positions on the desk.

For example, the following function may be used to move a selected window number in the sequence (if it exists) to the top of the pile (i.e., the end of the sequence). This can also be defined generically:

$$\begin{array}{l} \hline \hline = [W] \hline \hline \text{top} : \mathbb{N} \rightarrow \text{seq } W \rightarrow \text{seq } W \\ \hline \forall n : \mathbb{N}; s : \text{seq } W \cdot \\ \hline \text{top } n \ s = \text{if } n \in \text{dom } s \ \mathbf{then} \ \text{squash}(\{n\} \triangleleft s) \frown \langle s(n) \rangle \ \mathbf{else} \ s \\ \hline \hline \end{array}$$

If the window number n is in the sequence of windows s then it is removed from the sequence (by eliminating that element and squashing the resulting function back into a sequence). This element is then concatenated to the end of the sequence. If the window number is not valid, the sequence of windows is unaffected. The exact technical details require some knowledge of Z, but the above example illustrates the fact that important concepts can be captured formally using relatively short definitions.

In this simple example, we shall ignore the complication of window identifiers. We simply use the position of the window in the sequence to identify it, assuming that the user of the system keeps track of which window is which.

71.4.4 Abstract System State

The window display may be modeled as a sequence of windows against a background “window” which is the size of the display screen itself. The order of the sequence defines which windows are on top in the case of overlapping windows, in ascending order. Only parts of windows that are contained within the background area are displayed.

SYS <hr/> <i>windows</i> : seq <i>Pixmap</i> <i>screen, background</i> : <i>Pixmap</i> <hr/> <i>screen</i> = <i>background</i> \oplus (dom <i>background</i> \triangleleft \oplus / <i>windows</i>)

In the specification of the abstract state earlier, the components *windows* (a sequence of pixel maps), *screen* (as displayed to the user), and *background* (the display if no windows are present), are packaged together in a **schema** box called *SYS*. The **declarations** with their associated type information are above the line and **predicates** defining constraints between these components are (optionally) included below the line. Here, what appears on the display screen is defined in terms of the background pixel map overridden by the sequence of windows in the system, constrained to the background area as defined by its domain of pixel positions.

The screen area is the same as the background area. This can be formalized as follows:

$$\text{SYS} \vdash \text{dom } \textit{screen} = \text{dom } \textit{background}$$

It is useful to prove such properties correct, either informally, even just mentally, or formally, in order to validate that the specification behaves as expected. Discovering that an expected property does not hold may expose an error in a specification, perhaps in the form of an extra constraint that is required but has been omitted.

Note that the user can see only the display screen. We can specify this view formally by hiding (existentially quantifying) other components in the *SYS* schema to produce a new *View* schema, defined horizontally:

$$\textit{View} \cong \text{SYS} \setminus (\textit{windows}, \textit{background})$$

Initially there are no windows in the system:

$$\textit{InitSYS} \cong [\text{SYS}' \mid \textit{windows}' = \langle \rangle]$$

It is important to define the *initial state* and also to ensure that it exists. (Otherwise the system cannot start to operate.) The state at initialization normally consists of the abstract state for the system with some extra constraints. By including *SYS'* in the definition above, all the components in *SYS* are defined, with the extra decoration ' added to each component name. The prime (or dash) ' is used by convention in Z to indicate the state *after* an operation. Here we are interested in the state after initialization. Again, we can formulate a property to check that our intuition about the specification is correct:

$$\textit{InitSYS} \vdash \textit{screen}' = \textit{background}'$$

That is, the screen display at initialization should consist of just the background.

Next we can define general properties about the *change of state* for operations on the system. By convention in Z, Δ (“delta”) is used to indicate a change of state where both an unprimed *before state* SYS (for example) and a primed *after state* (e.g., SYS') are defined:

$$\Delta SYS \hat{=} [SYS; SYS' \mid background' = background]$$

Here we have added the extra constraint that the background never changes for any operation. This means that we do not have to consider and define this for each individual operation that uses ΔSYS subsequently, since the predicate $background' = background$ is automatically included (conjoined) with any other predicates that are defined.

Note that if the before and after states are not related in an operation scheme, then the after state can take on any value. This is the opposite of most programming languages, where unreferenced variables retain their values by default. However, this style is useful in specifications since it allows *nondeterminism* to be included easily, where more than one outcome of an operation is allowed. Eventually, of course, the implementer will have to choose a particular outcome, but if the choice is not important at the specification level then leaving the options open gives the implementer a greater choice, possibly allowing different optimization strategies in different implementations of the same specification.

Some operations may leave the state of the system unchanged, for example, during a status operation or if an error in the input is detected. Here the Ξ (“xi”) convention is used in Z:

$$\Xi SYS \hat{=} [\Delta SYS \mid \emptyset SYS' = \emptyset SYS]$$

The predicate $\emptyset SYS' = \emptyset SYS$ is a shorthand way of ensuring that the tuple formed from all the SYS components is the same as that formed from all the primed SYS' components.

71.4.5 Operations

In order to use the system, we must have the ability to create windows. These are created on top of all the existing windows. We specify that they must fit within the display background.

$$\begin{array}{l} \text{--- } AddWindow0 \text{ ---} \\ \Delta SYS \\ \textit{window?} : Pixmap \\ \text{---} \\ \text{dom } \textit{window?} \subseteq \text{dom } \textit{background} \\ \textit{windows}' = \textit{windows} \frown \langle \textit{window?} \rangle \\ \text{---} \end{array}$$

In the aforementioned definition, the ΔSYS component automatically includes all the SYS and SYS' unprimed before and primed after state components, together with the constraint that the background remains unchanged. The $\textit{window?}$ component is an input (as indicated by the Z convention of the added “?”). A **precondition** for the operation is that the window area must be contained within (i.e., be a subset of) the background area. If this is so, then the sequence of windows after the operation has the required window concatenated to it. This means that the window appears on top of any other windows already in the system. Note that by default, predicates on separate lines in a schema are conjoined by using “ \wedge .”

The ability to update windows is very useful. This may involve changing the size of the window or its contents or moving it about the screen. Again, the updated window must still fit within the display area.

UpdateWindow0 <hr/> ΔSYS $\text{which?} : \mathbb{N}$ $\text{window?} : \text{Pixmap}$ <hr/> $\text{which?} \in \text{dom windows}$ $\text{dom window?} \subseteq \text{dom background}$ $\text{windows}' = \text{windows} \oplus \{\text{which?} \mapsto \text{window?}\}$

Here two inputs are provided, both which window number is to be updated and the new value for the window. The window to be updated must already be in the system and, as for the *AddWindow0* schema, the new window must be within the background for the update to be successful. The sequence of windows is overridden with a new entry for the selected window.

It is desirable to be able to uncover a window that may be partially or even totally obscured by other windows. This can be done by moving the window to the end of the sequence of displayed windows:

ExposeWindow0 <hr/> ΔSYS $\text{which?} : \mathbb{N}$ <hr/> $\text{which?} \in \text{dom windows}$ $\text{windows}' = \text{top which? windows}$
--

Sometimes it is useful to simply rotate the order of the displayed windows, one at a time, moving the bottommost window to the top.

RotateWindows0 <hr/> ΔSYS <hr/> $\text{windows} \neq \langle \rangle$ $\text{windows}' = \text{top } 1 \text{ windows}$

Note that sequences are numbered from one updates in Z .

We also wish to be able to delete windows. For instance, we could delete the topmost window (the last window in the sequence):

RemoveTop0 <hr/> ΔSYS <hr/> $\text{windows} \neq \langle \rangle$ $\text{windows}' = \text{front windows}$
--

Alternatively, we may wish to specify which window is to be removed:

RemoveWindow0 <hr/> ΔSYS $\text{which?} : \mathbb{N}$ <hr/> $\text{which?} \in \text{dom windows}$ $\text{windows}' = \text{squash}(\{\text{which?}\} \triangleleft \text{windows})$
--

The aforementioned schema definitions give a flavor of the way operations are typically presented in a Z specification. They are intended to illustrate that a number of different operations on a system may be specified succinctly by using Z, providing a suitable abstract state has been formulated.

71.4.6 Error Conditions

The operations covered so far detail what should happen in the event of no errors. Normally operations can also handle error conditions in some controlled manner. It is useful to report the status of an operation. For example, the following reports could be issued:

$$\begin{array}{l} \textit{Report} ::= \text{ "OK" } \\ \quad | \text{ "Not a window" } \\ \quad | \text{ "No windows" } \\ \quad | \text{ "Invalid window" } \end{array}$$

Here a *free type* definition defines *Report* to be a set with four possible unique values.

It is helpful to report the fact that the operation was successful if this is the case:

$$\begin{array}{l} \text{---} \textit{Success} \text{---} \\ \hline \textit{rep!} : \textit{Report} \\ \hline \textit{rep!} = \text{ "OK" } \\ \hline \end{array}$$

By convention in Z, “!” indicates an output from an operation.

If errors do occur, then these need to be reported. For example, an invalid window may be specified:

$$\begin{array}{l} \text{---} \textit{NotAWindow} \text{---} \\ \hline \exists \textit{SYS} \\ \textit{which?} : \mathbb{N} \\ \textit{rep!} : \textit{Report} \\ \hline \textit{which?} \notin \text{dom } \textit{windows} \\ \textit{rep!} = \text{ "Not a window" } \\ \hline \end{array}$$

In this case, no change of state occurs, as specified by $\exists \textit{SYS}$ given earlier. As a precondition, a check is made on whether the window number supplied as an input is not a valid existing window in the system, and if this is so an appropriate report is issued as an output.

It is possible that there are no windows displayed when one is required:

$$\begin{array}{l} \text{---} \textit{NoWindows} \text{---} \\ \hline \exists \textit{SYS} \\ \textit{rep!} : \textit{Report} \\ \hline \textit{windows} = \langle \rangle \\ \textit{rep!} = \text{ "No windows" } \\ \hline \end{array}$$

A specified window may not be within the background area:

$\underline{BadWindow}$ $\exists \text{SYS}$ $window? : Pixmap$ $rep! : Report$	<hr/> $\neg (\text{dom } window? \subseteq \text{dom } background)$ $rep! = \text{“Invalid window”}$
--	---

We may include these errors with the previously defined operations that ignored error conditions to produce *total* operations:

$$AddWindow1 \hat{=} (AddWindow0 \wedge Success) \vee BadWindow$$

$$UpdateWindow1 \hat{=} (UpdateWindow0 \wedge Success) \vee BadWindow \vee NotAWindow$$

$$ExposeWindow1 \hat{=} (ExposeWindow0 \wedge Success) \vee NotAWindow$$

$$RotateWindows1 \hat{=} (RotateWindows0 \wedge Success) \vee NoWindows$$

$$RemoveTop1 \hat{=} (RemoveTop0 \wedge Success) \vee NoWindows$$

$$RemoveWindow1 \hat{=} (RemoveWindow0 \wedge Success) \vee NotAWindow$$

Here the schema operators of conjunction (\wedge) and disjunction (\vee) are used to combine schemas. For both operators, components are merged. If components have the same name, then they must be type-compatible or the specification becomes meaningless. Using schema conjunction, predicates in each schema are logically conjoined. Similarly, if schema disjunction is used, then the predicates in the two schemas are combined using logical disjunction.

The operations are total in that their preconditions are true. This can be checked by calculation, which is a useful way of ensuring that all error conditions have been handled. This is something that is very easily overlooked if only informal specification using natural language and/or diagrams is used.

71.4.7 Status Operations

The contents of an existing window may be of interest:

$\underline{GetWindow0}$ $\exists \text{SYS}$ $which? : \mathbb{N}$ $window! : Pixmap$	<hr/> $which? \in \text{dom } windows$ $window! = windows\ which?$
---	---

By using Ξ SYS, the state of the system does not change during this operation. Status operations normally have one or more outputs returning some aspect of the state of the system. Here a particular window is returned.

We can make this operation total as well:

$$GetWindow \triangleq (GetWindow\ 0 \wedge Success) \vee NotAWindow$$

71.4.8 Conclusion

Given the abstract state, initial state, and operation schemas defined in this section, the operation of the system consists of starting in the initial state, followed by an arbitrary sequence of the specified operations on the state, as allowed by the preconditions of the operations. If the preconditions of all the operations are true, then any order of operations is allowed.

This section has presented the use of the Z notation (Spivey 2001, ISO 2002) in a modeling style, as it is widely used for specifying systems. It should be remembered that Z is a general-purpose specification language and can be used in other styles if desired. However, the use of an abstract state and operations on that state has been found to be a style that is easy to understand (once the notation and conventions have been learned), and this is the approach that is often adopted in practice.

For those wishing to learn Z, there are many well-established textbooks available (e.g., see Jacky 1997, Lightfoot 2001). An international standard for Z is available (ISO 2002) and an earlier de facto standard for Z, with a matching type-checker called *fuzz* by the same author, is also widely used (Spivey 2001).

71.5 Technology Transfer and Research Issues

Claims that formal methods can guarantee correct hardware and software, eliminate the need for testing, etc., have previously led some to believe that formal methods are something almost magical (Hall 1990). More significantly, beliefs that formal methods are difficult to use, delay the development process, and raise development costs (Bowen and Hinchey 1995b) have led many to believe that formal methods offer few advantages over traditional development methods. Formal methods are not a panacea; they are just one of a range of techniques that, when correctly applied, have proven themselves to result in systems of the highest integrity in the long term (Bowen and Hinchey 1995a, Bowen and Hinchey 2012).

In the past, the uptake of formal methods has been hindered, at least in part, by a lack of tools. Many of the successful projects discussed in Hinchey and Bowen (1999) required significant investment in tool support. Just as the advent of compiler technology was necessary for the uptake of high-level programming languages, and CASE (Computer Aided Software Engineering) technology provided the impetus for the emergence of structural design methodologies in the 1970s, a significant investment in formal methods tools is required for formal methods to be practical at the level of industrial application. The RODIN tool that supports Event-B (Abrial 2009) is a good example of a robust tool that is now available.

Method integration is one approach that may aid in the acceptance of formal methods and may help in the technology transfer from academic theory to industrial practice. This has the advantage of providing multiple views of a system, for example incorporating a graphical representation that is likely to be more acceptable to nonspecialists, while retaining the ability to propose and prove system properties and to demonstrate that requirements are not contradictory before rather than after implementation.

The Unified Modeling Language (UML) provides a popular software development framework which could benefit from a formal methods approach. For example, amid concerns over the lack of formality (or even uniform interpretation) in UML, the OMG (Object Management Group) issued a request for proposals on re-architecting UML version 2.0.

Cleanroom is a method that provides a middle road between correctness proofs and informal development by stipulating significant checking of programs before they are first run (Prowell et al. 1999). The testing phase then becomes more like a certification phase since the number of errors should be much reduced. *Static analysis* involved rigorous checking of programs without actually executing them. SPARK Ada (Barnes 2003) is a restricted version of the Ada programming language that includes additional comments that facilitate formal tool-assisted analysis, especially worthwhile in high-integrity system development. Such approaches may be more cost-effective than full formal development using refinement techniques.

In any case, formal development is typically not appropriate in all software systems. However, many systems could benefit from selected use of formal methods at some level (perhaps just specification) in their most critical parts (sometimes called “lightweight” formal methods). In particular, many errors are introduced at the requirements stage and some formality at this level could have very beneficial results because the system description is still relatively simple.

Formal methods are complementary to testing in that they aim to avoid the introduction of errors whereas testing aims to remove errors that have been introduced during development. The best balance of effort between these two approaches is a matter for debate (King et al. 2000). In any case, the existence of a formal specification can benefit the testing process by providing an objective and exact description of the system against which to perform subsequent program testing. It can also guide the engineer in deciding which tests are worthwhile (e.g., by considering disjunctive preconditions in operations and ensuring that there is full test coverage of these).

The use of formal methods can and should be used in combination with other software engineering approaches. It is often complementary to many techniques. For example, formal methods could be combined with an agile approach to software development (Black et al. 2009).

In practical industrial use, formal methods have proved to have a niche in high integrity systems such as safety-critical applications where standards may encourage or mandate their use in software at the highest levels of criticality. Formal methods are also being successfully used in security applications such as smart cards where the technology is simple enough to allow fully formal development. They are also useful in discovering errors during cryptographic protocol analysis (Meadows 2003).

Formal methods have largely been used for software development, but they are arguably even more successful in hardware design where engineers may be more open to the use of rigorous approaches because of their background and training. Formal methods can be used for the design of micro-processors where errors can be costly because of the large numbers involved and also because of their possible use in critical applications (Jones et al. 2001). Fully formal verification of significant hardware systems is possible even within the limits of existing proof technology.

Full formal refinement is the ideal but is expensive and can sometimes be impossible to achieve in practice. Retrenchment (Banach and Poppleton 1999) is a suggested liberalization of refinement designed for formal description of applications too demanding for true refinement. Examples are the use of infinite or continuous types or models from classical physics and applications including inconsistent requirements. In retrenchment, the abstraction relation between the models is weakened in the operation postcondition by a *concession* predicate. This weakened relationship allows approximating, inconsistent, or exceptional behaviors to be described in which a *false* concession denotes a refinement.

There are many different formal methods for different purposes, including specification (e.g., the Z notation) and refinement (e.g., the B-Method). There have been moves to develop the B-Method. The simpler Event-B approach has good tool support using RODIN (Abrial 2009). The Alloy tool has been influenced by the Z-style of specification (Jackson 2012). There have also been moves to related different semantic theories like algebraic, denotational and operational semantics using a Unified Theories of Programming (UTP) approach (Hoare and He 1998). A promising approach is that of separation logic, an extension of Hoare logic that allows improved modular reasoning about programs that use dynamically allocated pointers (Reynolds 2002). In any case, there continue to be research and technology transfer challenges in the field of formal methods.

Key Terms

Formal methods: Techniques, notations, and tools with a mathematical basis, used for specification and reasoning in software or hardware system development.

Formal notation: A language with a mathematical semantics, used for formal specification, reasoning, and proof.

Logic: A scheme for reasoning, proof, inference, etc. Two common schemes are *propositional logic* and *predicate logic*, which is propositional logic generalized with quantifiers. Other logics, such modal logics, including *temporal logics* which handle time are also available. Examples include TLA (Temporal Logic of Actions), ITL (Interval Temporal Logic), and Duration Calculus. Schemes may use *first-order logic* or *higher-order logic*. In the former, functions are not allowed on predicates, simplifying matters somewhat, but in the latter they are, providing greater power. Logic includes a calculus which allows reasoning in the logic.

Operation: The performance of some desired action. This may involve the change of state of a system, together with inputs to the operation and outputs resulting from the operation. To specify such an operation, the *before state* (and inputs) and the *after state* (and outputs) must be related with constraining predicates.

Precondition: The predicate which must hold before an operation for it to be successful. Compare *post-condition*, which is the predicate which must hold after an operation.

Predicate: A constraint between a number of variables which produces a truth value (e.g., *true* or *false*).

Proof: A series of mathematical steps forming an argument of the correctness of a mathematical statement or theorem. For example, the *validation* of a desirable property for a formal specification could be undertaken by proving it correct. Proof may also be used to perform a formal *verification* that an implementation meets a specification. A less formal style of reasoning is *rigorous argument*, where a proof outline is sketched informally, which may be done if the effort of undertaking a fully formal proof is not considered cost-effective.

Refinement: The stepwise transformation of a specification towards an implementation (e.g., as a program). Compare *abstraction*, where unnecessary implementation detail is ignored in a specification.

Relation: A connection or mapping between elements in a number of sets. Often two sets (a *domain* and a *range*) are related in a *binary relation*. A special case of a relation is a function where individual elements in the domain can only be mapped to at most one element in the range of the function. Functions may be further categorized. For example, a *partial function* may not map all possible elements that could be in the domain of the function, whereas a *total function* maps all such elements.

Set: A collection of distinct objects or *elements*, which are also known as *members* of the set. In a typed language, types may consist of maximal sets, as in the Z notation.

Specification: A description of *what* a system is intended to do, as opposed to *how* it does it. A specification may be *formal* (mathematical) or *informal* (natural language, diagrams, etc.). Compare an *implementation* of a specification, such as a program, which actually performs and executes the actions required by a specification.

State: A representation of the possible values which a system may have. In an abstract specification, this may be modeled as a number of sets. By contrast, in a concrete program implementation, the state typically consists of a number of data structures, such as arrays, files, etc. When modeling sequential systems, each operation may include a *before state* and an *after state* which are related by some constraining predicates. The system will also have an *initial state*, normally with some additional constraints, from which the system starts at initialization.

A glossary of the Z mathematical and schema notation is included here for the reader's convenience. For more information on the Z notation, see the *Z Reference Manual* (Spivey 2001) and the ISO international standard (ISO 2002).

Glossary of Z Notation

Names

a, b	Identifiers
d, e	Declarations (e.g., $a : A; b, \dots : B \dots$)
f, g	Functions
m, n	Numbers
p, q	Predicates
s, t	Sequences
x, y	Expressions
A, B	Sets
C, D	Bags
Q, R	Relations
S, T	Schemas
X	Schema text (e.g., $d, d p$ or S)

Definitions

$a == x$	Abbreviated definition
$a ::= b \dots$	Free type definition (or $a ::= b \langle \langle x \rangle \rangle \dots$)
$[a]$	Introduction of a given set (or $[a, \dots]$)
$a_.$	Prefix operator
$._a$	Postfix operator
$._a_.$	Infix operator

Logic

$true$	Logical true constant
$false$	Logical false constant
$\neg p$	Logical negation
$p \wedge q$	Logical conjunction
$p \vee q$	Logical disjunction
$p \Rightarrow q$	Logical implication ($\neg p \vee q$)
$p \Leftrightarrow q$	Logical equivalence ($p \Rightarrow q \wedge q \Rightarrow p$)
$\forall X \bullet q$	Universal quantification
$\exists X \bullet q$	Existential quantification
$\exists_1 X \bullet q$	Unique existential quantification
let $a == x; \dots \bullet p$	Local definition

Sets and expressions

$x = y$	Equality of expressions
$x \neq y$	Inequality ($\neg(x = y)$)
$x \in A$	Set membership
$x \notin A$	Nonmembership ($\neg(x \in A)$)
\emptyset	Empty set
$A \subseteq B$	Set inclusion
$A \subset B$	Strict set inclusion ($A \subseteq B \wedge A \neq B$)
$\{x, y, \dots\}$	Set of elements
$\{X \bullet x\}$	Set comprehension
$\lambda X \bullet x$	Lambda-expression—function
$\mu X \bullet x$	Mu-expression—unique value
let $a == x; \dots \bullet y$	Local definition
if p then x else y	Conditional expression

(x, y, \dots)	Ordered tuple
$A \times B \times \dots$	Cartesian product
$\mathbb{P}A$	Power set (set of subsets)
$\mathbb{P}_1 A$	Nonempty power set
$\mathbb{F}A$	Set of finite subsets
$\mathbb{F}_1 A$	Nonempty set of finite subsets
$A \cap B$	Set intersection
$A \cup B$	Set union
$A \setminus B$	Set difference
$\bigcup A$	Generalized union of a set of sets
$\bigcap A$	Generalized intersection of a set of sets
<i>first</i> x	First element of an ordered pair
<i>second</i> x	Second element of an ordered pair
$\#A$	Size of a finite set

Relations

$A \leftrightarrow B$	Relation ($\mathbb{P}(A \times B)$)
$a \mapsto b$	Maplet ((a, b))
$\text{dom}R$	Domain of a relation
$\text{ran}R$	Range of a relation
$\text{id}A$	Identity relation
$Q ; R$	Forward relational composition
$Q \circ R$	Backward relational composition ($R ; Q$)
$A \triangleleft R$	Domain restriction
$A \triangleleft R$	Domain anti-restriction
$A \triangleright R$	Range restriction
$A \triangleright R$	Range anti-restriction
$R(A)$	Relational image
<i>iter</i> $n R$	Relation composed n times
R^n	Same as <i>iter</i> $n R$
R^\sim	Inverse of relation (R^{-1})
R^*	Reflexive-transitive closure
R^+	Irreflexive-transitive closure
$Q \oplus R$	Relational overriding ($(\text{dom}R \triangleleft Q) \cup R$)
$a \underline{R} b$	Infix relation

Functions

$A \leftrightarrow B$	Partial functions
$A \rightarrow B$	Total functions
$A \mapsto B$	Partial injections
$A \mapsto B$	Total injections
$A \mapsto B$	Partial surjections
$A \twoheadrightarrow B$	Total surjections
$A \twoheadrightarrow B$	Bijjective functions
$A \twoheadrightarrow B$	Finite partial functions
$A \twoheadrightarrow B$	Finite partial injections
$f x$	Function application (or $f(x)$)

Numbers

\mathbb{Z}	Set of integers
\mathbb{N}	Set of natural numbers $\{0, 1, 2, \dots\}$

\mathbb{N}_1	Set of nonzero natural numbers ($\mathbb{N} \setminus \{0\}$)
$m + n$	Addition
$m - n$	Subtraction
$m * n$	Multiplication
$m \text{ div } n$	Division
$m \text{ mod } n$	Modulo arithmetic
$m \leq n$	Less than or equal
$m < n$	Less than
$m \geq n$	Greater than or equal
$m > n$	Greater than
$\text{succ } n$	Successor function $\{0 \mapsto 1, 1 \mapsto 2, \dots\}$
$m .. n$	Number range
$\text{min } A$	Minimum of a set of numbers
$\text{max } A$	Maximum of a set of numbers

Sequences

$\text{seq } A$	Set of finite sequences
$\text{seq}_1 A$	Set of nonempty finite sequences
$\text{iseq } A$	Set of finite injective sequences
$\langle \rangle$	Empty sequence
$\langle x, y, \dots \rangle$	Sequence $\{1 \mapsto x, 2 \mapsto y, \dots\}$
$s \widehat{\ } t$	Sequence concatenation
$\widehat{\ } / s$	Distributed sequence concatenation
$\text{head } s$	First element of sequence ($s(1)$)
$\text{tail } s$	All but the head element of a sequence
$\text{last } s$	Last element of sequence ($s(\#s)$)
$\text{front } s$	All but the last element of a sequence
$\text{rev } s$	Reverse a sequence
$\text{squash } f$	Compact a function to a sequence
$A \upharpoonright s$	Sequence extraction ($\text{squash } (A \triangleleft s)$)
$s \upharpoonright A$	Sequence filtering ($\text{squash } (s \triangleright A)$)
$s \text{ prefix } t$	Sequence prefix relation ($s \widehat{\ } v = t$)
$s \text{ suffix } t$	Sequence suffix relation ($u \widehat{\ } s = t$)
$s \text{ in } t$	Sequence segment relation ($u \widehat{\ } s \widehat{\ } v = t$)
$\text{disjoint } A$	Disjointness of an indexed family of sets
$A \text{ partition } B$	Partition an indexed family of sets

Bags

$\text{bag } A$	Set of bags or multisets ($A \mapsto \mathbb{N}_1$)
$\llbracket \]$	Empty bag
$\llbracket x, y, \dots \rrbracket$	Bag $\{x \mapsto 1, y \mapsto 1, \dots\}$
$\text{count } C x$	Multiplicity of an element in a bag
$C \# x$	Same as $\text{count } C x$
$n \otimes C$	Bag scaling of multiplicity
$x \sqsubseteq C$	Bag membership
$C \sqsubseteq D$	Subbag relation
$C \uplus D$	Bag union
$C \ominus D$	Bag difference
$\text{items } s$	Bag of elements in a sequence

Schema notation**Vertical Schema**

$$\frac{.S \quad \text{---}}{d}$$

$$\frac{\text{---}}{p}$$

New lines denote “;” and “ \wedge .” The schema name and predicate part are optional. The schema may subsequently be referenced by name in the document.

Axiomatic definition

$$\frac{d}{p}$$

The definitions may be nonunique. The predicate part is optional. The definitions apply globally in the document.

Generic definition

$$\frac{=[a, \dots]=}{d}$$

$$\frac{\text{---}}{p}$$

The generic parameters are optional. The definitions must be unique. The definitions apply globally in the document.

$s \hat{=} [X]$	Horizontal schema
$[T; \dots]$	Schema inclusion
$z . a$	Component selection (given $z : S$)
θS	Tuple of components
$\neg S$	Schema negation
$\text{pre } S$	Schema precondition
$S \wedge T$	Schema conjunction
$S \vee T$	Schema disjunction
$S \Rightarrow T$	Schema implication
$S \Leftrightarrow T$	Schema equivalence
$S \setminus (a, \dots)$	Hiding of component(s)
$S \downarrow T$	Projection of components
$S ; T$	Schema composition (S then T)
$S \gg T$	Schema piping (S outputs to T inputs)
$S[a/b, \dots]$	Schema component renaming (b becomes a , etc.)
$\forall X \bullet S$	Schema universal quantification
$\exists X \bullet S$	Schema existential quantification
$\exists_1 X \bullet S$	Schema unique existential quantification

Conventions

$a?$	Input to an operation
$a!$	Output from an operation
a	State component before an operation
a'	State component after an operation

S	State schema before an operation
S'	State schema after an operation
ΔS	Change of state (normally $S \wedge S'$)
$\exists S$	No change of state (normally $[S \wedge S' \mid \theta S = \theta S']$)
$d \vdash p$	Theorem

Further Information

A number of organizations have been established to meet the needs of formal methods practitioners; for example:

- Formal Methods Europe (FME) organizes a regular Formal Methods (FM) conference, formerly the VDM symposia and the leading international conference in the field, as well as other activities for users of various formal methods.
- The British Computer Society Specialist Group on Formal Aspects of Computing Science (BCS-FACS) organizes regular talks and periodic workshops on various aspects of formal methods, including being associated with a series of Refinement Workshops.
- The Z User Group (ZUG) has organized a regular international conference, historically known as the Z User Meeting (ZUM), for users of the Z notation. The International B Conference Steering Committee (Association de Pilotage des Conférences B, APCB) organized a similar International B Conference series. Since 2000, these have combined as a single conference that more recently has also covered Abstract State Machines (ASM), Alloy, and VDM, becoming known as the ABZ conference.

There are a number of journals devoted specifically to formal methods. These include *Formal Methods in System Design* and *Formal Aspects of Computing* (FAC). The FAC journal is published by Springer in association with BCS-FACS. Other European-based journals, such as *The Computer Journal*, *IET Software* (formerly *IEE Proceedings—Software* and the *Software Engineering Journal*) and *Information and Software Technology*, publish articles on, or closely related to, formal methods, and they have run special issues on the subject.

While there are no US-based journals that deal specifically with formal methods, they regularly are featured in popular periodicals such as *IEEE Computer*, *IEEE Software*, and the *Communications of the ACM*, as well as in journals such as the *Annals of Software Engineering* *IEEE Transactions on Software Engineering* *ACM Transactions on Software Engineering and Methodology* (TOSEM), the *Journal of the ACM*, and *Innovations in Systems and Software Engineering: A NASA Journal* (published by Springer). Survey papers on the state of the art and practice in formal methods have also appeared in the *ACM Computing Surveys* (e.g., see Woodcock et al. 2009).

In addition to the conferences mentioned earlier, The International Conference on Formal Engineering Methods series (ICFEM) and the Software Engineering and Formal Methods (SEFM) conference (Hinchey et al. 2008) also cover formal methods. A number of more specialist conferences have been established. For example, the Integrated Formal Methods (IFM) International Conference concentrates on the use of formal methods with other approaches or in combination. The International Workshop on Formal Methods for Industrial Critical Systems (FMICS) focuses on industrial applications, especially using tools. The IFIP (International Federation of Information Processing) FORTE international conference has concentrated on *Formal Description Techniques* (FDTs). The IFIP WG 6.1 International Conference on Formal Methods for Open Object-Based Distributed Systems (FMOODS) has also been established and more recently combined with FORTE.

Some more wide-ranging conferences give particular attention to formal methods; primary among these are the ICSE (International Conference on Software Engineering) and ICECCS (International Conference on Engineering of Complex Computer Systems) series of conferences. Other specialist conferences in the safety-critical sector, such as SAFECOMP (the International Conference on Computer

Safety, Reliability and Security), and SSS (the Safety-critical Systems Symposium) regularly cover formal methods. The long-established Software Engineering Workshop (SEW) also features formal methods papers.

There have been some collections of case studies on formal methods with various aims and themes. For some industrial applications and approaches, see Hinchey and Bowen (1999), Boulanger (2012), Gnesi and Margaria (2012). The book (Frappier and Habrias 2006) collected together a number of formal specification methods applied to an invoicing case study where the presentations concentrate on the *process* of producing a formal description, including the questions raised along the way. For some research directions in formal methods, see Boca et al. (2010).

A handbook is “a book of information, guidance, or information, as for an occupation, travel, or reference,”* a definition that fits this volume and section very well. A “discipline” is “a branch of instruction or learning; behavior in accord with rules of conduct.”† More established subjects such as physics and chemistry or disciplines such as the practice of architecture have handbooks that are a compendium of facts, organized for ready reference (such as the specific heat of materials or the standard width of an aisle in an office building) or procedures (such as safety practices).

Software engineering is not yet a fully mature discipline, and it is certainly not a set of facts! Nor are there widely accepted software engineering handbooks.

It is tempting to say that as software engineering matures, it is becoming an engineering discipline. Today, however, software engineering is not widely considered an engineering discipline, at least not in the traditional sense. We will say more about this in the subsequent sections.

* *Random House Dictionary of the English Language*, 1968, New York.

† Op. cit.

It is, however, a branch of instruction and learning that has been around for almost 50 years and about which a good deal is known.* The story of software engineering to date is the story of the development of a practical discipline in response to the demands of the marketplace and the inherent and ever-increasing complexity of software.

The papers in this section of the *Computing Handbook Set* are intended to provide you self-contained descriptions of what is known in specific areas of the discipline. The purpose of this chapter is to provide you a framework and the context in which software engineering has evolved so far, a brief survey of educational efforts, an overview of its elements, and a sketch of how software engineering is practiced.

72.1 Origins of Software Engineering

Why has this meeting been scheduled? Why have we agreed to participate?

I believe it is because we recognize that a practical problem of considerable difficulty and importance has arisen: The successful design, production and maintenance of useful software systems. The importance is obvious and the more so since we see only greater growth in demands and requirements in the future. The consequences of poor performance, poor design, instability and mismatching of promise and performance are not going to be limited to the computing fraternity, or even their nearest neighbors, but will affect considerable sections of our society whose ability to forgive is inversely proportional to their ignorance of the difficulties we face. The source of difficulty is distributed through the whole problem, easy to identify, and yet its cure is hard to pinpoint so that systematic improvement can be gotten.

—Keynote speech by A.J. Perlis.†

The aforementioned quote from the opening speech at a meeting in 1968, generally cited as the start of software engineering, provides the motivation at that time—and it is still true today! Software for general-purpose computers has been created since the earliest days of computers (generally, late 1940s) and the term “software engineering” was used privately by some before 1968.‡ In the mid-1960s, there was an awakening to the fact that creating large, complex software on time, within budget, and that performed as imagined it would by the customers for the software was becoming a huge problem. The dimensions of the problem were multiple, involving not only technical and economic concerns, but also extremely serious military defense concerns—hence, the involvement of the NATO Science Committee.

It was the height of the Cold War during which the Western Democracies felt seriously threatened by the Soviet Union and their allies—and *vice versa*. Computers were already an integral part of defense systems and as their necessary functional complexity grew so did the size and complexity of the software needed. This drove not only the development of military defense systems on both sides of the Iron Curtain but also in the West the commercial development of large, comprehensive operating systems and applications systems.

As intellectually interesting as it may be, our purpose here is not to fully explore the origins and growth of software engineering from its beginnings to today but to give a brief recounting of that history^{§,¶} in the

* Software engineering was introduced in the early 1970s as a specialization of computer science, and since the mid-1980s, it has been accepted as a formal field of study in academia.

§ This should not be read as a definitive history of software engineering, nor should the periods defined by dates be taken as absolutes. There are no histories of software engineering currently, but Freeman (1975) and Zerkowitz (1979), both give overviews of the field at that time and provide multiple references to a variety of papers and books.

belief that it will provide you some necessary context for the effective use of this Handbook section. There is a lot to learn from that history and the efforts to create a software engineering discipline; we encourage you to delve into it. There is no comprehensive history of software engineering, but Wikipedia* and some textbooks will have additional references beyond what are given in the subsequent sections.

72.1.1 Early Efforts to Create a Discipline (1960s)

In the 1960s, the general view in industry was that creating software was purely an adjunct to designing the hardware and the overall system of people, procedures, computers, and other hardware such as sensors and actuators. This view prevailed within the computing community (both industrial and academic) itself, although not as strongly. In addition, creating software was considered, in practice, to be largely a matter of creating the necessary algorithms and then programming them.

Very little attention was paid by anyone to topics such as requirements analysis, specification, design, testing, and maintenance as they pertained to software. (In fairness, all of these issues were mentioned at the NATO meetings.) It is notable that starting in the 1960s and continuing through the 1970s, large programming efforts were usually referred to as “systems programming,” hinting at the fact that one was engaged in more than just programming an algorithm.

Thus, it is not surprising that the early efforts at improving the development of software focused on the activity of programming. The small size of available memory and the speed of computers (compared to today) emphasized this concentration of effort. Indeed, it was—and to a somewhat lesser extent, still is—important to make sure that the software that is controlling the hardware is efficient and easy to create. In the academic research community, the creation of languages and the development of mathematically based techniques are better defined problems than the topics of requirements elicitation, design, and maintenance—and they fit better into the mold of what was (is) considered legitimate academic research. In short, a bottom-up approach to what is inherently a system-level problem was largely followed, starting with what people knew and were comfortable with—the programming activity. This phenomenon is still seen today, and new paradigms and ideas often commence at the programming level and then move up to higher levels of abstraction in the development “process,” for example, after structured programming, we saw the advent of structured design and structure analysis and design; same for object-oriented programming, design, and analysis and design, and so on; the latest fad is aspect-oriented programming, etc., and feature-oriented software development (Apel and Kästner, 2009) is seeing the light.

72.1.2 Programming Methods (~1968 to 1975 and Beyond)

In software engineering, we speak of a programming method as a set of rules, guidelines, steps, or other ways of organizing the process of creating a program at the programming language level. This is distinct from the use of “method” in object-oriented programming (itself a “method” in the software engineering sense) where “method” denotes a subroutine associated with a class (Bruegge et al., 2000). In at least one programming method, the so-called Booch method (Booch, 1993), the two meanings merge to the extent that the Booch method is based on the use of methods and other devices in object-oriented languages.

The most widely known and influential technique at the time was one pioneered by E.W. Dijkstra called “structured programming” (Dijkstra, 1968). It was described, dissected, and analyzed (not always accurately[†]) in dozens of books and thousands of papers. It was promoted by some as *the* answer to the

* http://en.wikipedia.org/wiki/History_of_software_engineering, accessed January 17, 2013.

† A review of Dijkstra’s papers in (Freeman, 1975, pp. 487ff) points out that he was fundamentally advancing the idea of “constructive programming” (creating programs that are probably correct because of the manner in which they are created) and a set of techniques and program structures (not a hard and fast algorithm nor a set of inviolable structures). The core of his approach was largely ignored at the time and even more so today.

“software problem.” Many practitioners in search of a quick fix to their development problem rushed to adopt it. Development of structured programming techniques and tools predominated in many discussions and improvement activities in the late 1960s and much of the 1970s.

Other programming methods you may encounter include iterative programming, functional programming, parallel programming, genetic programming, object-oriented programming, extreme programming, generative programming, and a plethora of X-programming methods, where X = the name of a programming language (e.g., C++ programming method). Almost all of these came about after it was realized that structured programming alone could not solve all software development problems, but that improvements could be made in the way software is created. The technical aspects of some of these are discussed in Section I (Computer Science) programming languages part.

While it turned out to not be a “silver bullet”—a term that Fred Brooks popularized in his 1986 paper (Brooks, 1995)—that so many sought, attention to structured programming did result in some worthwhile improvements. A fundamental result was the realization that the types of language structures that one employed and the way in which one structured the organization of a program could have significant effects on the resulting programs along the dimensions of efficiency and ease of construction and maintenance. A similar, very positive result was the design or redesign of many programming languages and techniques to incorporate some or most of the underlying concepts of structured programming (Wirth, 1971). By the end of the twentieth-century, most of the techniques and structures of structured programming were widely accepted and in use.

Perhaps the most fundamental result was the planting of the seeds necessary for improving the entire method of developing software and the beginning of a focus on modularity (Parnas, 1972) and design methods (Freeman and Wasserman, 1975). Both these topics were discussed at the first NATO conference in 1968, reflecting the fact that the importance and some aspects of both were already known and recognized.

A general definition of a “module” is a “separable component, frequently one that is interchangeable with others, for assembly in units of differing size, complexity, or function,”* with “modularity” and “modularization” being the associated adjective and verb. It is a concept that has long been used in many contexts, including engineering, and when applied to software has the same meaning as elsewhere. The value of modularity in software is not hard to see, but achieving it is much harder and that led to a large amount of attention being paid to it beginning in the 1970s. The seminal paper in this area is the famous one (Parnas, 1972).†

While many of the efforts centered, appropriately, on the mechanisms in programming languages (Wirth, 1974) to enable and encourage modularity some soon became embedded in design methods intended to proceed the writing of the code necessary to implement a design. Like the tenets of structured programming, the ideal of modularizing code is now common throughout software development. A particular form or aspect of modularization is the idea of reusable software exemplified by the notion of separately compiled units, packages, and generics in the Ada programming language (Ada, 2012).

72.1.3 Software Design Methods (~1972 to 1985 and Beyond)

As the limits of programming methods, including modularization, by themselves to “solve” the software problem became evident, the search for the next possibility quickly turned to design techniques and methodologies. By analogy, a design method (or technique) can be considered to be the same sort of construct (i.e., rules, guidelines, steps, etc.) as a programming method, only applied to the problem of creating a design for software that is expressed in something other than executable code (or, its

* Random House Dictionary, op. cit.

† A review of Parnas’ papers highlights the fact that “Dave Parnas identified the information hiding principle and showed how to use it to construct workable, reusable modular structures that are stable over time.” (Hoffman and Weiss, 2001, preface).

equivalent, a higher-level language)—that is, it is at a higher level of abstraction. A design methodology (or, often, a development methodology) is an organized system of methods and rules of application to guide the overall development of a software-intensive system.

Note that the distinction between programming methods, design methods, and design methodologies is often weak and for the most part unimportant—unless one is trying to compare alternatives. The important factors are the scope of application and the focus of the item under consideration. A programming method based on a specific language may well not be applicable to work in a different language (a scope of application issue). Similarly, any method focused on the specifics of programming will probably not be of any use in organizing the overall workflow of a large development project (a methodology issue).

The origin of many of the concepts of a software design method, especially those employing structure, organized levels of abstraction, and a notation other than a programming language can be traced back to the work of Doug Ross at MIT in the 1960s on numerically controlled machine tools and the techniques for programming them more or less automatically that resulted in the APT language (Ross, 1978). This work led to the development of structured analysis and design technique (SADT) (Marca and MacGowan, 1988) that received significant use in the design of some of the most complicated and sophisticated software-intensive systems in the 1970s and 1980s. There were also attempts to import concepts from other design fields such as engineering design and architecture into the design of software; except at a high level, many of these attempts have not been notably successful in directly changing the practice of software design.

A popular and useful technique for software that is similar to SADT in some respects, structured design, was developed and promoted in the 1970s (Yourdon and Constantine, 1979). A number of other design techniques were developed and used during this period to a varying degree of success. As the importance of data started to grow, along with the realization that collections of data (databases) needed to be designed as well as the programs that accessed them, data design methods—in some cases as distinct from software design methods that tend to focus on the process aspect of software—focused on database design started to appear (Brown, 1975; Chen, 1976).

In the 1980s, as more languages of various sorts appeared (and some older ones such as Cobol started to fade away) as well as new application areas and hardware types, we saw the appearance of design (and programming) methods oriented toward specific language, applications, or hardware. This trend continues today, with many papers and books discussing specific approaches for program or software system or overall system design utilizing specific languages, focused on specific hardware types, or application areas.

The popularity of structured design and other design techniques employing structuring concepts led naturally to the development of structured analysis techniques for use in the stage preceding design (DeMarco, 1979, and others). Some of these bear some resemblance to SADT and did gain a good bit of usage, but in general were not as popular in practice as structured design. At the same time, less technically oriented methods were being developed in the business data processing and information systems communities focused more on the early stages of the development of an overall system.

72.1.4 Software Development Methodologies (~1975 to 1985 and Beyond)

These developments led, in turn, to the creation of more holistic or complete development methodologies intended to provide guidance throughout the lifecycle of a software-intensive system from the time a customer first expresses a need that can be fulfilled by such a system, through complete development, and then on into usage, modification, and de-commissioning phases. These more comprehensive methodologies were generally aimed at and most useful in large organizations dealing with large and complex systems whose lifetimes needed to extend over decades and involve perhaps thousands of people developing and modifying various aspects of the systems.

The largest such organization—and most influential in the early development of software engineering—was the United States Department of Defense (DoD). The Ada programming language was designed specifically to address software engineering issues and was mandated for use by defense contractors once the language was well defined and implemented. The process to define the language was unique in that it went through a series of public iterations on which anyone could offer comments a “straw man proposal.” A similar effort was started by the DoD to define a development methodology to accompany the use of Ada, but the effort stalled out after an initial iteration (Freeman and Wasserman, 1982).

Other organizations, however, were more successful in creating and adopting “standard” development methodologies, including the major equipment manufacturers (IBM, Hewlett-Packard, etc.), defense contractors (TRW, Northrup Grumann, Lockheed, etc.), commercial consultancies (Arthur Anderson—now Accenture, Price-Waterhouse, etc.), and large user organizations (banks, transportation companies, manufacturers, etc.). A representative review of the situation as of the early 1980s can be found in (Freeman and Wasserman 1983).

72.1.5 Development Lifecycles (~1980 to 1995 and Beyond)

A *project* is an organized activity with a beginning, end, schedule, budget, and related factors and constraints; *project management* is the discipline of planning, organizing, and controlling a project; all projects typically go through a similar set of *stages* (time periods), depending on the type of project, characterized by the dominant activity in that period; and the organization of the stages is called a *project lifecycle*. These terms have been used in engineering and construction projects for well over a hundred years, but came into much wider use during and after World War II because of the many large projects undertaken in the course of the war.

As the activity of software development became more complex and involved more people over longer time spans, and as it became clear that many of the large systems would be in use and undergo “maintenance” over many years (as of 2012, parts of some software systems have been in use close to 50 years), the concepts and terminology of project management were adapted to software and software-intensive systems. This began in the 1960s in large organizations, but it was not until the mid-1970s or later that much discussion and research attention was focused on the steps involved.

Initially, the “standard” organization of activities was the *waterfall model*, a linear sequence of steps usually defined as requirements analysis and specification, software design, implementation, installation, usage, and maintenance (Royce, 1987). The steps were usually depicted as a set of boxes connected by one-way arrows and arranged in a “waterfall.” Many organizations adopted this model as a way of putting structure on the often-chaotic software development process and of controlling it. Adoption and usage of the model, quickly illustrated the simplicity and naiveté of the model, leading to the development (and eventual adoption) of more realistic models. Chief among these was the spiral model (Boehm, 1988) that goes through successive iterations of a basic set of steps. An early comparison of several models can be found in Kerola and Freeman (1981).

As software development has expanded beyond large organizations or one-person, one-off efforts and technical developments including personal computers and the Internet have occurred—to say nothing of the range of applications and the demands of the marketplace—a number of other lifecycle models have been developed and employed. Reviews of the situation today can be found in Part XI, and in the appropriate sections of good software engineering textbooks.

72.1.6 Tool Support for Software Development (1968–1995 and Beyond)

Programs to assist in the writing of other programs (e.g., language syntax checkers) and systems of programs (e.g., linkers, loaders, assemblers, and compilers) have existed almost as long as programs. With the widespread interest in the Unix operating system (which came with a number of tools useful to the

programmer) in the late 1960s (e.g., Keringhan and Plauger, 1976), the search for other tools became more prominent. Initially, most tools were focused on programs but as design methods and methodologies were introduced, experimentation with the types of tools broadened. They included drawing tools for graphical representations of design (Díaz-Herrera and Flude, 1980), consistency checkers for specifications and designs, and version control tools.

Testing tools have been in use at least since the 1960s. For example, Pullen and Shuttee (1968) describe “MUSE, a tool for testing and debugging a multi-terminal programming system” became popular.

Work on automated or semi-automated software development dates back at least to the early 1950s (e.g., Carr, 1952) when the term “automatic programming” was used; it usually referred to efforts to automate the translation of higher-level languages into executable code, although the concept of using artificial intelligence in the programming process* was already known (Perlis, 1959). In the early to mid-1960s, research on “compiler compilers” (programs used to generate compilers for higher level languages) was a favorite topic, for example, (Cheatham and Standish, 1970); this work laid the foundation for many of the language tools in common use today.

Using computers to assist or automate parts of the software development process (typically called computer-aided software engineering—CASE) became a hot topic in the 1980s and is still a common topic in software engineering today. Integrated development environments (IDEs) brought together a number of technical and managerial tools to work together in a coordinated way (ECMA, 1993).

72.1.7 Process Maturity Modeling (1989–2000 and Beyond)

The final major component of modern software engineering came into prominence with the publication of (Humphrey, 1989).† This book, and several that followed it along with extensive implementation, training, and standard-setting activities, takes an organizational point of view on the overall activity of creating software (generally understood to be large, complex software systems, although some attempts have been made to apply the concepts to individual work as well).

The fundamental idea is that organizations differ in their ability to create software in predictable, repeatable ways. The “software process,” as Humphrey calls it, consists of the set of tools, methods, and practices used to produce a software product and the view is that these are, or should be, actively managed by the organization. He defines five increasing levels of software process maturity (initial, repeatable, defined, managed, and optimizing) and ways of “measuring” an organization’s place on the attendant scale. Much of his work then focuses on how organizations can improve their performance.

Government organizations (primarily the US Defense Department, the world’s largest buyer of software), some large industrial organizations, and some standards setting bodies (notably the ISO standards process) have adopted in whole or in part this concept.

ISO 9000-3 is a subset of guidelines for applying ISO 9001 to the development, supply, and maintenance of software. ISO 9001 is intended to be used when conformance to specified requirements is to be assured by the supplier during several stages, which may include design, development, production, installation, and servicing.

The ISO/IEC 15504 or Software Process Improvement and Capability Determination (SPICE) is a set of standards for the software development process and related business management functions, initially derived from process lifecycle standard ISO/IEC 12207 and from maturity models like Bootstrap, Trillium, and the Sw-CMM.

* Research efforts at applying artificial intelligence concepts and techniques to creating software also started in the 1960s; see Freeman (1974) for an early review.

† Watts Humphrey was awarded the 2003 U.S. National Medal of Technology by President George W. Bush for the impact of his work—the highest award that any software engineering expert has been awarded as of 2012.

These process improvement concepts do not specify anything about the technical details of the methods, tools, and procedures that are used in an organization, only how they should be managed. Some see this as a major failing, but on the whole, application of the concepts has helped organizations improve their ability to create software in predictable, repeatable ways and in so doing they usually adopt one or more development methodologies.

72.1.8 Education and Training (1974–2004 and Beyond)

Education and training are often the drivers in defining the content of a discipline because of their influence on future behavior rather than being a formalization of current and past activity. This was and still is the case in software engineering since, at least in the United States, research is tied to education at the best universities and much of the training in organizations follows their current research directions. Because leaders in the computer science field were prominent among the attendees at the two NATO conferences mentioned earlier and because they carried the message back to their colleagues and students, the importance of finding better approaches to developing software quickly became a major theme in computer science research and hence in the educational efforts of the researchers.* At the second NATO meeting on software engineering (Buxton and Randell, 1969), a session was devoted to discussion of software engineering education.

The first known meeting devoted entirely to software engineering education was an internal IBM meeting in Toronto, Canada, in 1974 that was organized by the late Harlan Mills.† The first broad meeting was organized at the University of California, Irvine, in early 1976 (Freeman et al., 1976) and brought together practitioners and software researchers, as well as representatives of research funding agencies. This meeting served as a baseline of needs expressed by practitioners and served to introduce a number of people with similar interests to each other. This resulted in a number of formative activities over the next few years (Budgem et al., 2003; Ford, 1994).

One of these outcomes was a collaboration that resulted in the first published foundation for software engineering education (Freeman and Wasserman, 1978). For better or worse, the paper served as the basis for essentially all academic programs in software engineering education for the next 10 years or more. As the need for software engineering intensified in industry, especially in defense contracting firms and large computing equipment manufacturers, a number of efforts to define better and support a discipline were undertaken and a number of courses and a few degree programs were designed.

The Software Engineering Institute (SEI) at Carnegie Mellon University founded in 1984, championed educational efforts as one of their main, early activities. A series of conferences on software engineering education and training was started in 1987 and continues annually today. Most universities and colleges today have at least a few courses in software engineering (usually in computer science departments) and an increasing, but not large, number have degree programs (usually at the Master's level). In many basic courses in software engineering and information systems, software engineering concepts are embedded in more general courses on programming and other basic courses (although they are often not identified specifically as software engineering topics). Software engineering training is also a popular topic at community and for-profit colleges, while corporate in-house training programs are perhaps less popular today because of the availability of courses elsewhere—and, also sometimes because companies have turned their attention away from training more generally and in some instances from software engineering in particular.

* One of the authors of this chapter, Freeman, was a graduate student at Carnegie Mellon University in 1968. The week after the first NATO meeting, Alan Perlis who keynoted that meeting and was chairman of the department, met with a group of us to reprise the meeting's discussions and later gave us each a copy of the proceedings (my copy long since purloined). The author was already engaged in research focused on improving software development and that early exposure encouraged him to continue in that pursuit and to develop software engineering courses in the early 1970s and to integrate some of the ideas into other courses as well.

† Harlan Mills was also the chair of the First National Conference on Software Engineering. September 11–12, 1975. Mayflower Hotel, Washington, DC.

A variety of efforts have tried to produce comprehensive “bodies of knowledge” for software engineering, standards for practice, and even certification exams. While useful, these have been of use for a limited time because of the rapid change in technology, the market, and some aspects of the field—to say nothing of the lack of people to develop these artifacts.

Much of the curriculum design for current BS programs was based on the EC2000 accreditation criteria from Accreditation Board for Engineering and Technology (ABET) and the joint IEEE/ACM task force draft accreditation criteria for software engineering (Engel, 1999),* and the curriculum guidelines were approved in 2004 (Lethbridge et al., 2006). “The program must include approximately equal segments in software engineering, in computer science and engineering, in appropriate supporting areas, and in advanced materials. This material should cover about three-quarters of the overall academic program, with the remainder to include institutional requirements and electives.”†

The software engineering portion of the program should cover processes and techniques for developing and maintaining software systems. Substantial software design and software architecture work must be included. Engineering responsibility and practice must also be stressed, including ethical, social, legal, economic, and safety issues.

In the supporting areas, we have communications and mathematics. Oral and written communications, including the ability to work in teams, are covered. The mathematics contents focus primarily on discrete mathematics, and probability and statistics (this is particularly useful in process improvement analyses).

The scientific basis for software engineering is primarily computer science, similarly as the natural sciences are for other engineering disciplines.‡ The computer science and engineering portion of a BS program would include foundational topics such as algorithms and data structures, computer architecture, databases, programming languages, operating systems, and networking.

The advanced portion of the program provides depth in one or more areas of study in software engineering and in one or more significant application domains.

The curriculum should also emphasize software practice and development process and these aspects are given a strong hands-on component using the software engineering laboratory. There should be a substantial senior design project (or SwE practicum) component, where a major project is performed in teams. For an earlier historical review of software engineering education refer to (Tomayko, 1999).

72.2 Engineering and Software Engineering

When the term software engineering was introduced 40 years ago at the NATO 1968 conference, it “was deliberately chosen as being provocative, in implying the needs for software manufacture to be based on the types of theoretical foundation and practical disciplines, that are traditional in the established branches of engineering.” The term is now widely used in industry, government, and academia: thousands of IT professionals go by the title software engineer; numerous publications, groups and organizations, and professional conferences use the term in their names, as do many educational programs, both at the undergraduate and graduate level (including the Ph.D.).

Is software engineering likely to become a mature engineering discipline in the traditional sense of the word? Could there be a basis for understanding the complexity of software such that we can “engineer” it to have predictable quality and behavior?

As a practical matter, definitions of software engineering in abstract terms are often not overly useful in practice because they are existential in nature and there are wide variations in the importance of specific topics in different situations. In software engineering research endeavors, however,

* G. Engel, “Accreditation criteria for software engineering,” *IEEE Software*, 31–34, 1999.

† The majority of these concepts were captured in the design of the curriculum guidelines for software engineering as part of the ACM/IEEE computing curricula effort. One of the authors, Diaz-Herrera, was the co-editor of Volume IV.

‡ Some still consider Computer Science a branch of mathematics.

they are somewhat more useful. Consequently, a general understanding of what software engineering is will be helpful in your use of this handbook.

72.2.1 What Is Engineering?

A dictionary definition is an instructive place to start:

1. *The art or science of making practical application of the knowledge of pure sciences...*
2. *The action, work, or profession of an engineer.*
3. *Skillful or artful contrivance; maneuvering.**

The first definition is probably what you understand informally and is the most general definition. The focus is on “practical,” as it should be, especially to satisfy the imperatives placed on the field of software engineering.

The second definition sounds circular, but is also useful in the case of software engineering. As the field expands to new application areas and new elements, practice—that is, what software engineers do—often is ahead of any educational programs or more formal definitions. As an example, software engineers were dealing with human–computer interfaces before that topic was routinely included in software engineering courses.

The third definition is most often found in discussions of non-technical matters—for example, “The customer engineered the procurement so that his company would not be dependent on any one supplier.” Of course, it also applies to technical work as well—for example, when a software engineer is faced with a problem for which there is not a straightforward solution.

The second definition in the preceding text begs the question: Who is an engineer?

According to the Model Law (NCEES, 2013) prepared by the National Council of Engineering Examiners, an “engineer” is an

individual who is qualified to practice engineering by reason of special knowledge and use of the mathematical, physical, and engineering sciences and the principles and methods of engineering analysis and design, acquired by engineering education and engineering experience.

In the same act, the term “practice of engineering means”

any service or creative work, the adequate performance of which requires engineering education, training, and experience in the application of special knowledge of the mathematical, physical, and engineering sciences to such services and creative work as consultation, investigation, evaluation, planning and design of engineering works and systems, planning the use of land and water, teaching...

The question is whether we can substitute “software engineering” for “engineering” and still have valid statements. For this to work, we would need to replace physical sciences by computer science.

72.2.2 What Is Software Engineering?

The curriculum volume for software engineering (ACM, 2004) listed the following definitions:

1. The establishment and use of sound engineering principles (methods) in order to obtain economically software that is reliable and works on real machines (Bauer, 1972).
2. ... the application of a systematic, disciplined, quantifiable approach to the design, development, operation, and maintenance of software, and the study of these approaches; that is, the application of engineering to software. (Wikipedia, retrieved March 1, 2013)

* Random House Dictionary, op.cit.

3. ... concerned with developing and maintaining software systems that behave reliably and efficiently, are affordable to develop and maintain, and satisfy all the requirements that customers have defined for them. (<http://computingcareers.acm.org/>, retrieved March 1, 2013)
4. Software engineering is that form of engineering that applies the principles of computer science and mathematics to achieving cost-effective solutions to software problems. (CMU/SEI-90-TR-003)
5. ... the technological and managerial discipline concerned with systematic production and maintenance of software products that are developed and modified on time and within cost estimates. (Fairley, 1985)
6. The application of a systematic, disciplined, quantifiable approach to the development, operation, and maintenance of software. (IEEE, 1990)

The SE 2004 volume adopted the following definition:

Software Engineering is about creating high-quality software in a systematic, controlled, and efficient manner. As such, there are important emphases on analysis and evaluation, specification, design, implementation and evolution of software. In addition, there are issues related to management and quality, to novelty and creativity, to individual skills, and to teamwork and professional practice that play a vital role in software engineering.

A definition that one of us has used for many years captures the broad sweep of software engineering:

Software engineering is the systematic application of methods, tools, and knowledge to achieve stated technical, economic, and human objectives for a software-intensive system.

This definition is purposely general because the specific methods, tools, etc. may vary with the application, the organization, and over time. Note the use of “software-intensive” to signify that in general software engineering is dealing with hardware and human systems as well as software, either directly in the absence of a larger systems methodology or, at least, in conjunction with such an encompassing methodology.

Denning proposes the merging of human-centered design and software engineering process into a profession of software architects, the central practice of which “unites system-oriented engineering and customer-oriented designers” (Denning, 1996). This proposal also focuses on standard practices in a domain of expertise. We should take this recommendation seriously. But, because of its possible misinterpretation with today’s use of the term software architecture, the term software systems architecture may be more suitable to describe such a discipline (see also Rehtin, 1997). This definition also risks ignoring the very important implementation, versus architecting, activities that practical software engineering must encompass.

Ian Sommerville (Sommerville, 1999) also concurs with the notion that software engineering is something else, and introduced the idea that at best it is a “soft” systems engineering discipline, “In essence, the type of systems which we are interested in are socio-technical software-intensive systems...” Furthermore, Sommerville claims that “there is no technical solution to software complexity.”

Andriole and Freeman (1993) also propose a new discipline of “software systems engineering” that aims to integrate the two disciplines that often operate fairly disconnected from each other. The still developing nature of software engineering as a discipline is underscored by the variety of these definitions.

72.2.3 How Does Software Engineering Differ from Traditional Engineering?

If the set of activities associated with the creation of software is to be considered engineering, we must establish appropriate relationships, in terms of similarities and differences, with conventional

engineering disciplines. Software is different from the object of much engineering because of its intangibility and plasticity, of course. There are also important differences between software engineering and traditional engineering (Díaz-Herrera, 2009; Shaw, 1990).

Some specific differences between software engineering and traditional engineering include the following:

- Software engineering builds on a different basis or foundation, because the product it designs and creates is an abstract or logical artifact instead of a concrete or a physically realizable entity.
- Software engineering foundations are primarily in computer science, not in the natural sciences.
- Underpinning all successful engineering is the notion of measurement. This is absolutely fundamental to the engineering process and engineered products, and it is probably the part of software engineering that differs the most from traditional engineering. Measurement as practiced in other engineering disciplines is impossible for software engineering, as DeMarco recently put it (DeMarco, 2009), “Software development is inherently different from a natural science such as physics, and its metrics are accordingly much less precise in capturing the things they set out to describe.”

The three primary things one can measure in software are size, development time, and defects (Humphrey, 1995). These measurements, however, do not address predictability of behavior—a critical aspect of engineered products. There are no universal relationships between software quality and what we can measure in software and, in particular, with predictable behavior (Sommerville, 1999).

- Although some software engineering techniques are based on discrete mathematics, rather than on continuous state systems, there is no software engineering mathematics despite the long quest for a successful axiomatic approach to programming (Shustek, 2009).
- Even if we succeed in finding ways to prove programs correct, software engineering deals with systems that are too complex to be treated by mathematical analysis alone.

In terms of *engineering practice*, software engineering is a different kind of “engineering.” The difference that most people think of first is that software is not tangible and is infinitely malleable; most engineering disciplines, in practice, deal with tangible objects (e.g., bridges, mechanical devices, chemicals, and circuits). A major exception is industrial engineering,* which is largely mathematical or abstract, but measurable. Electrical (or electronic) engineering would also appear to be an exception since it deals with physical effects that are not visible—but they can be measured and their effect often seen or otherwise detected—and they are realized in physical circuits.

Another major difference is obvious in the first aforementioned definition; there is no “pure science” on which software engineering is based. This is a major issue in practice and theory that we briefly address in the following text.

There are more practical differences as well—the lack of common standards, a deficiency of case studies and handbooks (which this volume addresses to some extent), the rapidly changing nature of what software engineers do, the lack of much effort spent on developing the structures and artifacts of a traditional engineering discipline, and so on. Many of these are common to any new field as it develops and, especially, when the activities of its practitioners and researchers are so much in demand, leaving little time or motive for most people to devote time to what appear to be long-term, even irrelevant, activities. Over time, this will change.

Fundamentally, however, software engineering will always differ from traditional engineering in its technical details because of the invisibility and malleability of the object of its efforts. It shares this differentiation with computer science as discussed in the subsequent section.

* Agresti grouped the collection of Industrial Engineering techniques and tools that appear to offer some prospect for software (Agresti, 1981).

72.2.4 How Does Software Engineering Differ from Computer Science?

Software engineering is more than and less than computer science—put more properly, they share a lot in common, but each addresses issues that the other discipline does not address. This viewpoint was discussed as early as the NATO Conferences (Buxton and Randell, 1969, p. 46).

Chemical engineering, for example, is largely based on chemistry; civil engineering is largely based on mechanical properties known from physics; electrical engineering is largely based on electromagnetic properties known from physics; and so on. While all may have management issues in practice, these tend to be common across many areas of traditional engineering and none in their basic formulation are concerned with human interactions with the systems with which they deal.

Software engineering does not have a well-established science on which most of its tenets can be based. Computer science is also still a developing discipline, although more mature than software engineering, thus making the definition of a software engineering discipline even more difficult.

The major commonality that software engineering and computer science share is, of course, software. Software (programs and systems of programs) is one of two major topics that computer science deals with—the other being the mechanisms (processors) that can execute programs. Software engineering was started by including in the definition of computer science the study of the processes used to create software (the essence of software engineering) but as software engineering has paid more attention to topics such as management, some argue that it needs to be a discipline separate from computer science. Whether or not it should be a separate discipline is an argument that will not be settled any time soon, but is largely an issue of organizational politics and is not terribly relevant to the practical conduct of software engineering.

Differentiating factors include the importance of management, the processes of creating software, technical issues like human–computer interfaces, and so on. This can be explained by noting that computer science, like traditional sciences, is fundamentally focused on *understanding* something, while software engineering, like traditional engineering, is focused on *creating* something. At the same time, the non-traditional nature of computer science blurs this distinction somewhat.

The gap currently is wide between the software engineering knowledge that has been codified, verified, and organized into repeatable, teachable courses and curricula on the one hand and what the practicing software engineer must employ to be successful in many situations on the other (Díaz-Herrera et al., 2007). The objective of software engineering research is to organize and narrow this gap so that future generations can learn how to do software engineering in some way besides making large and costly mistakes!

72.3 Software Engineering Research

Research in software engineering refers mostly to applied research, and a more rigorous, scientific approach is needed (see evidence-based software engineering later in this section of the handbook). We can analyze, in our academic laboratories, existing and proposed software methods and techniques in the light of new software engineering principles. It is a fact that, since the introduction of the term software engineering in 1968, there have been many proposals being put forward to alleviate the software crisis. Rarely, if ever, have these proposals been backed by hard data as evidence of effectiveness. The arrival of Ph.D. programs in software engineering will accelerate the scientific understanding of software.

We need to examine project failures to discover why they fail. Just like ordinary engineering failures (such as a bridge collapsing), major software disasters must be investigated, causes analyzed, principles discovered, and solutions reported and disseminated. This kind of software practice research is difficult to do in a traditional academic setting (Shaw, 2002).

Someday, we may have completely automated ways of producing complex software. While some progress has been made, we are still a long way from reaching that goal. Research aimed at that goal

(sometimes called “automatic programming”) has been around for longer than software engineering and has taken various forms ranging from artificial intelligence approaches to algorithmic processes. The latter approach has been successful at the level of code generation and program generation for well-structured situations (e.g., I/O drivers for hardware), but progress at higher and broader levels of system generation has not made much progress in unstructured and/or new areas.

72.4 Elements of Software Engineering

The rapidly developing and diverse nature of software engineering, as illustrated earlier, mean that any list of the primary elements in a software engineering curriculum or the primary activities of software engineering will be incomplete and/or soon out of date. Focusing on software, the elements of software engineering typically include *methods* for the various development activities as summarized in Table 72.1 as well as and corresponding verification and validation activities, and *tools* to support and/or automate each of these, including IDEs, plus *skills and knowledge* of software engineering, computer science, engineering management, human perception and behavior, and one or more application domains (see also Díaz-Herrera, 2001).

Notice two characteristics of this set of categories: First, it is focused on methods that are for the most part carried out by human beings and only secondarily (if at all) on the nature of software (in the same way that chemical engineering is influenced by chemical properties of materials). Second, the categorization is still very general.

The great majority of software produced today is still developed following ad-hoc methods and it remains true that “software engineers have not been able to put together a coherent engineering design method for the systematic production of software, specifically for large, complex, ill-defined systems” (Denning, 1996).

The reasons for these problems are many-fold (ACM, 2004):

1. Software products are some of the most complex of man-made systems, and software by its very nature, has intrinsic difficulties (e.g., complexity, visibility, and changeability) that are not easily overcome (Brooks, 1995).
2. Programming techniques and processes that worked effectively in the 1950s and early 1960s, to develop modest-sized programs by an individual or a small team, did not scale-up well to the development of large, complex systems (systems with millions of lines of code, requiring years of work, by hundreds of engineers).
3. The pace of change in computer and communications technology drives the demand for new and evolved software products. Our successes in this area have created customer expectations and competitive forces that stress the quality of software and their development schedules.

The thought of treating software engineering as an engineering discipline is, of course, not new. For several years now, people both in academia and in industry and government have fostered this very idea.

What is new today is the widespread impetus from many fronts to consider software development as engineering. To wit consider the following major milestones:

- A *code of ethics* for software approved by the ACM and the IEEE-CS (Gotterbarn, 1999)
- The processes for outlining the body of knowledge for software engineering has resulted in two widely contributed and distributed versions (Bourque and Dupuis, 2001). SWEBOK V2 (2004 Version) also known as Technical Report ISO/IEC TR 19759 is currently under review to produce V3 under the direction of Dick Fairley.
- *Accreditation criteria* for educational programs in software engineering (see IEEE Spectrum, 1997) accepted by ABET in 1999 (Engel, 1999).
- Texas legislature has being *licensing professionals* in software engineering since July 1999.
- Pioneering undergraduate programs in the United States at Rochester Institute of Technology* in New York, Monmouth University† in New Jersey and Milwaukee School of Engineering‡ led the way to the development of several such programs in the United States and in the European and Australian universities.
- In 1997, we discussed the possibility of creating *Ph.D. programs* in software engineering (Díaz-Herrera, 1997). Two such programs have been put in place, the first at the Naval Postgraduate School§ and the other at Carnegie Mellon University.§,**

The best way to define the elements of software engineering is by extension. The aforementioned historical material is one example. A good text is another. The content of the curriculum in software engineering from a highly regarded school is a third type of definition. Ultimately, however, the elements of software engineering, at the present state of understanding, are defined by what practicing software engineers need and do in their daily work.

72.5 What Is Used in Practice?

It is impossible to answer the question “What is actually used in practice?” nor is that the purpose of this handbook. We would note that there is no comprehensive, objective survey data on the subject (however, see Lethbridge, 2000). One can find surveys from time to time in the trade press, typically focused on a specific language, tool, or methodology; often times these are little more than promotion pieces by a vendor. We point the reader to later parts of this section discussing empirical and evidence-based software engineering.

Amount of use of “software engineering” or “software engineer” is equally unknown. In some jurisdictions, use of the term “engineer” is illegal unless the jobholder is certified as an engineer in that jurisdiction, for example.

Some engineering based companies that employ engineers of many kinds classify some employees as software engineers while other, similar companies specifically do not unless the employee has a degree in software engineering while yet others have no policy, leaving it to the employee to use whatever title they want. Perhaps the largest usage of “software engineer” is basically as a substitute for and synonymous with “programmer” in terms of what the employee does.

72.6 Where Does One Need Software Engineering?

Software engineering originated from difficulties with large, complex software-intensive systems; has been developed with heavy support from industry and government organizations that are usually those that are developing, or contracting for, such systems; and is most often found today in large organizations and/or projects. To some extent, this is because it is perceived (not necessarily accurately) that utilizing software engineering is more expensive, cumbersome, or overly bureaucratic than many organizations feel they can afford. While sometimes true, this need not be the case and often is not when one computes the total lifecycle cost of developing software.

At least until fairly recently and perhaps still today, there are organizations that do not utilize software engineering even though they are building large systems. This tends to be more the case in commercial organizations that are not engineering-oriented overall; in fact, sometimes software engineering is rejected by such organizations precisely because of the term “engineering,” that they mistakenly believe refers to something very technical that does not apply to them.

So, does this mean that only large organizations should use software engineering? Absolutely not!

There is nothing inherent in the concepts and elements of software engineering that prevents it from being used in organizations of any size and on projects of any size. It can be used by one person developing a single program, a small team in an organization small or large, teams of any size developing large systems, development spread over geographically distributed groups, and so on. What is needed is to choose carefully the specific elements to be used and the overall process framework to guide the work.

The principles and elements of software engineering are often the embodiment of good, common-sense practice that are just as useful for an individual working alone as they are for a team of thousands in a large organization. Obvious examples are the programming methods that are often part of a software engineering environment—types of language used, structuring principles, review techniques, and so on. These are techniques that are applied by individuals even when they are working in a large group and are just as valuable when they are working alone. Even program review techniques that may call for code reading by another person embody the principle of careful review of work, that is, formal inspections; while it may be more valuable when the review is conducted by someone other than the author of the code, the fundamental principle of review still applies.

Similarly, the concept of following a defined lifecycle with definite stages, explicit entry and exit criteria from each stage, and so on is a concept that is important in small organizations and/or on small projects down to the level of individuals. If one is writing a program alone, it is important to understand the requirements before beginning to program, design the structure of the program if it is more than the simple coding of a straightforward algorithm, then test the program, document it, etc. The depth and formality of most of these steps will certainly be less than if working in a team and/or on a large system, but the structuring of one’s activity (workflow) can be beneficial.

Watts Humphrey (1995, 1997) in the two books referenced developed the idea that software engineering is not just a large team, large organization activity.

72.7 Summary

Software is complex and the software industry is large, global, and growing. The increasingly public importance of software-intensive systems in our daily lives, for our safety and security, and for national and global economies makes it imperative to be able to deliver high quality software. We need to find effective ways of evaluating innovative concepts, methods, and tools for developing high quality software.

Over the past 50 years, the act of creating the software that is necessary to implement our visions of automation using a computer has come to be understood as extremely difficult to carry out and, thus, it has been recognized that a discipline akin to more established engineering disciplines might make the

task less difficult. The quest outlined earlier has certainly made possible many aspects of modern software systems, but it is not yet a full discipline either in the intellectual or practical sense of the term “discipline.”

One overriding theme of the development of software engineering over the past 45 years has been the successive broadening of scope of what must be included in the discipline—from programs to designs to systems to methodologies and beyond. A second theme has been the inclusion of topics such as management and human behavior that are not found in traditional engineering disciplines (civil, chemical, mechanical, and electrical), or are considered separate from the main body of the discipline. A third theme has been the rapid expansion in scope to creating software for countless new applications and situations, usually under increasing pressure to produce the product more rapidly and with less effort.

The practical definition of the discipline has certainly taken shape in the form of a fair number of standards and compilations of knowledge (including this volume). Yet, the still rapidly changing landscape of knowledge and demands keeps the definition fluid, at best. As so often happens, what seems clear in theory is less clear in practice. Perhaps, the most important driver of the disciplinary definition remains the courses and curricula that exist, although at the same time far too many of those do not address the real needs of practice.

As a research discipline, we are probably even further away from a consistent disciplinary definition. Indeed, some would argue that the engineering and management approach will never be completely successful and that the way to address the “software problem” is to automate as much of the software creation process as possible. Even within the engineering paradigm, there are important differences in researcher’s beliefs of what the important research questions are and how to attack them—two characteristics that define a discipline of research.

Could there be a basis for understanding the complexity of software such that we can *engineer* it to have predictable quality and behavior?

The answer to this fundamental question is unknown—that is the objective of some software engineering research. Thus, at present, software engineering usually has to address the challenges of architecting complex software-intensive systems, of the kind described earlier, by more heuristic and less analytical methods. As DeMarco (2009) says, “software development is and always will be somewhat experimental.” In this way, software development is a different kind of engineering, the kind of engineering associated with computing.

Whatever your point of view and interest in the discipline of software engineering, the history of the past 45 years can be illuminating and helpful to put into context the information that you will find in this handbook. The origins of that history as outlined here will provide you a basis for further exploration of that history in areas that pertain to your needs.

There may be a problem with trying to retrofit this fundamentally computing sub-discipline with the traditional “engineering” paradigm; maybe, what we should be doing is exploring how it can be molded into that paradigm within computing. Computer science is on the way to accomplishing this; it became not a “science” discipline, but rather the “science of computing,” and the same can be said of IT—the technology of computing.

We implemented the vision of computing as a distinct branch of knowledge, a discipline in its own right, that culminated with the creation of the computing college—“standing alone, headed by its own dean, with the same stature as traditional colleges,” as (Denning, 1998) put it. In addition, here is where software engineering rightfully belongs as the “engineering of computing.”

73.1 What Is a Profession?

The term “profession” is used informally to refer to a very wide range of occupations. However, most writers reserve the term for occupations that share a number of characteristics: an explicit body of knowledge, some sort of entrance control, a code of ethics, and a recognized need for continuing education (see, e.g., Davis 2009). Professions are generally governed by collaborations between professional organizations and governmental agencies. Professional credentials may be internationally portable. Occupations that impact individuals’ physical and/or financial well-being are most likely to have evolved into professions. Examples include law, health (medicine, dentistry, and nursing), architecture, and accounting. In the United States, each of the aforementioned examples has a body of knowledge that is embedded in a set of entrance examinations. Entrance control is enforced by specialized educational prerequisites for the examinations. All of these professions have explicit codes of ethics. In the United States, members of these professions are required to have government-sanctioned licenses, and continuing education is a requirement for retaining a valid license.

73.2 Engineering as a Profession

Until a few centuries ago, “engineers” were primarily those involved with the design and construction of fortifications and weaponry. However, in the eighteenth century, the occupation “engineer” began to be extended to cover those who designed and built the technological elements (mines, steam engines, canals, bridges, tunnels, locomotives, etc.) that were at the heart of the changes in manufacturing and transportation generally referred to as the Industrial Revolution (Armytage 1961). During this period, the term “civil engineer” was coined to contrast with the more traditional military uses of engineering. This usage is still

found in some countries (e.g., Chile). At the same time, the practice of engineering gradually acquired the characteristics described in the preceding section. These characteristics were acquired slowly over time, and the rate and process of acquisition was quite variable across countries. For example, while entrance to the profession was initially achieved by apprenticeship to a practicing engineer, the nineteenth century saw the creation of specialized schools dedicated to the training of engineers. In France, the last decades of the eighteenth century saw the establishment of the *École Polytechnique* and *École des Mines*. The first engineering school in the United States was Rensselaer Polytechnic Institute (Troy, New York), established in 1824 “for the application of science to the common purposes of life.” During the course of the nineteenth century, other countries followed the example of France and the United States and established engineering schools. In the United Kingdom, this effort began with the establishment of the London Mechanics’ Institute in 1823 (Armytage 1961: 144). Engineering entered the UK academic world a bit later; the first courses in civil and mechanical engineering began in 1838, and the first chairs in engineering were created at University College in 1841; both institutions were part of the University of London. In most countries, control of university engineering programs and guaranteeing their quality was the responsibility of ministries of education. This was not possible in the United States, with its federal structure and public/private university system. The gap was eventually filled by the Engineers’ Council for Professional Development (now called ABET) established in 1932 as a confederation of professional societies (including the American Institute of Electrical Engineers, a predecessor of the Institute of Electrical and Electronics Engineers [IEEE]). ABET is responsible for the accreditation of US programs in engineering and computing; it also accredits many programs in other countries. ABET accreditation requires that a program in a given engineering discipline meet discipline-specific requirements that are derived from an explicit or implicit body of knowledge for that discipline. Graduates must also recognize the need for lifelong learning in their discipline. Finally, students graduating from an accredited program must have an understanding of professional and ethical responsibility. Corresponding to this requirement, professional societies in the engineering disciplines have developed discipline-specific codes of ethics. Codes of ethics have also been developed by organizations representing engineering more broadly. For example, the US-based National Society for Professional Engineers (NSPE) has developed a code of ethics (NSPE 2007). Governmental regulation of engineering generally involves some sort of collaboration between an arm of government, the organization accrediting engineering education, and one or more professional organizations. In the United States, professional licensure of engineers is regulated by the states, but the requirements and the examinations required for licensure are administered by a professional organization, the National Council of Examiners for Engineering and Surveying (NCEES). Aspiring professional engineers must pass the examinations and have appropriate education and experience; the number of years of experience required is less for those who have completed an ABET-accredited undergraduate degree. Similar structures exist in Canada and Australia; more unitary approaches are used in other countries. It is important to note that (at least in the United States) professional engineers may have their state-issued licenses revoked if they violate the NSPE code of ethics.

73.3 Emergence of Software Engineering

The phrase “software engineering” first saw widespread use in North Atlantic Treaty Organization (NATO) conferences held in 1968 (Naur and Randell 1969) and 1969 (Randell and Buxton 1970). These conferences were a response to a generally perceived “software crisis” that had arisen from experience with the problems associated with designing, developing, and maintaining reliable large-scale software. At the 1968 conference, Friedrich Bauer defined software engineering as “establishment and use of sound engineering principles to obtain economically software that is reliable and works on real machines efficiently” (Naur and Randell 1969). The idea was that just as engineering principles were needed to design and build complex artifacts in the physical domain, they would also be necessary for doing the same in the software domain. During the ensuing decades, the phrase “software engineering” has seen increasingly widespread use. Many scholarly journals, magazines, and research and

practitioner conferences have been established to disseminate research and current practice in software engineering and its subdisciplines (see the other chapters). Software engineering research programs are found in universities (most usually in departments of computer science) and in industrial and government laboratories. Courses or modules in software engineering and its subdisciplines are offered by most universities. Many computer science departments offer entire degree programs at undergraduate or Master's level. Some universities have established independent departments of software engineering, usually contained within colleges of engineering. Software engineering clearly has roots and affiliations in computer science, but its name and the associated rhetoric suggest an affiliation with engineering. These alternative affiliations have had an impact on the emergence of the profession of software engineering.

73.4 Software Engineering as a Profession

More than 40 years after the NATO conferences that gave birth to “software engineering” as a concept, the discipline has attained recognition from universities and research funding agencies. At the same time, “software engineer” sees wide use as a job category in industry. While the acceptance of software engineering in academia and industry demonstrates the extent of the change since 1968, it is not so clear whether we can reasonably talk about a profession of software engineering. The following sections will look at this issue.

73.4.1 Body of Knowledge

In late 1998, the Association for Computing Machinery (ACM) and the IEEE Computer Society (IEEE-CS) began a joint effort to develop a body of knowledge for software engineering.* The eventual outcome of this effort was the Software Engineering Body of Knowledge (SWEBOK), first released in 2004 (IEEE-CS 2004b). SWEBOK became an international standard (ISO/IEC TR 19759) in 2005. SWEBOK is built around 10 knowledge areas: requirements, design, construction, testing, maintenance, configuration management, software management, process, tools and methods, and quality. Furthermore, as the discipline of software engineering is subject to rapid change, the SWEBOK project includes an ongoing revision process, described in Appendix B of the SWEBOK document. At about the same time, the two leading professional societies in the general area of computing (ACM and IEEE-CS) began an effort to develop curriculum recommendations for undergraduate programs in software engineering. This effort produced the SE2004 curriculum recommendations (IEEE-CS 2004a). The list of topics included in the curriculum was heavily influenced by the SWEBOK document (IEEE-CS 2004a: 12). More recently, curriculum guidelines for professional Master's programs in software engineering have also been proposed (ISSEC 2009). This Master's curriculum is also based on an explicit body of knowledge; the “core body of knowledge” was derived from the SWEBOK by making relatively minor changes to some of the SWEBOK knowledge areas.

73.4.2 Accreditation

The path to the accreditation of software engineering programs varies by country. Accreditation of US engineering programs by a federation of professional societies (now called ABET) began 80 years ago.† Computing programs are far more recent, and accreditation efforts date back only to the establishment

* Note that ACM withdrew from this effort in 2000. At this time, ACM had taken a strong position opposing licensure of software engineers, and development of a body of knowledge was seen as a step toward licensure. These developments will be discussed further in the subsequent sections.

† Note that ABET now accredits programs outside the United States. These accreditations include software engineering programs.

of the Computer Science Accreditation Board (CSAB) in the 1980s. This entity worked alongside ABET and adopted many of its principles and processes. In the late 1990s, CSAB moved closer to ABET, eventually merging into the larger organization in 2000 when CSAB became an ABET member society. As a result of this merger, ABET now accredits computing programs (computer science, information systems, and information technology) as well as programs in computer engineering and software engineering. ABET accreditation of software engineering programs was first proposed in 1997, and software engineering accreditation criteria were approved in 1998. To understand how all of this works, it is necessary to know a bit more about ABET's organizational structure. ABET is organized into four commissions: the two relevant to this discussion are the Engineering Accreditation Commission (EAC) and the Computing Accreditation Commission (CAC). As might be expected, EAC and CAC are responsible for engineering and computing programs, respectively. The accreditation criteria for a program are set by one or more "sponsoring" societies and must be approved by the relevant commission. For example, electrical engineering criteria are set by IEEE and approved by EAC, while computer science criteria are set by CSAB and approved by CAC. Since software engineering shares aspects of computing and engineering, its criteria are written by CSAB and approved by EAC. The inclusion of CSAB within ABET is one approach to resolving the potential conflict created by software engineering's competing (engineering and computing) affiliations.

Other countries have taken different paths toward resolving the question of who is to accredit software engineering programs. In the United Kingdom, the British Computer Society (BCS) is a chartered engineering organization that is a member of Engineers UK, a federation of professional engineering societies. Since Engineers UK is responsible for accrediting engineering programs in the United Kingdom, BCS can accredit computing programs (including software engineering) within the Engineers UK mandate. In Australia, the Australian Computing Society and Engineers Australia make joint accreditation visits to software engineering programs. However, some countries have found it more difficult to achieve shared responsibility for software engineering accreditation. The Canadian situation is a case in point. Computing programs in Canada are accredited by the Canadian Information Processing Society (CIPS), while engineering programs are accredited by Engineers Canada through the Canadian Engineers Accreditation Board. The situation is exacerbated by the fact that Engineers Canada has trademarked the words "engineer" and "engineering" in Canada and aggressively defends the rights associated with the trademark (Adams 2004). For example, when the computer science department at Memorial University (Newfoundland) attempted to offer a software engineering degree, the university was sued by Engineers Canada. In response, Memorial has trademarked the phrase "software engineering." The CIPS perspective can be found at CIPS (undated). This conflict has never been definitively resolved. It is also worth noting that different countries have different cultural and legal contexts for program accreditation. In the United States, accreditation of engineering programs is part of the culture of engineering, especially because of its link to professional licensure. Accreditation is therefore the norm for US engineering programs. However, the decision to accredit a US computing program involves several factors, including institutional characteristics, academic organization, and local and regional competition. By contrast, other countries (e.g., Germany) have legal requirements for the accreditation of university programs.

73.4.3 Code of Ethics

Most engineering disciplines have developed their own codes of ethics; similar codes have also been developed by national organizations representing engineering more broadly, such as NSPE or Engineers Canada. At the same time, some national computing societies have developed codes of ethics for computing professionals. For example, each of the British, Australian, and Canadian professional societies has a code of ethics (CIPS 2005, BCS 2011, ACS 2012). However, these codes are not specific to software engineering. In the 1990s, ACM and IEEE-CS addressed this need (see Davis [2009], for a detailed history of this effort) by jointly developing a code of ethics for software engineers (ACM 1999); the code was approved by both societies in 1998.

73.5 Professional Qualifications for Software Engineering: Licensure versus Certification

There are two general approaches to providing generally recognized qualifications for a practicing professional. The first approach confers a legal status that carries rights, privileges, and obligations. In the United States, this status is called a “license to practice a profession,” and it will be referred to here as “licensure.” An alternative approach is for a professional to acquire certificates that demonstrate proficiency in a particular body of knowledge; this general approach will be referred to as “certification.” Note that by contrast with licensure, certification is always voluntary and has no legal implications.

73.5.1 Licensure

Many professions require practitioners to hold government-sanctioned licenses or equivalent designations (e.g., “chartered status” in the United Kingdom and Australia). Government supervision of such qualifications is almost always shared with professional societies. It is clear that governments will enforce the regulation of professions that have significant impact on health and safety. The same is true for professions that impact the financial and legal status of individuals and corporations, such as law and accountancy. The situation for engineering is less clear, and there is much cultural variation both within engineering and across countries. In the United States, for example, civil engineers generally hold licenses, but electrical or industrial engineers generally do not. One reason for this difference is that the individual with ultimate responsibility for the design of a project affecting public safety (e.g., a nuclear power plant or oil refinery) must be a licensed engineer; such responsibilities are much more likely for civil engineers than for electrical or industrial engineers. In some Latin American and European countries, the acquisition of professional status as an engineer has social benefits. An engineer with officially recognized professional status is entitled to use the personal title “engineer.” Such individuals have higher status in society; they frequently use the title in telephone directory listings and similar places. In these countries, virtually all individuals who are entitled to call themselves “engineer” make use of the title.

What is the situation for software engineering? In countries using the “chartered engineer” licensing model (Canada, Australia, and United Kingdom), the opportunity to attain chartered status has relatively easily been extended to software engineers. In the United States, where the question of licensing or certifying software engineers has been an active topic of discussion for many years, the situation is far less clear. For example, in 1991, the lower house of the New Jersey legislature passed a bill to license “software designers,” although the bill eventually died in the upper house (Davis 2009). Shortly thereafter (in early 1993), the IEEE-CS created a Steering Committee for the establishment of software engineering as a profession. At that time, the ACM also expressed interest in assessing professionalism in software engineering. This interest led to collaboration with IEEE-CS, and eventually (in early 1994) to the creation of a joint ACM/IEEE-CS steering committee to deal with this general topic. This committee set up task forces dealing with several aspects of professionalism: code of ethics, body of knowledge, program accreditation, and curriculum recommendations. The question of licensing software engineers frequently arose during these discussions. For example, some software engineering professionals felt that the adoption of a software engineering code of ethics could be seen as one step along the path to licensure (Davis 2009: 211). Furthermore, 1996 saw a forum on the licensing of software professionals; many of the participants were also part of the joint steering committee. The forum attendees were strongly divided on the issue of licensing software professionals. In 1997, the Licensing Committee of the Texas Board of Professional Engineers formally requested ACM and IEEE-CS to work on defining a body of knowledge on which software engineering licensing examinations could be based (Davis 2009: 321). In late 1998, the two societies created a Software Engineering Coordinating Committee (SWECC) to oversee all of these efforts. They agreed to work with the Texas Board of Professional Engineers to “identify a technical basis for recognizing competency in software engineering and [enact] rules that recognized software engineering as a distinct engineering discipline” (Davis 2009: 356). At the same time,

the National Council of Examiners for Engineering and Surveying passed a resolution in support of “licensing software engineering throughout the nation.” However, the position of the ACM representatives on SWECC was not universal within the ACM software engineering community. This is illustrated by the ACM’s creation in 1999 of an Advisory Panel on Professional Licensing in Software Engineering “to assess the current role of ACM as part of a joint effort with IEEE-CS to oversee and actively participate in the development of professional and licensing guidelines through SWECC” (Davis 2009: 359). After receiving a report from this advisory panel, the ACM Council “firmly decided [in May 1999] that it would not endorse licensing software engineers at this time, and that ACM would withdraw from any activity that gave the appearance of condoning the licensing of software engineers” (Allen et al. 2000). However, the question of licensing software engineers was debated in the flagship magazines of the two societies (De Marco 1999, El-Kadi 1999, Frailey 1999a,b); these position papers present strongly opposing views of the suitability of licensure. This situation has persisted over the past decade: IEEE-CS supports professional licensure for software engineers, and ACM continues to oppose it.

At about the same time (in 1999), Texas became the first state to institute professional licensure for software engineers. Since then, several other states have announced their intention to do the same. However, the path to engineering licensure in all US states requires that an applicant take two examinations administered by NCEES: the Fundamentals of Engineering (FE) and Principles and Practice of Engineering (PE) examinations. The FE examination consists of a morning part that is the same for all applicants; it includes mathematics (calculus, differential equations, and linear algebra), basic sciences (chemistry and physics), and engineering sciences (statics, materials, and thermodynamics). For some engineering disciplines (chemical, civil, electrical, environmental, industrial, and mechanical), the FE afternoon examination is discipline-specific; for all others, it deals with additional general engineering topics. The PE exam is specific to each of 24 engineering specialties. For civil, electrical, and mechanical engineers, PE exams are offered for multiple specialties. Since no PE examination was available for software engineering in 1998, Texas allowed practitioners with 12 years of experience and an ABET-accredited degree (or 16 years of experience for those with a related degree) to be licensed (Bagert 2004). In response to requests from engineering licensing boards in 10 states, NCEES announced in August 2009 that it had approved the development of a new PE examination for software engineers. IEEE-USA (an IEEE entity devoted to the career and public policy interests of IEEE’s US members) is co-sponsoring the examination development effort, assisted by IEEE-CS, NSPE, and the Texas Society of Professional Engineers. The first step is to conduct a professional activities and knowledge study, which will survey a diverse sample of software engineering professionals to determine the topics to be covered in the exam. However, the creation of a PE examination in software engineering will not do much to increase the number of licensed software engineers, since the FE examination is not a good fit to undergraduate software engineering curricula, and even less so to other computing curricula.

73.5.2 Certification

As stated earlier, certification and licensure are distinct approaches to professional qualifications that carry different implications. While licensure is always associated with legal restrictions and constraints, certification is voluntary and has no legal implications. It is important to distinguish between product-based certifications and broad-based professional certification schemes (Seidman 2009: 354). Product-based certifications are administered by companies (e.g., Microsoft, IBM, and Cisco). A corporate product-based certification requires passing an examination linked closely to products or sets of products produced by or associated with the company offering the examination. For example, Microsoft offers a range of product-based certifications (see, e.g., Microsoft [2012]). According to this site, “The Microsoft Certified Systems Engineer (MCSE) certification helps enable IT professionals to demonstrate their ability to design and implement an infrastructure solution with Windows Server 2003-based business solutions.” Note that this is the only Microsoft certification that uses the word “engineer.” Interestingly, the appearance of “engineer” in this certification gave rise to legal action in

Canada. In an out-of-court settlement, Microsoft agreed that Canadian holders of this certificate would refer to themselves only by the acronym MCSE. The MCSE certification has now been superseded by a “Microsoft Certified IT Professional” certification. Both Cisco and IBM avoid using the word “engineer” in their certification programs.

By contrast, broad-based certification schemes are intended to recognize professional competence in a recognized body of knowledge. They are offered by societies that represent communities of professionals. Examples include Project Management Professional, Certified Financial Planner, and board certifications for medical professionals. The IEEE-CS’s effort to develop a certification scheme for software engineering professionals began in the late 1990s (Seidman 2009: 354–356). The IEEE-CS began by surveying the community and conducting discussions with industry representatives and potential certificate holders. The examination development process followed: lists of task and knowledge statements were created and validated by the community; these materials were used to develop test specifications, which in turn were used to construct test questions. After several rounds of evaluation, the Certified Software Development Professional (CSDP) examination was released in 2002. The original idea had been for the phrase “software engineering” to appear in the name of the designation, but this was dropped in the face of opposition from NSPE and IEEE-USA. Since 2002, nearly 1000 individuals have earned the CSDP designation; more than 460 of these certificates are still valid (Dzerzhinskiy 2012). Over time, the CSDP body of knowledge has been revised to keep it in concordance with the ongoing revisions of SWEBOK. Candidates for CSDP certification must meet the following requirements before they can take the examination; licensed software engineers and senior members of IEEE are automatically eligible. Otherwise, candidates must satisfy the following criteria: (a) hold a bachelor’s degree, hold a Certified Software Development Associate (CSDA) certificate (see subsequent sections), be a university-level educator, or be a full member of IEEE and (b) have an advanced degree in software engineering and at least 2 years (about 3500 h) of experience in software engineering/development, or have at least 4 years (about 7000 h) of experience in software engineering/development. The IEEE-CS soon realized that these requirements are too onerous for most candidates from developing countries. This led to the development of an entry-level certification program, the CSDA. While the CSDA program has no formal eligibility requirements, recommended guidelines for candidates indicate that candidates should be recent software or computer engineering graduates, undergraduates in the final year of a bachelor’s degree program in software or computer engineering, or non-degree professionals with more than 2 years of programming experience.

Certification of software engineering professionals is also offered by the International Software Quality Institute (iSQI), an independent nonprofit organization in Germany. iSQI offers certification examinations in software architecture, software testing, and project management. The testing examination is also offered at an advanced level.

There is now an international standard (ISO/IEC 24773:2008) for certification schemes for software engineering. This standard was developed by a working group within a joint technical committee of the International Organization for Standardization (ISO), and the International Electrotechnical Commission (IEC). In order to conform to this standard, a certification scheme must demonstrate that it incorporates the certification processes described in a previous international standard ISO/IEC 17024 for certification processes, and that the body of knowledge used by the scheme can be mapped to SWEBOK.

73.6 Conclusions

It has been more than 40 years since the phrase “software engineering” was first used to describe the processes associated with developing and maintaining large-scale software systems. During this period, software engineering has acquired some of the characteristics of a profession. It has a reasonably well-accepted body of knowledge and code of ethics. The pace of change in the computing industry (and in software engineering research) entails the need for ongoing continuing education. However, entrance control is somewhat variable; while there are many university courses of study in software engineering whose quality is governed by governmental or private accreditation agencies, employers far too frequently hire and

designate employees as software engineers who lack any formal professional credentials. Furthermore, the terms “software engineer” and “software developer” tend to be conflated. The often careless usage of “software engineer” to designate a software developer tends to weaken the emerging professionalism of the discipline. This situation is exacerbated by the fact that major professional societies (ACM and IEEE-CS) have come to different conclusions as to the pace at which the profession of software engineering is emerging. At the same time, there is increasing pressure to bring software engineering into the professional-credentials sector occupied by the broader community of engineers. As we have seen, this is quite variable by country; the variability has more to do with professional-society politics than with substance. In some countries (the United Kingdom and Australia), it has been relatively easy to do so. In others, (Canada and the United States), the pace has been slower. In all cases, though, the direction of movement has been toward government-sanctioned credentials (licensing or chartered status). The recent introduction of broad-based society-sponsored professional certification examinations has opened another way for software engineers to obtain professional credentials. However, the uptake of these credentials has so far been slow driven almost exclusively by practitioner interest; there have been few if any signs of employer interest or involvement. It seems clear that the future of software engineering professionalism will be driven by industry and government. Software quality increasingly impacts public health and safety as well as corporate profits. If either of these drivers leads to an increased emphasis on the competence and professionalism of the software engineers developing the products of the future, we can expect to see a similarly increased emphasis on the professional credentials held by these software engineers.

Key Terms

Accreditation: A defined process to determine whether a university academic program meets specified quality standards.

Body of knowledge: A description of the definition and concepts underlying a discipline. It is usually accompanied by an annotated bibliography.

Certification: A process to determine whether a practitioner has mastered a given body of knowledge.

Chartered engineer: An individual recognized as a professional engineer in certain countries, including the United Kingdom, Australia, and New Zealand.

Code of ethics: A list of ethical expectations for professionals in a specific profession.

CSDA: An entry-level certification examination for software engineering professionals developed by the IEEE Computer Society.

CSDP: A certification examination for experienced software engineering professionals developed by the IEEE Computer Society.

Entrance control: A means of restricting access to a profession, most usually by requiring graduation from an accredited university program.

Licensing: A means of restricting the practice of a profession to those who meet specific requirements, including education, experience, and possibly an examination.

Profession: An occupation characterized by an explicit body of knowledge, entrance control, code of ethics, and a recognized need for continuing education.

Professional: An individual who has received government (and often professional-society) approval to practice a specific profession.

Further Information

Information about professional status for engineers is country-specific. For the United States, the best source is the licensure page of the National Society for Professional Engineers (<http://www.nspe.org/Licensure/index.html>). The appropriate source for Canada is the Engineers Canada licensure page (<http://www.peng.ca>). For the United Kingdom, the best source is the Engineering Council’s Chartered

Engineer page (<http://www.engc.org.uk/professional-qualifications/chartered-engineer/about-chartered-engineer>). A relatively recent working paper (Adams 2004) contrasts the development of software engineering as a profession in the United States, the United Kingdom, and Canada.

74.1 Introduction

In late 1999, the Association for Computing Machinery and the IEEE-Computer Society approved the Software Engineering Code of Ethics and Professional Practice 5.2 (hereafter, the Code). The Code was later translated into Arabic, Croatian, French, German, Hebrew, Italian, Japanese, Mandarin, and Spanish by other computing societies and individuals for their use. The Code encourages software engineers to undertake positive actions and to resist pressures to act unethically. Several major companies have adopted the Code, and its principles have been incorporated into their standards of practice. The Code has also been included as part of employment contracts, which are signed at the time of employment.

The Code describes the ethical and professional obligations against which peers, the public, and legal bodies can measure a software developer's behavior. The development of large complex and safety critical systems is a difficult process. Software development and software developers have not been acclaimed for their successes or professional reputation. There is a long history of highly publicized software failures accompanied by frequent efforts to sidestep the responsibility for those failures by blaming them on "bugs," which somehow creep into the software.

The United States Navy has developed "smart ships" where shipboard applications are being run by software so that fewer sailors are needed to control key ship functions. The smart ships computer system reduced the crew size by 10% and saved more than 2.8 million a year. However, in September of 1997, the software suffered a systems failure, and the propulsion system failed leaving the ship dead in the water. It had to be towed into port (DiGiorgio, 1998).

The failure on the USS Yorktown was described as “a software glitch” implying that the problem was a minor error of little significance. A military ship used to protect populations, a ship, which is vulnerable to attack by opposing forces, was left dead in the water.

A closer look at this “software glitch” illustrates the problem of minimizing responsibility for the final quality of the software. It is common knowledge among computer professionals that computers cannot divide by zero. Most computer systems, including calculators in cell phones, have a basic error check routine, which protects against the results of attempting to divide by zero. The software on the Aegis missile cruiser USS Yorktown was not designed to tolerate such a simple failure. The absence of computer code to protect against a zero divide was considered “a software glitch.” This was a failure to include a basic principle of software design. In other professions, similar small professional failures—a physician leaving a small instrument inside a patient after open heart surgery or an engineer “slightly” underestimating the amount of concrete necessary for a dam to hold back a wall of water—would result in legal charges of malpractice or negligence.

This tendency to minimize and shift the responsibility for these events are not acceptable to the practicing professional. It misleads the public about the professional commitment of software engineers and misleads those seeking to enter the profession about their broad responsibilities.

Besides affecting “trust,” this tendency to minimize descriptions of software errors is very dangerous because of the impact of computers. This minimizing of “bugs” and “glitches” lends a degree of “normalcy” to software failures. This sense of “normal errors” only re-enforces the lack of ethical sensitivity and professionalism among software developers. Software engineer’s complex development issues of coordinating human requirements with computing technical issues are made more difficult by developer’s missing the professional and ethical responsibilities involved of their work.

As the impact of the behavior of a group of specialists assumes wider significance, two pressures develop, one from society at large interested in assuring that the behavior of the specialists will not cause any (more) harm to society. This societal concern is manifested in attempts to regulate the specialists by legislation. The other pressure that develops comes from within the ranks of the specialists, in this case software engineers, to organize as a group with a well-defined discipline including a commitment to high-quality practice concerned with the well-being of society at large.

The common elements in all of these efforts are the definition of a domain of practice, which is accomplished in part by circumscribing a body of knowledge and supporting curricula, mandating a level of practical experience (sometimes working with an accepted member of the profession), and a commitment to a level of quality practice generally defined in a code of ethics and professional practice. Many codes of ethics try to educate and inspire the members of the professional group that adopts the code. Codes also inform the public about the responsibilities that are important to a profession.

The Software Engineering Code of Ethics and Professional Conduct 5.2 is the result of one such effort to professionalize software engineering. The Code “instructs practitioners about the standards that society expects them to meet, and what their peers strive for and expect of each other” (Code5.2, 1999). Software engineers need to anticipate unintended consequences, including negative impacts on society, individuals, and the environment. Even developers with the best of intentions can walk into ethical traps. The Code is designed to help software engineers reduce unintended negative professional and ethical consequences of their work.

Additionally, codes are not meant to encourage litigation, and they are not legislation but they do offer practical advice about issues that matter to professionals and their clients, and they do inform policy makers. These concepts have been adopted in the development of this Code.

74.1.1 Brief History and Purpose

The Board of Governors of the IEEE Computer Society established a steering committee in May 1993 for evaluating, planning, and coordinating actions related to establishing software engineering as a profession. In that same year, the ACM Council endorsed the establishment of a Commission on

Software Engineering. By January 1994, both societies formed a joint steering committee “to establish the appropriate set(s) of standards for professional practice of software engineering upon which industrial decisions, professional certification, and educational curricula can be based.” To accomplish these tasks, they recommended adopting standard definitions; defining a required body of knowledge and recommended practices; defining ethical standards; and defining educational curricula for undergraduate, graduate, and continuing education. The joint steering committee established a series of task forces to achieve these goals. The initial task forces included: software engineering body of knowledge and recommended practices, software engineering ethics and professional practices (SEPP), and software engineering curriculum.

Most computing societies already have their own Codes of Ethics; why was there a need for yet another code? Codes of ethics state high-level principles, which cut across all professions; but individual professions need to address those elements, which are unique to a specific profession; thus, a software engineering Code needs to address requirements elicitation and software maintenance—subjects that are not addressed in a chemical engineers code of ethics. Software engineering professionals understand the significance of their work and their ethical obligations to their products’ stakeholders. As the Preamble to the full version of the Code states, “Because of their roles in developing software systems, software engineers have significant opportunities to do good or cause harm, to enable others to do good or cause harm, or to influence others to do good or cause harm” (Code5.2, 1999). There was near unanimity that software engineers must behave proactively when they are aware of potential difficulties in a system. Several clauses in the Code require preemptive reporting of potentially dangerous situations and even outline a procedure for whistle blowing.

Software engineers generally agree about their obligations. In reviews, the Code received a consistently high level of agreement about the behavior expected of a professional software engineer. However, various forces pressure software engineers to not always fulfill these obligations and there is something needed to address these pressures.

The development of this Code was unique in that it was designed as a code for a profession with global impact. Ideally “the code instructs practitioners about the standards that society expects them to meet, and what their peers strive for and expect of each other” (Code5.2, 1999). The purpose of the SEPP task force is to document the ethical and professional responsibilities and obligations of software engineers (Code3.0, 1997).

74.1.1.1 Role of Professional Organizations

The Code addresses both the responsibilities of the practicing professional and of the profession.

Unlike other codes, this Code is not designed to be self-serving to the profession. It requires software engineering professionals to be ethically responsible to all of those who are affected by their products. Several authors (Bayles, 1981; Johnson, 2001) have specified hallmarks of a professional; generally they include: having a code of ethics expressing ideals of service, licensing procedures, and a representative professional association. A profession also requires a monopolistic knowledge that circumscribes a clearly defined territory. The traditional model of a profession is based on the interaction between an individual professional and a recipient of the benefit of the professional’s skill. The recipient may be an individual, organization, or the public at large.

The professionalization of any discipline involves the realization that being a professional involves more than the rigid application of formal principles to the artifacts of that discipline (Davis, 1987). The practice of medicine is more than the application of drugs to the human body. Physicians are concerned with the well-being of their patients. In the professionalization of a discipline, there is a realization of the impact on society of the application of the special skills and knowledge of the practitioner of that profession. There is also an acceptance of the responsibility that comes with the privilege of being allowed to apply those principles. The professional’s unique understanding of professional situations and how to deal with them places an extra set of ethical obligations on the professional. These obligations are sometimes referred to as professional ethics.

A code of ethics is like a Swiss Army knife, serving many important and useful functions. It is a statement to members about the ethical stand of an organization and profession, a conscience of the profession, an announcement to non-members what the profession stands for (although most often stated in terms of the actions of individuals), and it imposes responsibilities on the professional organizations.

It is not so much that the Code lays down strict rules for the profession to follow, rather that they reflect the maturity of the social contract into which the profession has developed where justice and rights become accepted into the profession. One element that separates professionals (in the philosophical sense) is that they pledge themselves to certain moral responsibilities and a higher order of care. The code leads to that kind of pledge. It is a necessary step to establish a profession.

Professional computing organizations such as the IEEE have been involved in the development standards. Professional organizations have codes of ethics and codes of practice, which require the computing professional to consider a broader range of stakeholders, to consider a range of stakeholders, which includes all those whose lives are affected by the software project and the way it was implemented.

74.2 Code

74.2.1 Purpose and Principles

As Software Engineering developed as a discipline it had considered its primary goal as the “competent creation” of software artifacts, but it has gone beyond that minimalist position to move toward professionalism. The Code goes beyond mere competent creation. Although creation is an important part of software engineering, it is not the primary goal. As an engineering profession, the public good is the primary goal. Although the Code refers to the importance of competence, the Code advocates the primacy of responsibility for public well-being more than others. It reflects the importance of responsibilities to the public that go far beyond competent creation.

The goal of software engineering, as described in the preamble to the Code, is much broader.

Computers now have a central and growing role in commerce, industry, government, medicine, education, entertainment, social affairs, and ordinary life. Those who contribute, by direct participation or by teaching, to the design and development of software systems have significant opportunities both to do good and to cause harm and to influence and enable others to do good or cause harm. To ensure, as much as possible, that this power will be used for good, software engineers must commit themselves to making the design and development of software a beneficial and respected profession. In accordance with that commitment, software engineers shall adhere to the following code of ethics. (Code5.2, 1999)

As the Code developed from version 3.0 to version 5.2, a shortened version of the Code, including only a brief preamble and the eight principles, was appended to the longer version of the Code containing clauses describing how the principle applies to software engineering, under each principle (Gotterbarn et al. 1997).

The Code contains eight keyword principles related to the behavior of and decisions made by professional software engineers, be they practitioners, educators, managers and supervisors, or policy makers, as well as trainees and students of the profession. The principles identify the various relationships in which individuals, groups, and organizations participate and the primary obligations within these relationships (Preamble, The Code3.0, 1997).

74.2.1.1 Software Engineering Code of Ethics and Professional Practice (Short Version)

The short version of the code summarizes aspirations at a high level of the abstraction; the clauses that are included in the full version give examples and details of how these aspirations change the way we act as software engineering professionals. Without the aspirations, the details can become legalistic and tedious; without the details, the aspirations can become high sounding but empty; together, the aspirations and the details form a cohesive code.

Software engineers shall commit themselves to making the analysis, specification, design, development, testing, and maintenance of software a beneficial and respected profession. In accordance with their commitment to the health, safety, and welfare of the public, software engineers shall adhere to the following eight principles:

1. PUBLIC—Software engineers shall act consistently with the public interest.
2. CLIENT AND EMPLOYER—Software engineers shall act in a manner that is in the best interests of their client and employer consistent with the public interest.
3. PRODUCT—Software engineers shall ensure that their products and related modifications meet the highest professional standards possible.
4. JUDGMENT—Software engineers shall maintain integrity and independence in their professional judgment.
5. MANAGEMENT—Software engineering managers and leaders shall subscribe to and promote an ethical approach to the management of software development and maintenance.
6. PROFESSION—Software engineers shall advance the integrity and reputation of the profession consistent with the public interest.
7. COLLEAGUES—Software engineers shall be fair to and supportive of their colleagues.
8. SELF—Software engineers shall participate in lifelong learning regarding the practice of their profession and shall promote an ethical approach to the practice of the profession.

74.2.2 Full Version: Principles and Illustrative Clauses

The eight principles reflect the order in which software professionals should consider their ethical obligations: The first principle is concerned with the public good. The primacy of well-being and quality of life of the public in all decisions related to software engineering is emphasized throughout the code. This obligation to the public is the final arbiter in all decisions:

In all these judgments concern for the health, safety and welfare of the public is primary; that is, the ‘Public Interest’ is central to this Code. (Code5.2, 1999)

These eight general principles have specific clauses describing the goals of good software engineering practice. There has been a transition away from regulatory codes designed to penalize divergent behavior and internal dissent, toward codes which are more normative, giving general guidance (Gotterbarn, 1999a). The intent of the Code was not to impose sanctions on those who violate it but to act as a guide in the relationship between software engineering practice and ethics. It is a declaration of the professional responsibility of those practitioners—licensed or not—who perform the activity, manage, or teach software development. Its statements can be used to help professionals carefully examine alternative actions when they recognize ethically charged situations. Consider the following situations in which software engineers may find themselves (Gotterbarn and Miller, 2004).

74.2.2.1 Good Practice

Long before system testing is complete, scheduled time and money for such testing has run out. The engineer responsible for testing is advised that the company will “let the users do the rest of the testing.”

Principle 3 speaks against such an approach and clause 3.10. “Ensure adequate testing, debugging, and review of software and related documents on which they work.” asserts the importance of system testing before release.

74.2.2.2 Maintenance

Version 4 of the code added specific language about the importance of ethical behavior during the maintenance phase of software development. The text reflects the amount of time a computer

professional spends modifying and improving existing software and also makes clear that we need to treat maintenance with the same professionalism as new development. The quality of maintenance depends upon the professionalism of the software engineer, because maintenance is more likely to be scrutinized only locally, whereas new development is generally reviewed at a broader corporate level.

Knowing that the firm developing a large piece of software for a government agency is unlikely to be awarded the contract to maintain the system after delivery, the company decides to spend less effort on both internal and external documentation. The money saved by this decision is used to pay for additional coders and testers, so that the system can be delivered on time.

This approach violates obligations to the Public in Principle 1 Clause 1.03. “Approve software only if they have a well-founded belief that it is safe, meets specifications, passes appropriate tests, and does not diminish quality of life, diminish privacy or harm the environment. The ultimate effect of the work should be to the public good.” and Principle 3.01. “Strive for high quality, acceptable cost, and a reasonable schedule, ensuring significant tradeoffs are clear to and accepted by the employer and the client, and are available for consideration by the user and the public” (Code5.2, 1999).

74.2.2.3 Public Is Paramount

A computer company is working on an experimental fighter. A quality control software engineer suspects that the flight control software is not sufficiently tested, although it has (finally) passed all its contracted test suites. She is being pressured by her employers to sign off on the software. Her employers say they will go out of business if they do not deliver the software on time. She signs off (adapted from McFarland, 1990).

This case is in violation of the product clause “1.03 Approve software only if they have a well-founded belief that it is safe, meets specifications, passes appropriate tests, and does not diminish quality of life, diminish privacy or harm the environment. The ultimate effect of the work should be to the public good.” Although Principle 2 seems to say the interests of the employer are relevant, that interest is mitigated by the interest of the public, in this case the pilot and those in her flight path. Principle 2 CLIENT AND EMPLOYER—Software engineers shall act in a manner that is in the best interests of their client and employer, consistent with the public interest.

Most situations faced by software engineers are more complex than these simple examples. This shortened version of the Code is not intended to be a stand-alone abbreviated code. The details of the full version are necessary to provide clear guidance for the practical application of these ethical principles. The software engineering code of ethics and professional practice is significant in that it constitutes the software developer’s response to the previously tolerated “misadventures” of software developers as illustrated in the Yorkton example in the preceding text.

74.2.3 Support for Version 5.2

The drafts of the Code, written by volunteers from places like Australia, Canada, Egypt, India, Ireland, the Philippines, the United Kingdom, and the United States, went through several revisions drafts subject to international review by professional societies, large multinational corporations, and small development firms, including the IEEE formal technical standard review process. Because of the way the Code was developed, it is not unreasonable to say that this Code represents a movement toward an international consensus of what software engineers believe to be their professional ethical obligations.

The weight of all the software engineers who reviewed the Code and the support of the professional societies that approved it make it easier to defend whistle blowing, refusal to certify inferior or unsafe software, and support other acts consistent with the moral and professional standards of software engineers. A Code that has been reviewed, voted on, and adopted by professional societies provides ethical direction for new software engineers and gives support to the ethical decisions of other software engineers.

74.2.4 Functions of the Code

Codes can serve many different functions. The choice of function determines the content and style of a code of ethics. It might be designed to be *inspirational* either for positive stimulus for ethical conduct by the practitioner (Martin et al. 1989) or to inspire confidence of the customer or user in the computing artifact and confidence in its creator (Anderson, 1995). Unfortunately, inspirational language tends to be vague, limiting the code's ability to help guide professional behavior.

Historically, there has been a transition away from regulatory codes, designed to penalize divergent behavior and internal dissent, toward more normative codes, which give general *guidance*. Although a professional can use a normative Code to examine alternative actions, such codes are only a partial representation of a profession's ethical standards (Gotterbarn, 1999b). Because the use of normative codes requires moral judgment on the part of the professional, they should not be considered a complete procedure for deciding what is right or wrong (see Section 74.3.3).

- Codes also serve to *educate* both prospective and existing software engineers about their shared commitment to undertake a certain level of quality in their work and their responsibility for the well-being of the customer and user of the developed product.
- Codes also serve to educate managers (see Principle 5 Code5.2, 1999) of software engineers, and to educate those who make rules and laws related to the profession, about expected behavior. Managers' and legislators' expectations will affect what is asked of software engineers and what laws are passed relating to software engineering, respectively. Directly and indirectly, codes also educate management about their responsibility for the effects and impacts of the products developed.
- Codes also indirectly educate the public at large about what professionals consider to be a minimally acceptable ethical practice in that field, even as practiced by nonprofessionals.
- Codes provide a level of *support for the professional* who decides to take positive action. An appeal to the imperatives of a code can be used as counter pressure against others' urging to act in ways inconsistent with the Code.
- Codes can be a means of *deterrence and discipline*. They can serve as a formal basis for action against a professional; for example, some organizations use codes to revoke membership or suspend licenses to practice. Because codes usually define in detail the minimal behavior for all practitioners, the failure to meet this expectation can be used as a reasonable foundation for litigation.
- Codes have been used to *enhance a profession's public image*. They prohibit public criticism of fellow professionals, even if they violate some ethical standard.

The specific functions selected for a code affect its potential impact. This Code, designed for software engineering, emphasizes education, guidance, support, and inspiration. The Code does not specifically address deterrence and discipline or include standards for prohibiting someone from practicing software engineering.

74.2.5 Response to the Code after Approval

The adoption by several computing societies, its translation into multiple languages, and its use by industry as a standard of practice indicate that the international committee that developed the Code captured the ethical ideas of software engineering.

The Code is a hybrid in several ways. Some confusion about codes of ethics arises from a failure to distinguish between closely related concepts about codes, which direct the behavior of practicing professions. Moving from less restrictive to more restrictive codes, there are codes of ethics that are primarily aspirational giving a mission statement for the profession. There are also codes of conduct that describe professional attitudes and some professional behavior. Codes of practice are very specific and tied closely to the practice of the profession. They are the easiest to use as a basis for legal action.

Because practicing professionals deal with human affairs, the underlying ethical principles are the same across professions. Studies have shown that most codes are a hybrid of these three types of code (Berleur and d'Udekem-Gevers, 1994).

The Code is a hybrid focused on software engineering. The Code shows the relation between high level aspirations and the particular practices of software engineering. The international committee made sure the Code focused on what was common to the profession. Even though cultures may differ on the ethics of having 1 wife or having 12 wives, the practice of software engineering is globally consistent in the view that safety critical systems should be tested before they are deployed.

74.3 Foundations and Functions of the Code

The Code is unique in several significant ways. It is the Code for a profession; it is a hybrid of a code of ethics, a code of conduct and a code of practice; its imperatives cross all three levels of ethical obligation—obligations to humanity in general, obligations to professionalism, and obligations to a specific discipline. It is designed to mitigate some philosophical objections to codes of ethics and includes suggestions on how to use the Code in decision making and resolve situations where principles of the Code seem to conflict (see Section 74.2.2).

The Code is organized into a short and a long version; each with its own preamble. The preamble of the short version summarizes aspirations at a high level of abstraction while the specific clause under each principle in the long version ground these aspirations in specific software engineering practices. The Code asserts that “Without the aspirations, the details can become legalistic and tedious; without the details, the aspirations can become high sounding but empty; together, the aspirations and the details form a cohesive code.” The clauses under the eight core principles that are included in the full version give examples and details of how these aspirations change the way we act as software engineering professionals.

74.3.1 Levels of Professional Obligation

Many codes are written at a high level of abstraction and only talk about some easily agreed upon human values like “honesty” and “competence” or they are detailed lists of discipline specific practices. Codes that are only out a high level of abstract do not help the individual professional make decisions and codes consisting of detailed practices are not flexible enough to address the rapidly changing computing environment. The detailed list will also be incomplete.

Each principle of this code addresses three levels of ethical obligations owed by professional software engineers. The first level identified is a set of ethical values, which professional software engineers share with all other human beings by virtue of their humanity. The second level obliges software engineering professionals to more challenging obligations than those required at Level one. Level two obligations are required because professionals owe special care to people who may be affected by their work. The third and deeper level comprises several obligations that derive directly from elements unique to the professional practice of software engineering. The clauses of each principle are illustrations of the various levels of obligation included in that principle.

Level one: Aspire (to be human). Statements of aspiration provide vision and objectives and are intended to direct professional behavior. These directives require significant ethical judgment.

Level two: Expect (to be professional). Statements of expectation express the obligations of all professionals and professional attitudes. Again, they do not describe the specific behavior details, but they clearly indicate professional responsibilities in computing.

Level three: Demand (to use good practices). Statements of demand assert more specific behavioral responsibilities within software engineering, which are more closely related to the current state of the art. The range of statements is from the more general aspirational statement to specific measurable requirements.

Although the description of these levels was removed from the Preamble after version 3 of the Code, it is still a philosophical foundation of the Code and underlies the content of the code. The idea is that a complete Code needs to address all three levels. In general, the Code address level one statements in the preambles (see Section 74.2.2), level two issues of professionalism in the eight principles, and software engineering discipline specific issues in the clauses under each principle.

74.3.2 Decision Making

There are several positive elements to this Code, which distinguish it from many other codes of professional ethics. One of the major functions of the Code is to help the software engineer make critical decisions and alert them to potential problems with their work.

Most codes of ethics have some problems. First, they only provide a finite list of principles that are often presented as a complete list; readers might presume that only the things listed should be of ethical concern to the professional. These principles are treated as either rules, which must be followed or as normative guidelines.

Second, many codes provide little (if any) guidance for situations where rules having equal priority appear to conflict. There is not guidance as to which principles should have higher priority. This ambiguity of priority leaves the ethical decision maker confused. The Software Engineering Code addresses both of these limitations.

The Code addresses the first problem in the preceding text. It explicitly rejects the concept of completeness. The problem with an incomplete Code is that it can leave a practitioner without guidance in new situations. To meet this potential difficulty, the software engineering code provides general guidance for ethical decision making, especially in those areas not explicitly mentioned in the Code.

It is not intended that the individual parts of the Code be used in isolation to justify errors of omission or commission. The list of Principles and Clauses is not exhaustive. The Clauses should not be read as separating the acceptable from the unacceptable in professional conduct in all practical situations. (Code5.2, 1999)

The question of the equal priority of all of the principles and clauses is addressed by stating that in all decisions, the public interest is the primary concern.

Unlike most engineering codes, the Code addresses the second problem about how to make decisions. The Preamble of the Code suggests ways to make decisions when two of its imperatives such as “Honor Contracts” and “Work for the Enhancement of Human Welfare” are in conflict. The Code addresses the problem of choosing between conflicting principles by having a hierarchy of principles, with the health, safety, and welfare of the public primary in all ethical judgments. The Code requires whistle blowing and 6.12, 6.13 suggest a procedure to follow in whistle blowing. This Code advocates a stakeholder analysis that goes beyond the limited concerns of safety, schedule, and budget. The National Society of Professional Engineers’ Code requires that an engineer report to a client, “if in the engineer’s judgment, a project is likely to fail,” whereas this Code requires that a software engineer report “...if in their judgment a project is likely to fail, to prove too expensive, to violate intellectual property law, or otherwise be problematic.”

To facilitate decision making the eight principles were reordered to reflect the order in which software professionals should consider their ethical obligations: Version 3.0’s first principle concerned the Product, while version 5.2 begins with the Public. The primacy of well-being and quality of life of the public in all decisions related to software engineering is emphasized throughout the code. This obligation is the final arbiter in all decisions: “In all these judgments concern for the health, safety, and welfare of the public is primary; that is, the ‘Public Interest’ is central to this Code.” To reinforce the clear priority of public concern, in several places the code asserts the priority of concern for the public over loyalty to employer or profession. It is a professional obligation to take positive action to address violations of the Code. A sequence of reporting is included in the structure of the Code. Clause 6.12 says that you should first address talk to the

person doing the violation. Clause 6.13 says that if following 6.12 does not resolve the matter, carry your concern to the appropriate authorities. Unlike other codes that mandate that one does not criticize fellow professionals, this Code requires that you do criticize those who are not following the Code.

74.3.3 Judgment

An ordered list of principles does not provide an in depth ethical analysis of a complex situation. “The Code is not a simple ethical algorithm that generates ethical decisions. In some situations standards may be in tension with each other or with standards from other sources. These situations require the software engineer to use ethical judgment to act in a manner which is most consistent with the spirit of the Code of Ethics and Professional Practice, given the circumstances” (Code5.2, 1999).

The Code does not leave the reader without support about how to make ethical decisions.

In most cases, using the Code to make decisions will require professional judgment to resolve the ethical tensions.

“Ethical tensions can best be addressed by thoughtful consideration of fundamental principles, ... These Principles should influence software engineers to consider broadly who is affected by their work; to examine if they and their colleagues are treating other human beings with due respect; to consider how the public, if reasonably well informed, would view their decisions; to analyze how the least empowered will be affected by their decisions; and to consider whether their acts would be judged worthy of the ideal professional working as a software engineer. In all these judgments concern for the health, safety and welfare of the public is primary; that is, the ‘Public Interest’ is central to this Code” (Code5.2, 1999 full preamble).

The first principle—consider who is affected—helps us refocus and the stakeholders beyond the developer and the customer. The second principle—due respect—requires a protection of human values. The third principle points to consideration of extended stakeholders in, those impacted by, our work. The fourth requires the best professional practice, working toward an ideal.

The Code provides specific details about software practitioners’ obligations, and if they ignore those obligations, they are not acting in good faith as professionals.

When working on a project, the Code says we must do adequate testing but does not quantify how much testing is adequate. The software engineer should not be working on a system if they lack sufficient judgment to use the various ways in the Code to help make that judgment, including talking to other developers competent in that domain. Judgment is required to extend the principles in the Code to new domain.

74.4 Research

In the following text are a few topics for research related to the development and content of codes of ethics.

74.4.1 How to Handle Enforcement

Many people think that enforcement and deterrence mechanism are necessary elements of a Code of Ethics. Codes of Ethics are generally adopted by organizations and it is up to the organization to establish mechanism to encourage people to follow the adopted Code and deter them from breaking it. In some monopolistic professions, licensing serves both as a credentialing mechanism and a means of deterrence from breaking a code of ethics. In most places, access to working as a software engineer is not controlled by licensing. The global nature of the development and impact of software development means that there would be jurisdictional issues in trying to turn ethical imperatives into laws. Two common problems for codes in computing are that they need to be able to address a rapidly changing environment and there

are difficulties in enforcing them. Turning a code into law makes it static and eliminates some of the other important functions of codes of ethics.

Within organizations, there is generally limited enforcement of a code of ethics. Codes get some teeth when they are used by a professional organization to make decisions. Codes of ethics do not define the procedures and sanctions for violating the Code. Codes are not self-referential. Organizations have bylaws, and the Code is a bylaw. The due process and sanctions for violating the code are defined outside the Code. Codes are the mind and conscience of a profession. The profession is what gives the rules nurture and enforcement.

74.4.2 Developing an Ethics Code for a Dynamic Profession

Including a detailed level of software engineering standards in a code would have been a mistake. Specific software engineering standards, which have been proposed by reviewers, such as requiring mutation testing for all mission critical software, are controversial and in flux. Any list of standards included in the Code would freeze the standard, and any list of standards would be incomplete.

The Code, as written does encourage us to exploit standards—but it should not name them. When the profession settles on standards, then we can incorporate them into an ethics code. Codes have different purposes, among them guidance, inspiration, and education. The Code can help lead us to serious discussions about the details of standards; the Code cannot prematurely set those standards.

74.4.3 Approaches to Ethics

Surprisingly, the major tension centered not around technical issues but rather on two distinct approaches to ethics: virtue ethics and rights/obligations ethics (Edgar, 1997). Virtue ethics holds the optimistic view that if people are simply pointed in the right direction, their moral character will guide them through ethical problems. Reviewers from this camp wanted a Code that was mostly inspirational, with minimum detail. They put a heavy emphasis on the autonomy of a professional's judgment. The other position—rights/obligations theory—consists of spelling out precisely one's rights and responsibilities. Believers in this theory wanted a very detailed Code. For example, one reviewer wanted the Code to include a standard of measurement for each imperative—to state exactly how many tests need to be done to ensure adequate testing. The rights/obligations folks used a legalistic model to evaluate each imperative. The problem was that any imperative acceptable to one group was not acceptable to the other. The Code addresses this significant tension in a number of ways.

To address the problem of insufficient guidance for decision making, the Code incorporates some directions for ethical decision making in the preamble and an acknowledgment that the Code's normative premises should not be read as complete descriptions or legalistic statements. It is still an open research question about testing the adequacy of this approach.

The Code addresses the rights—virtue tension in another way: through its structure. The Code is organized around eight broadly based themes. Under each theme or principle is a series of clauses giving examples of how that theme applies to software engineering practice. Thus, under "Principle 1, PUBLIC, Software engineers shall act consistently with the public interest" is the illustrative clause 1.04, "Disclose to appropriate persons or authorities any actual or potential danger to the user, the public, or the environment, that they reasonably believe to be associated with the software or related documents."

74.5 Summary

"The Software Engineering Code of Ethics and Professional Practice is a useful tool. It educates and inspires software engineers. The Code instructs practitioners about the standards that society expects them to meet and what their peers strive for and expect of each other. The Code offers

practical advice about issues that matter to professionals and their clients, and it serves to inform policy makers about ethical constraints imposed on software engineers.

The Code encourages the professional to do positive actions. The Code also encourages the professional to resist pressures to act unethically. The professional can appeal to the imperatives of the Code to indicate ethically accepted practice.

The Code indirectly educates the public at large about the responsibilities that are important to and accepted by the profession—what software engineers consider to be minimally acceptable practice—even when a nonprofessional practices it. Thus the code can be a catalyst to simultaneously raising the internal expectations of a profession and the expectations of the society at large.

The Code is a dynamic document, a method for education, inspiration, and continued study and debate. It provokes serious discussion about the software engineering discipline, its responsibilities, and its future. The Code directs us to be a part of that future as we improve our profession and ourselves” (Gotterbarn and Miller, 2009).

75.1 Introduction

You are without doubt in the software business, no matter what business you seem to be in. IT and software make the world go round, at ever increasing speeds. Computer-based, software-driven systems are pervasive in today's society. From the software in avionics flight control to the ubiquitous computers in smart phones, automotive, and consumer electronics, software provides features and functions in daily use. Increasingly, the entire system functionality is implemented in software. Where we used to split hardware from software, we see flexible boundaries entirely driven by business cases to determine what is the best package at which level in which component, be it software or silicon. For example, in 1960, only 8% of the functionality of the F-4 fighter aircraft was implemented in software; by 2000, 80% of the F-22's features were provided by software. The same is true for consumer and communication systems. A TV set in the 1970s had no software, while today its competitive advantages are software-driven [1,2].

Software and IT move on a fast pace. When looking in the rear mirror, we see many companies and endeavors, which failed due to overemphasizing technology and not sufficiently implementing a sound business strategy [3]. Take, for example, Netscape. For many of us, it was the first experience of the Internet. In 1995, it had a market share of 80%—more than enough to stay in the pole position forever, as companies such as Google or Amazon show. But already in 1997 it slowed down, lost market share, and in 2003 went into bankruptcy. What went wrong? One of the managers put it in simple words: “We had no product management; it was just a collection of features.” [4] More recently and in another domain, a previous Nokia senior manager claimed that the lack of product management and business insight is the primary reason for their loss of market shares in the past years [5]. On the other hand, we all know companies such as Apple and Microsoft and their excelling business management. So, what means software business understanding? We will in this article briefly introduce software

business and economics and show success factors toward improving software business understanding. Examples from very different environments (big vs. small and planned vs. agile) will show how we have introduced and improved software business understanding, and what was achieved.

The software business has manifold challenges. They range from the creation process and its inherent risks to direct balance sheet impacts. Many studies reveal that we focus too much on technology and features in the software business and not enough on value and products. Only 52% of the originally allocated requirements appear in the final product release [1]. This is primarily the consequence of this process not having a clear corporate owner with assigned accountability for its success. In a similar study looking at new product development from a broader scope, Cooper et al. [6] found in 105 business units from various industries that the top 20% of enterprises deliver 79% of their new products in time, while the average delivers only 51% in time. The Standish Group's Chaos Report annually surveys information technology and software projects* [1]. They found that only 32% of the projects finished on time and within budget, a staggering 24% were cancelled before delivery, and of the remaining projects, which finished late or over budget, they only delivered a fraction of the planned functionality. Late introduction of a product to market loses market share; cancellation of a product before it ever reaches the market is an even greater loss. Not only is software increasing in size, complexity, and percentage of functionality, it is also increasing in contribution to balance sheet and profit and loss (P&L) statements. The challenge in many IT and software companies lies in better connecting sales and marketing with strategy and product development.

Sounds familiar? Products are pushed to the extreme to be ever more efficient and done at low cost, but when they hit the market, they would not sell as expected. Or customers demand many changes, thus reducing margins dramatically from initial targets. As engineers, we often tend to overhear the voice of the customer. Technology matters, the schedule needs to be kept, features are lined up like a washing list. Poor business management causes insufficient project planning, continuous changes in the requirements and project scope, configuration problems, and defects. The obvious—yet late—symptoms are more delays and overall customer dissatisfaction due to not keeping commitments or not getting the product they expect. Being late with a product in its market has immediate and tremendous business impacts [3,6,7]. In contract business, this often means penalties, and in practically all markets it reduces customer loyalty and the overall returns from sales.

Product development, such as for IT infrastructure, software components, or embedded electronics, traditionally concentrates on the project perspective looking to execute in budget and time. In software, IT, and systems engineering, project execution can be rather easily improved by means of capability maturity model integration (CMMI) and agile principles. Project execution can be improved by means of the project management body of knowledge. Today, there is a lot of exciting results from optimizing projects in terms of cost and cycle time [1,8–10].

Successful product development, though, is more than executing in time and budget. It means to deliver the right products at the right time for the right markets. Naturally the success of a product depends on many factors and stakeholders. However, we realize that it makes a big difference whether many cooks somewhat steer the soup or whether one person is empowered to lead all activities for the product from inception to market and evolution—and hold accountable for the results. This is the product manager.

In many companies and organizations and also in most literature software business, relationships to software development and engineering remain vague. We often see product definition, road-mapping, and marketing decoupled from the engineering project-related processes, which creates deficiencies and overheads, such as heavy changes in requirements and missed market opportunities. While the general principles of business management are known, not much specific guidance is available for software business understanding. With this handbook entry we will provide

* www.standishgroup.com

an introduction and tutorial on software business understanding and provide some concrete experiences, so you as the reader can directly benefit.

From our experiences with many clients in different industries, success comes from anticipating and meeting the relevant customer needs together with being in time and budget. Technical product development, such as for defense systems, automotive components, communication solutions, or IT infrastructure, traditionally focuses on the project perspective and operationally executing a set of given constraints within the triangle of content, budget, and time. Often too late it becomes clear that needs were different from what is built.

This chapter describes software business understanding. It addresses the major activities and provides examples. The target audience is both interested newcomers who wish to get insight into what software business understanding actually means and what techniques are used, and students and industry experts who want to get a fully up-to-date yet concise summary of software business techniques, experiences, and trends.

We will start with the necessary foundations looking into terminology and how the discipline of software business (subsequently abbreviated as SPM) breaks down into different activities. The next section will explain why SPM is necessary. We will then get practical and hands-on and will show how SPM is implemented in the product life cycle. Introducing SPM in an organization is a big challenge for many companies. So we will highlight our experiences from introducing SPM to companies around the world and also provide an overview of SPM-related competencies. Finally, we summarize the article and provide an outlook on trends that impact SPM as a discipline. We conclude with a summary of relevant Internet resources and also a brief overview on good introductory literature.

75.2 Foundations

Software business and economics are about making software-related decisions in a business context. It means aligning software technical decisions with the business goals of the organization. Decisions like “Should we use a specific component?” may look easy from a mere technical perspective but can have serious implications on the business viability of the project and the resulting product.

75.2.1 Finance

Finance is a branch of economics that deals with resource allocation and management, acquisition, and investment. The field of finance deals with the concepts of time, money, and risk and how they are inter-related. It also deals with how money is spent and budgeted. Corporate finance is the task of providing the funds for a company’s activities. It generally involves balancing risk and profitability, while attempting to maximize an entity’s wealth and the value of its stock. To do this, a company must

- Identify and implement relevant business objectives and constraints, such as organizational or individual goals, time horizon, risk mitigation, and tax considerations
- Identify and implement the appropriate business strategy, such as which portfolio and investment decisions to take, how to manage cash flow, and where to get the funding from
- Measure the financial performance, such as cash flow and return on investment (ROI), and take corrective actions in case of deviation from objectives

75.2.2 Accounting

Accounting is related to finance. It allows people whose money is being used to run the company to know the results of their investment: Did they get the profit they were expecting or not? The primary role of accounting is to measure the company’s actual financial performance. Its purpose thus is to communicate financial information about a business entity to users such as shareholders and managers.

The communication is generally in the form of financial statements that show in money terms the economic resources under the control of management; the art lies in selecting the information that is relevant to the user and is reliable. Accounting systems are also a rich source of historical data for estimating.

75.2.3 Controlling

Controlling is part of finance and accounting. Controlling is the measurement and correction of performance in order to make sure that enterprise objectives and the plans devised to attain them are accomplished. Cost controlling is a specialized branch of controlling that is used to detect variances of the actual costs from the planned costs.

75.2.4 Cash Flow

To make a meaningful business decision about any specific proposal, that proposal will need to be evaluated from a business perspective. The concepts of cash flow instances and cash flow streams are used to describe the business perspective of a proposal. A *cash flow instance* is a specific amount of money flowing into or out of the organization at a specific time as a direct result of some proposal.

In a proposal to develop and launch product X, the payment for new development computers, if new hardware is needed, could be an example of an outgoing cash flow instance. Money would need to be spent to carry out that proposal. The sales income from product X in the 11th month after market launch could be an example of an incoming cash flow instance. Money would be coming in because of carrying out the proposal.

The term *cash flow stream* refers to the set of cash flow instances, over time, which would be caused by carrying out some given proposal. The cash flow stream is, in effect, the complete financial picture of that proposal. How much money goes out? When does it go out? How much money comes in? When does it come in? Simply, if the cash flow stream for Proposal A is more desirable than the cash flow stream for Proposal B then—all other things being equal—the organization would be better off carrying out Proposal A than Proposal B. Thus, the cash flow stream is an important input for investment decision-making.

A *cash flow diagram* is a picture of a cash flow stream. In the same sense that a picture is worth a thousand words, the cash flow diagram gives the reader a very quick overview of the financial picture of that subject. Figure 75.1 shows an example cash flow diagram for a proposal.

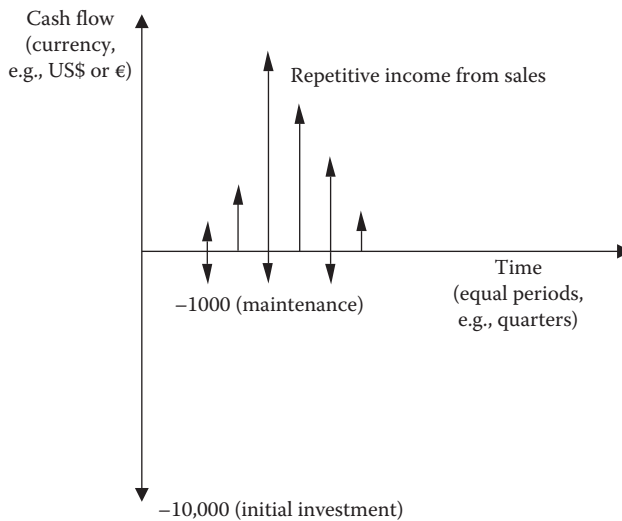

FIGURE 75.1 A cash flow diagram.

A cash flow diagram shows the cash flow stream in two dimensions, time runs from left to right and amounts of money run up and down. Each cash flow instance is drawn on the diagram at a left to right position relative to the timing of that cash flow after the start of the proposal. The horizontal axis is divided into units of time that represent either years, months, weeks, etc. as appropriate for the proposal being studied.

75.2.5 Decision-Making Process

If we assume that candidate solutions solve a given technical problem equally well, why should the business care which one is chosen? The answer is that there is usually a large difference in the costs and incomes from the different solutions. A commercial off the shelf compliant CORBA (object request broker architecture) product might cost a few thousand dollars, but the effort to develop a homegrown service that gave the same functionality could easily cost several hundred times. If the candidate solutions all adequately solve the problem from a technical perspective, then the one that maximizes the return on the organization’s investment is the one that should be chosen. To do this, the technical person should follow a systematic process for making decisions. That systematic process is shown in Figure 75.2. It starts with a business challenge at hand and describes the steps to identify alternative solutions, evaluate these solutions, implement one selected solution, and monitor performance of this solution.

Figure 75.2 shows the process as mostly stepwise and serial. The real process is more fluid. Sometimes, the steps can be done in a different order and often several of the steps can be done in parallel. The important thing is to be sure that none of the steps are skipped or shortcut. It is also important to understand that this same process applies at all levels of decision: from a decision as big as should a software project be done at all down to a decision on an algorithm or data structure to use in a software module. The difference is how financially significant the decision is and, therefore, how much effort should be invested in making that decision. The project-level decision is financially significant and probably warrants a relatively high level of effort to make the decision. Selecting an algorithm is much less financially significant and warrants a much lower level of effort to make the decision, even though the same basic decision-making process is being used.

More often than not an organization could carry out more than one proposal if it wanted to. Furthermore, usually there are important relationships between proposals. Maybe Proposal Y can only be carried out if Proposal X is also carried out. Or, maybe Proposal P cannot be carried out if Proposal Q is carried out, nor could Q be carried out if P were. Choices are much easier to make when there are mutually exclusive paths, either A, B, or C, or whatever is chosen. In preparing decisions, it is recommended to turn any given set of proposals, along with their various interrelationships, into a set of mutually exclusive alternatives. The choice can then be made among these alternatives.

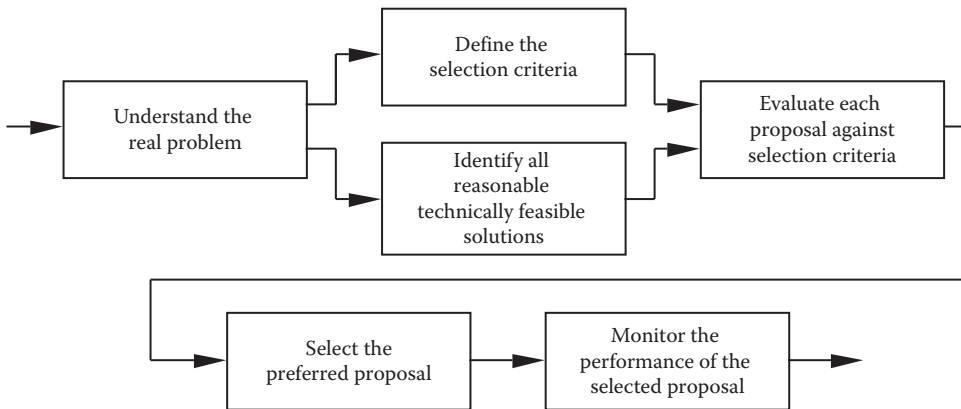

FIGURE 75.2 The basic business decision-making process.

75.2.6 Valuation

In an abstract sense, the decision-making process—be it a financial decision or not—is about maximizing value. The alternative that maximizes total value should always be chosen. A basis for comparison based on value is comparing two or more cash flows. It is a way of using equivalence to meaningfully compare proposals. Several bases of comparison are available, including

- Present worth
- Future worth
- Annual equivalent
- Internal rate of return
- (Discounted) Payback period

Due to the time value of money, two or more cash flows are equivalent only when they equal the same amount of money at a common point in time. Comparing cash flows only makes sense when they are expressed in the same time frame.

Note that value cannot always be expressed in terms of money. For example, whether an item is a brand name or not can significantly affect its perceived value. Relevant values that cannot be expressed in terms of money still need to be expressed in other terms, so that they can be made measurable.

75.2.7 Inflation

Inflation describes long-term trends in prices. Inflation means that the same things cost more than they did before. If the planning horizon of a business decision is longer than a few years, or if the inflation rate is over a couple of percent annually, it can cause noticeable changes in the value of a proposal.

75.2.8 Depreciation

Depreciation addresses how investments in capital assets are charged off against income over several years. Depreciation is an important part of after-tax cash flows, which is critical to accurately addressing income taxes. Software itself typically is not depreciated, but if you are working on proposals with a planning horizon longer than 1 year, the proposals involve capital assets (like buildings and equipment), and you need to accurately reflect the effects of income taxes in the decision analysis, then depreciation will be an important factor to include in the analysis. Another reason to understand depreciation is that your software project proposals will probably be compared against nonsoftware proposals so you should understand how the nonsoftware proposals are being evaluated.

75.2.9 Taxation

Government charge taxes in order to finance expenses the society needs, but no single organization would invest in. Companies have to pay income taxes, which can take between 20% and 50% of a corporation's gross profit. A decision analysis that does not account for income taxes can lead to the wrong choice. A proposal with a high pre-tax profit would not look nearly as profitable in post-tax terms. Not accounting for income taxes can also lead to unrealistically high expectations about how profitable a proposal is.

75.2.10 Time Value of Money

One of the most fundamental concepts in business—and therefore, in business decisions—is that money has time value; its value changes over time. A specific amount of money right now almost always has a different value than having the same amount of money at some other time. This concept has been around since the earliest recorded human history and is commonly known as “interest.” Anyone making a business decision needs to understand interest and how it affects that decision.

75.2.11 Earned Value Management

Earned value management is a project management technique for measuring project progress based on created value. At a given moment, the results achieved to date in a project are compared with the projected budget and the planned schedule progress for that date. Progress relates already consumed resources and achieved results at a given point in time with the respective planned values for the same date. It helps to identify possible performance problems at an early stage.

75.2.12 Efficiency

Economic efficiency is the relationship between the result achieved (see Effectiveness) and the resources used to achieve this result. Efficiency means “doing things right.” An efficient behavior, like an effective behavior, delivers results but keeps the necessary effort to a minimum.

75.2.13 Effectiveness

Effectiveness is about having impact. It is the relationship between achieved objectives to defined objectives. Effectiveness means “doing the right things.” Effectiveness looks only if defined objectives are reached and not how they are reached.

75.2.14 Productivity

Productivity is the ratio of output over input from an economic perspective. Output is the value delivered. Input covers all resources (e.g., effort) spent to generate the output, the influence of environmental factors (e.g., complexity, quality, time, process capability, team distribution, interrupts, feature churn, tools, and language). Productivity combines efficiency and effectiveness from a value-oriented perspective: Productivity is about generating value with lowest resource consumption.

75.2.15 Life-Cycle Economics

75.2.15.1 Product

A product is an economic good (or output), which is created in a process that transforms product factors (or inputs) to an output. When sold, it is characterized by attributes which mean a value to its users. It is a deliverable that creates a value and an experience to its users. A product can be a combination of systems, solutions, materials, and services delivered internally (e.g., inhouse IT solution) or externally (e.g., SW application) as is or as a component for another product (e.g., intellectual property [IP] stack).

75.2.15.2 Project

A project is a temporary endeavor undertaken to create with people a unique product or service. In software engineering, we distinguish different project types (e.g., product development, IT infrastructure, outsourcing, software maintenance, service creation, and so on).

75.2.15.3 Program

A program is a set of related projects. Programs are often used to identify and manage different deliveries to a single customer or market over a time horizon of several years.

75.2.15.4 Portfolio

A portfolio is the sum of all assets and their relationship to the enterprise strategy and its market position. Portfolios are used to group and then manage simultaneously all assets within a business line or company. Looking to an entire portfolio makes sure that impacts of decisions are considered, such as resource allocation to a specific project—which means that the same resources are not available for other projects.

75.2.15.5 Product Life Cycle

The sum of all activities needed to define, develop, implement, build, operate, service, and phase out a product or solution and its related variants. It is subdivided into phases that are separated by dedicated milestones, called decision gates. With the focus on disciplined gate reviews, the product life-cycle (PLC) fosters risk management and providing auditable decision-making information (e.g., complying with product liability needs or Sarbanes-Oxley Act section 404).

75.2.15.6 Project Life Cycle

The set of sequential project phases determined by the control needs of the organizations involved in the project. Typically, the project life cycle can be broken down into at least four phases, namely, initiation, concept/planning, execution, and closure. The project life cycle and the product life cycle are interdependent, that is, a product life cycle can consist of several projects and a project can comprise several products.

75.2.15.7 Proposals

Making a business decision begins with the notion of a *proposal*. Proposals relate to implementing a business objective, either on project, or product, or portfolio level. A proposal is a single, separate option that is being considered, like carrying out a particular software development project or not. Another proposal could be to enhance an existing program and still another might be to redevelop that same software from scratch. Each proposal represents a unit of choice—either you can choose to carry out that proposal or you can choose not to. The whole purpose of business decision-making is to figure out, given the current business circumstances, which proposals should be carried out and which ones should not.

75.2.15.8 Investment Decisions

Investment decisions are made by investors in order to spend money and resources on achieving a target. Investors are either inside (e.g., finance and board) or outside (e.g., banks) the company. The target relates to some economic criteria, such as achieving a high return on the investment, strengthening the capabilities of the company, or improving the value of the company.

75.2.15.9 Planning Horizon

When an organization chooses to invest in a particular proposal, money gets tied up in that proposal—so called “frozen assets.” The economic impact of frozen assets (“capital recover with return”) tends to start high and decreases over time. On the other hand, operating and maintenance costs of elements associated with the proposal tend to start low but increase over time. The total cost of owning and operating a proposal is the sum of those two costs. Early in time, frozen asset costs dominate and later in time the operating and maintenance costs dominate. There is a point in time where the sum of the costs is minimized or minimum cost lifetime.

To properly compare a proposal with a 4 year life span to a proposal with a 6 year life span, the economic effects of either of the following need to be addressed:

- Cutting the 6 year proposal by 2 years
- Investing the profits from the 4 year proposal for another 2 years

The planning horizon, sometimes known as the study period, is the consistent time frame over which proposals are considered. Effects such as economic life and the time frame over which reasonable estimates can be made will need to be factored into establishing a planning horizon. Once the planning horizon is established, several techniques are available for putting proposals with different life spans into that planning horizon.

75.2.15.10 Price and Pricing

A price is what is paid for in exchange for a good or service. A price is a fundamental aspect of financial modeling and is one of the four Ps of the marketing mix. The other three aspects are product, promotion, and place. Price is the only revenue-generating element amongst the four Ps, the rest being cost centers.

Pricing is part of finance and marketing. It is the process of determining what a company will receive in exchange for its products. Pricing factors are manufacturing cost, market place, competition, market condition, and quality of product. Pricing applies prices to purchase and sales orders, based on factors such as: a fixed amount, quantity break, promotion or sales campaign, specific vendor quote, price prevailing on entry, shipment or invoice date, combination of multiple orders or lines, and many others. The needs of the consumer can be converted into demand only if the consumer has the willingness and capacity to buy the product. Thus pricing is very important in marketing.

75.2.15.11 Cost and Costing

A cost is the value of money that has been used up to produce something, and hence is not available for use anymore. In economics, a cost is an alternative that is given up as a result of a decision. A sunk cost is the expenses before a certain time, typically used to abstract decisions from expenses in the past, which can cause emotional hurdles in forward looking. From a traditional economics point of view, sunk costs should not be considered in decision making.

Costing is part of finance and business management. It is the process to determine the cost based on expenses (e.g., production, software engineering, distribution, and rework) and based on the target cost to be competitive and successful on a market. The target cost can be below the actual estimated cost. Therefore, costing always includes cost management.

75.2.15.12 Performance Measurement

Performance measurement is the process where an organization establishes the parameters within which programs, investments, and acquisitions are measured to control whether they are reaching the desired results. It means to evaluate whether performance objectives are actually achieved, to control budgets, resources, progress and decisions, and to learn and improve performance.

75.2.15.13 Termination Decisions

Termination means to end a project or product. Termination can be planned for a long-time (e.g., when foreseeing that a product will reach its life-time) or can come rather spontaneously (e.g., when performance targets are not achieved). In both cases, the decision must be carefully prepared, considering always the alternatives of continuing versus terminating. Cost of different alternatives must be estimated, covering topics such as replacement, information, suppliers, alternatives, assets, and utilizing resources for other opportunities. Sunk cost must not be considered in such decision-making because they have been spent and will not reappear as a value.

75.2.15.14 Replacement and Retirement Decisions

A replacement decision is a special case of for-profit decision analysis that happens when an organization already has a particular asset and they are considering replacing it with something else, like deciding between keeping a legacy software system and redeveloping it from the ground up. Replacement decisions use the same business decision process as described earlier but there are additional challenges: sunk cost and salvage value. Retirement decisions are about getting out of an activity altogether, such as when a software company considers not selling a software product any more, or a hardware manufacturer thinks about not building and selling a particular model of computer any longer.

75.2.15.15 Friction-Free Economy

Economic friction is everything that keeps markets from having perfect competition. It means distance, cost of delivery, restrictive regulations, or imperfect information. In high-friction markets, customers do not have many suppliers to choose among. Having been in a business for a while or owning a store in a good location determines the economic position. It is hard for new competitors to start business and compete. The marketplace moves slowly and predictably. Friction-free markets are just the reverse. New competitors crop up all over, and customers are quick to respond. The marketplace is anything but predictable. Software and IT clearly are friction-free. New companies can easily create products and often do that at much lower cost than the established companies due to not considering all legacies. Marketing and sales can be done via the Internet that offers with social networks and basically free distribution mechanisms all to ramp up a global business. Software engineering economics aims at providing mechanisms to evaluate different concepts for starting, growing and safe-guarding a software business in such a friction-free economy.

75.2.15.16 Ecosystems

An ecosystem is an environment consisting of all the mutually dependent stakeholders, business units, and companies working in a particular area. In a typical ecosystem, there are producers and consumers, where the consumers add value to the consumed resources. A software ecosystem is, for instance, a supplier of an application working with companies doing the installation and support in different regions. Neither one could exist without the other. Ecosystems can be permanent or temporary. Software engineering economics provides the mechanisms to evaluate alternatives in establishing or extending an ecosystem, for instance assessing whether to work with a specific distributor or have the distribution done by a company doing service in an area.

75.2.15.17 Offshoring and Outsourcing

Offshoring means executing a business activity beyond sales and marketing outside the home country of an enterprise. Enterprises typically either have their offshoring branches in low-cost countries or they ask specialized companies abroad to execute the respective activity. Offshoring should therefore not be confused with outsourcing. Offshoring within the own company is called captive offshoring. Outsourcing is the result-oriented relationship with a supplier, who executes business activities for an enterprise, which traditionally were executed inside the enterprise. Outsourcing is site-independent. The supplier can reside in direct neighborhood of the enterprise or offshore, which is outsourced offshoring. Software engineering economics provides the basic criteria and business tools to evaluate different sourcing mechanisms and control their performance.

75.2.16 Risk and Uncertainty Management

75.2.16.1 Goals, Estimates, and Plans

A goal in software economics is mostly a business goal (or business objective). It is external to the specific software or IT project and sets constraints which a plan has to consider. It relates business needs, such as increasing profitability, to investing resources, such as starting a project or launching a product with a given budget, contents, and timing. Goals are for instance to reach a certain milestone at a given date or to extend testing by some time to achieve a desired quality level.

An estimate is the well-founded evaluation of how much resources and time would be necessary to achieve a stated goal. Estimates are typically internally generated and not necessarily externally visible. They should not be driven by the goals, because this could make the estimate overly optimistic. Of course, the underlying solutions which drive the estimates should be aligned with the goals. Estimates are generated by experts familiar with the product or project. In software projects, this could be the effort necessary to deliver at a given milestone.

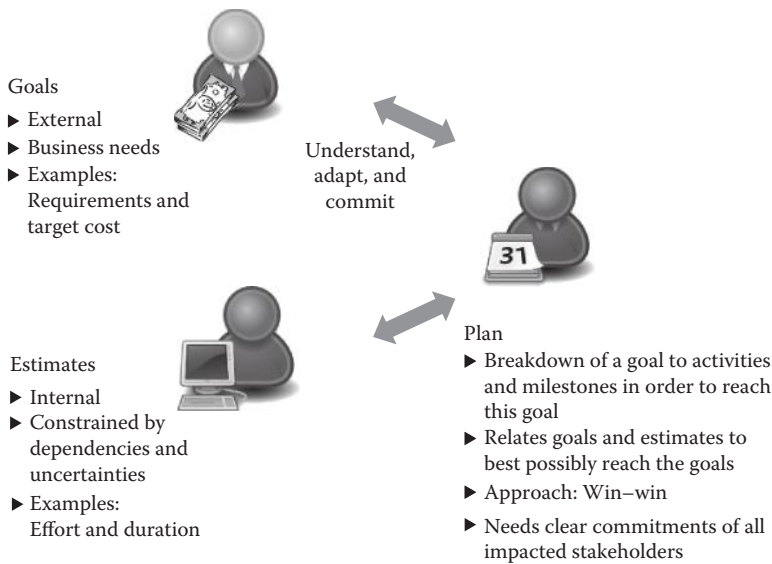

FIGURE 75.3 Relating goals, estimates, and plans.

A plan is the break-down of a goal to activities and milestones in order to reach this goal. The plan should be in line with the goal and the estimate, which is not necessarily easy and obvious, such as when a software project with given requirements would take longer than the target date foreseen by the client. In such cases, plans demand a review of initial goals as well as estimates and the underlying uncertainties and inaccuracies. Creative solutions with the underlying rationale of achieving a win-win position are applied to resolve conflicts. The plan needs to achieve commitment with impacted stakeholders to be useful (Figure 75.3).

75.2.16.2 Estimation Techniques

Estimations are used to analyze and forecast the necessary resources or time to implement requirements. Four families of estimation techniques exist:

- Expert judgment
- Analogy
- Decomposition
- Statistical (or parametric) methods

75.2.16.3 Addressing Uncertainty

Estimates are inherently uncertain and that uncertainty should be addressed in business decisions. Techniques for addressing uncertainty include

- Consider ranges of estimates
- Sensitivity analysis
- Delay final decisions

75.2.16.4 Prioritization

Prioritization means to compare alternatives based on different criteria and then rank those alternatives to deliver the best possible value. In software projects, often requirements are prioritized in order to deliver most value to the client or to allow for building increments where a first delivery ensures that the client sees a value.

75.2.16.5 Decisions under Risk

Decisions under risk techniques are used when the decision maker can assign probabilities to the different possible outcomes. The specific techniques include

- Expected value decision-making
- Expectation variance and decision-making
- Monte Carlo analysis
- Decision trees
- Expected value of perfect information

75.2.16.6 Decisions under Uncertainty

Decisions under uncertainty techniques are used when the decision maker cannot assign probabilities to the different possible outcomes. The specific techniques include

- Laplace rule
- Maximin rule
- Maximax rule
- Hurwicz rule
- Minimax regret rule

75.2.17 Economic Analysis Methods

75.2.17.1 For-Profit Decision Analysis

Figure 75.4 describes the process for identifying the best alternative from a set of mutually exclusive alternatives. Decision criteria depend on the business objectives and typically include ROI or return on capital employed (ROCE).

The for-profit decision techniques do not apply when the organization's goal is not profit—which is the case in government and in non-profit organizations. In these situations, the organization has a different goal, which means that a different set of decision techniques are needed, such as cost–benefit or cost-effectiveness analysis.

75.2.17.2 Cost–Benefit Analysis

Cost–benefit analysis is one of the most widely used methods for evaluating individual proposals. Any proposal with a benefit–cost ratio of less than 1.0 can usually be rejected without any further analysis because it would cost more than it would benefit. Proposals with a higher ratio need to consider the associated risk of an investment and compare the benefits with the option taking the same money to the bank.

75.2.17.3 Cost-Effectiveness Analysis

Cost-effectiveness analysis shares a lot of the same philosophy and methodology with benefit–cost analysis. There are two versions of cost-effectiveness analysis. The *fixed-cost* version maximizes the benefit given some upper bound on cost. The *fixed-effectiveness* version minimizes the cost needed to achieve a fixed goal.

75.2.17.4 Break-Even Analysis

Given functions describing the costs of two or more proposals, break-even analysis helps in choosing between them by identifying points where the costs are equal. Below a break-even point, one proposal is preferred and above that point the other is preferred.

75.2.17.5 Business Case

The business case is the consolidated information summarizing and explaining a business proposal from different perspectives (cost, benefit, risk, and so on) for a decision maker, often used for assessing the value of a product or requirements of a project, which can be used as a basis in the investment

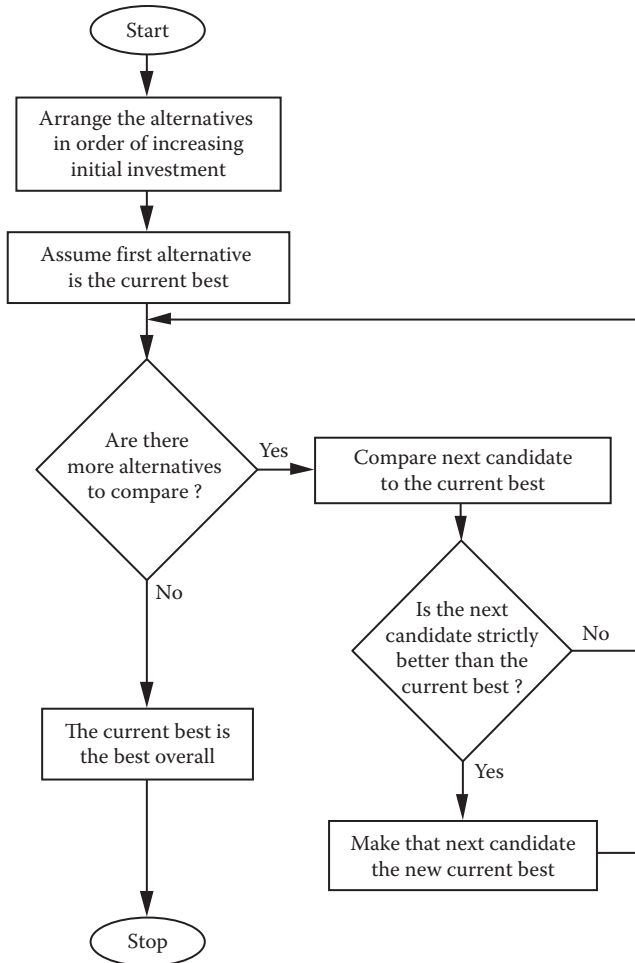

FIGURE 75.4 The for-profit decision-making process.

decision-making process. As opposed to a mere profit-loss calculation, the business case is a “case,” which is owned by the product manager and used to support achieving the objectives.

75.2.17.6 ROI

Generally speaking, it would not be smart to invest in an activity with a return of 8% when there’s another activity that’s known to return 16%. An organization’s *minimum attractive rate of return* (MARR) is the lowest internal rate of return the organization would consider to be a good investment. The MARR is a statement that an organization is confident it can achieve at least that rate of return.

Another way of looking at the MARR is that it represents the organization’s *opportunity cost* for investments. By choosing to invest in some activity, the organization is explicitly deciding to not invest that same money somewhere else. If the organization is already confident, it can get some known rate of return, other alternatives should be chosen only if their rate of return is at least that high. A simple way to account for that opportunity cost is to use the MARR as the interest rate in business decisions. An alternative’s present worth evaluated at the MARR shows how much more or less (in present day cash terms) that alternative is worth than investing at the MARR.

75.2.17.7 ROCE

The ROCE is a measurement of the profitability of a company or business unit. It is defined as the ratio of a gross profit before taxes and interest and the average total assets minus short-term debt minus cash. It describes the return on the used capital.

75.2.17.8 Cost of Quality

The cost of software is determined by many factors. Generally speaking, some cost relate to generating value (e.g., designing a piece of software), while others do not increase value (e.g., rework and errors). The cost of quality is the cost to deliver a certain level of quality, covering the content (e.g., functional requirements), and the related quality attributes (e.g., security and reliability). It contrasts with the cost of non-quality (e.g., the cost for defect correction or redesigning requirements that have been wrongly interpreted). There is not a clear line between these two basic cost factors in software engineering and IT. For example, some testing is necessary to deliver the right quality, while excessive testing means a waste of resources. Software engineering economics strives for making such cost transparent and providing the mechanisms to optimize this balance.

75.2.17.9 The Good-Enough Principle

Often, it is in software projects and products not obvious what precise targets should be achieved. Requirements are stated, but the marginal value of adding a bit more functionality cannot be measured. The result could be a late delivery or too high cost. The good-enough principle relates marginal value to marginal cost and provides guidance to determine criteria when a deliverable is good enough to be delivered. These criteria depend on business objectives and on a prioritization of different alternatives, such as ranking requirements, or relating schedule to content and cost. Software engineering economics provides the mechanisms to define and measure criteria for “good-enough.”

75.2.17.10 Multiple Attribute Evaluation

The topics discussed so far are used to make decisions based on a single decision criterion, money. The alternative with the best present worth, the best incremental IRR, the best incremental benefit–cost ratio, etc. is the one selected. Aside from technical feasibility, money is almost always the most important decision criterion, but it is certainly not always the only one. Quite often there are other criteria, other “attributes,” that need to be considered and those attributes cannot be cast in terms of money. Multiple attribute decision techniques allow other, non-financial criteria to be factored into the decision.

There are two families of multiple attribute decision techniques that differ in how they use the attributes in the decision. One family is the “compensatory,” or single-dimensioned, techniques. This family collapses all of the attributes onto a single figure of merit. The family is called compensatory because, for any given alternative, a lower score in one attribute can be compensated by—or traded off against—a higher score in other attributes. The compensatory techniques include

- Nondimensional scaling
- Additive weighting
- Analytic hierarchy process

In contrast, the other family is the “non-compensatory,” or fully dimensioned, techniques. This family does not allow trade-offs among the attributes. Each attribute is treated as a separate entity in the decision process. The non-compensatory techniques include

- Dominance
- Satisficing
- Lexicography

75.2.17.11 Optimization Analysis

The typical use of optimization analysis is to study a cost function over a range of values to find the point where overall performance is best. Software's classic space-time trade-off is an example of optimization; an algorithm that runs faster will often use more memory. Optimization balances the value of the faster run time against the cost of the additional memory.

75.3 Practice

Leadership and teamwork: Install an effective core team. Often, different stakeholders have unaligned agendas, which make the project late and cause lots of overheads and rework. First thing is to formally create a core team with the product, marketing, project, and operations managers for each product (release) and make it fully accountable for the success of a product. These persons represent not only the major internal stakeholders in product or solution development but also sufficiently represent different external perspectives. The core team leads the product development in all its different dimensions. They typically meet once a week to go through all open issues, risks, and relevant aspects of the product. Decisions are taken and implemented by the respective function. We suggest announcing and making this core team operational as early as possible in the product life cycle but certainly when the product or release is defined. The success factor is to give this core team a clear mandate to "own" the project. We see most need for active support in building an effective core team that agrees that they together have to steer the course. Too often, we face silo organizations in marketing, business management, and engineering that do not work together. This means in many cases, not only to build teams, to train, and to coach but also to adjust annual targets and performance management. As we often realize: Culture changes when targets are adjusted.

Managing risks and uncertainty: Enforce the product life cycle. Like the core teams, we urge to make a standardized product life cycle mandatory for all product releases, that is, all engineering projects. Most companies today have such life cycle defined but rarely use it as the pivotal tool to derive and implement decisions. Too often, requirements changes are agreed in sales meetings without checking feasibility, and technical decisions are made without considering business case and downstream impacts. A useful product life cycle has to acknowledge that requirements may never be complete and may indeed be in a "continuum" state. The product life cycle should guide with clear criteria, that is, determining what is good enough or stable enough. This implies that it is sufficiently flexible to handle different types of projects and constraints. This is achieved with basic tailoring techniques and guidance, which elements are mandatory and which should be adjusted to the specific environment. To foster discipline and visibility, the mandatory elements of gate reviews, such as checklists or minutes, must be explicit and auditable. To avoid reporting overheads, we recommend using online workflow support to instrument such product life cycle. Aside ease of execution, such automation facilitates reuse, data quality, and consistency. Today you can find lots of workflow management systems. We suggest to practically evaluating potential solutions versus your own needs, as it otherwise can become a burden.

Mastering stakeholder needs: Evaluate needs and requirements. Requirements must be understood and evaluated by the entire core team to ensure that different perspectives are considered. Each single requirement must be justified to support the business case and to allow managing changes and priorities. We often found requirements simply being "collected" yielding lots of unnecessary features that add to complexity but not to customer perceived value. In fact, almost 50% of all delivered features are rarely used and do not provide any payback [1,8,11]. If a product is developed on such an unjustified basis, it is in trouble because its requirements will continuously change. A product (release) must address a need and must have a strong business vision. This vision (i.e., what will be different with the release of the product) must be coined into a story. The story then translates to business objectives and major requirements. Good business management first understands the customer's needs and business case and then develops

necessary features. Requirements are a contract mechanism for the project internally and often for a client externally. They must be documented in a structured and disciplined way, allowing both technical as well as market and business judgment. Their evaluation should specifically look to completeness, consistency, and understandability. Ask a tester to write a test case before processing the requirement. Ask the marketer in the team to check whether he can sell the feature as described. This avoids discussing in the clouds. Requirements should not be perfect or we risk paralysis by analysis. Determine what is good enough and ensure that any further insight is adequately considered. After evaluation, requirements are approved by the core team. Only thereafter they are formally allocated to the project and engineering effort is spent. Requirements and business objectives must be managed (planned, prioritized, agreed, and monitored) throughout the life cycle to assure focus [3,11–14]. We suggest having a project plan that is directly linked with requirements. Work packages within this project plan should show the value they contribute with such links to requirements. This allows not only to focus on what matters but also to also monitor the earned value of the project from begin to end—and to proactively manage risks, such as effort being burned without creating value. Note that your change management needs to be equally formal and disciplined because most issues we face in troubled projects result from creeping requirements and insufficient impact analysis. To ease change management, we suggest installing traceability from requirements upwards to the business case and downwards to test cases.

Business objectives and accountability: Assure a dependable portfolio. Managing release roadmaps and the own portfolio as a mix of resources, projects, and services must be the focus of each product manager. Often, roadmaps are not worth the paper they are printed due to continuous changes and thus lack of buy-in from sales, operations, and service. Projects are started ad-hoc, while necessary reviews and clean-ups in portfolios never happen. With moving targets, sales has no guidance how to influence clients, and engineering will decide on its own which technologies to implement with what resources. When it comes to his own portfolio, the product manager has to show leadership and ensure dependable plans and decisions that are effectively executed. Dependable means that agreed milestones, contents, or quality targets are maintained as committed—unless a change is agreed and documented. Be aware as a product manager, that each ad-hoc content or release change will create the perception that your portfolio is not managed well. Apply adequate risk management techniques to make your portfolio and commitments dependable. Projects may need more resources, suppliers could deliver late or technology would not work as expected. For instance, platform components used by several products might use resource buffers, while application development applies time boxing. If there is a change to committed milestones or contents within your portfolio, they must be approved first by the core team and where necessary by respective steering boards, and then documented and communicated with rationales.

75.4 Business Value

Do aforementioned practices mean better business performance? We performed root cause analyses of hundreds of products that underperformed and found similar causes reappearing. Root causes included business cases that were never re-evaluated, unbalanced portfolios that strangulate new products, insufficient management of new releases and service efforts, and the lack of vision that caused requirements to continuously change. This is underlined by observations such as Cooper's studies indicating that the top 20% of enterprises deliver 79% of new products in time, while the average delivers only 51% of projects in time [6]. The same holds for productivity and performance. Looking, for instance, to how productivity is impacted by good business planning, we found that with a requirements change rate beyond 20% in a project, productivity falls and as such business performance [1,8].

We have been working with hundreds of business managers and achieved reduction of delays of 20% per year [3]. Explanatory factors for this positive impact of business management include leadership and teamwork, managing risks and uncertainty, mastering stakeholder needs, and

accountability toward agreed business objectives and accountability—managed by one empowered person across the product life cycle.

Improved product and business management has a profound positive impact on the overall business. For better understanding and knowledge transfer from this handbook entry to your work, we will present a case study from introducing software business understanding in a global information and communication technology (ICT) company with strong focus on corporate consistency. It showed success after ca. 12–18 months of working in the new scheme. This is what should be considered a normal learning curve when strengthening business management and introducing product management.

Strengthening the business focus as sketched earlier, at a major ICT supplier showed that duration (time to market), schedule adherence, and deliverable quality all sustainably improved while introducing and improving business management. The data are drawn from a single business unit over 3 years to allow comparability. The business unit that we selected was amongst the first to introduce consistent business management in a defined way. It operates in North America, Europe, and Asia, thus assuring representative results independent of geography. The products of that business unit are components used in communication networks. Examples of usage include voice over IP and video solutions. They comprise platform products that are developed typically every few years and then customized for contract projects. The approach behind is product-line driven, so that platform products would have the basic functionality and customer products are enhancements (or changes) to those platforms. There are also network management systems included, which help to configure and operate these products.

In order to achieve business success, the product manager has several objectives: Creating a winning product and business case and delivering value to customers. As a control variable, we took the degree of implementation of the product manager role. Naturally, there was a product manager role available since long; however, the responsibilities, competencies, and operational behaviors were very heterogeneous. Only with an orchestrated approach toward defining a competence profile for product managers, aligning their roles and responsibilities versus other roles in the same organization (e.g., marketing manager, project manager, and regional sales) triggered more consistent and effective behaviors. We mapped the implementation degree of the product manager role to three phases [3]:

- Phase 1: Establish foundations. A sense of urgency was created with some critical stakeholders in the organization to strengthen the role of product manager. Leading product managers were brought together and assessed success factors and the elements of the role. We aligned the new role elements to other related roles, such as marketing manager or project manager, on the one hand, and we benchmarked with other companies to formally establishing the role.
- Phase 2: Prepare and pilot. The standard product life cycle was enriched with more templates, self-assessment tools, training materials, and hands-on success stories. Training modules were piloted for key functional competences, such as the writing of a customer business case.
- Phase 3: Deploy. The longest phase dealing with deployment was performed using progress measurements for monitoring and deficiency identification. Incumbent product managers and the newly trained community provided continuous feedback helping in identifying further improvement needs.

The impact of each of these three phases could be deducted from our history database by means of mapping product releases (projects) to dates and organizations. We looked to an overall total of 178 projects without any filtering (Figure 75.5). Each phase has a representative set of projects. As a rule of thumb, one would need at least 10 projects per dependent variable being analyzed. Size is represented from very small projects (few person weeks) up to several hundred person years. The dependent variables of our study are average duration, average delay as percentage of schedule overrun compared to originally committed release dates and quality level in terms of defect detection percentage after handover. We achieved within 3 years of strengthening systematic business and product management in phase 3 (deployment) an improvement of 36% in average duration, 85% in delays, and 82% in quality (Figure 75.6).

75.3.1 Outlook: Where Is the Software Business Heading?

We will finally look at trends in software business. These trends indicate close collaboration between industrial needs and research at both universities and enterprises. Business trends naturally are influenced and determined by external trends that impact our society and therefore buyer behaviors as well as individual needs. Such external trends are characterized by: Demand for value, everything is fashion, individualism, ever-changing expectations, demand for ubiquitous services, global competition, economic and ecologic behaviors, and the need for security and stability. From these trends, we can look to what this means for software business.

1. *Innovation with market and solution focus rather than technology-driven.* Product needs and solutions go far beyond those of the software itself. They include service, evolution, integration of business processes, and the like. It is about speed to needs. Software business has to cope with this need and not get cornered by only looking toward what are mere software features. In the end, the customer is not interested in features, but in his needs and how they are best satisfied by products and services.
2. *Value creation with customers.* Value-oriented engineering will grow rapidly, that is, improving the evaluation of requirements within a business case from a portfolio management perspective. Customers are part of the value creation. This implies dynamic segmentation down to the single-buyer segment. Questions include: What is the customer business case behind the requirements? Is the own business case valid and in line with the customer or user business case? What is the contribution of requirements to this business case?
3. *Innovative market rules and business models.* Software has such low entry levels that a new competitor is simply a mouse-click away. Friction-free deliveries further add to this competitive trap. It is therefore important to develop customer and user needs continuously from scratch and innovate how their current and prospective customers can further improve their own business. Examples include community source with networks of stakeholders developing and maintaining software, wikinomics with a global and open access to information and resources, and blue ocean approaches to create new value for customers rather than fighting on price alone.
4. *Quality focus.* Quality starts at the start of a product concept and a project. Quality needs are manifold and can contradict each other. Software business has to deal with these constraints and must offer win-win solutions. Furthermore, it has to develop a quality perspective in the product development, covering for instance the usage of commercial components, including a variety of partners or suppliers, managing the quality delivered by such external partners, and adapting systems quality features as business needs change.
5. *Supplier networks and eco-systems.* Aside from the classic competitive schemes, customers today want to have sustainable networks of suppliers. The traditional concept of supply-chain will be replaced by adaptive supply networks. Suppliers are even more than ever subject to continuous evaluation and replacement where necessary. The success of a supplier depends on how well he is able to create communities and business models together with customers and other suppliers.
6. *Agility to manage uncertainties.* It is increasingly important to predict changes to products and customer or market needs on an individual level. Which requirements are most volatile and at same time exposing the project to highest risk? How can they be addressed by sufficiently flexible solution architecture?
7. *Effective knowledge management.* Knowledge management techniques becomes more and more necessary for capturing the wide-spread knowledge on customers, markets, products, technologies and especially stakeholders, in order to be less people-dependent, and to mature products and business management in an ever more changing environment.

Whether your customer is internal to your company or a traditional external client-user of your product, whether your product is shrink-wrapped and shipped or it is a service or embedded system, creating and addressing customer needs is the primary driver for good business and for good software.

76.1 Introduction

Open source software is software available in source code form that allows users to view, modify, extend, and, in many cases, further distribute subject to the terms of the applicable license. Use of open source software offers many advantages, including its ready availability and no royalty or license fees. In addition, many open source software applications and modules are continuously being improved, debugged, tested, and updated by a community of users and, therefore, may represent the best solution available from both a quality and cost standpoint.

Open source software rarely comes without some restrictions and conditions. Depending on the license, these restrictions and conditions range from fairly minor to very significant, and may be incompatible with a company's planned use of the open source software.

76.2 Underlying Principles

The availability of open source software at no readily apparent cost to programmers creates much confusion regarding the ownership of rights in the software and what restrictions the owner can impose on use and modification of the code.

* This chapter is an expanded version of an article that first appeared in the June 2012 issue of *Computer*, which is published by the IEEE Computer Society.

Even though open source software may appear to be “free,” open source software reflects the distinction between the definition of “free” as meaning “for zero price” (*gratis*) versus “with little or no restriction” (*libre*), with open source software being truly “free” only in the second sense of the word. As the father of the open source movement, Richard Stallman stated, “Think free as in speech, not free beer.”

76.2.1 Copyright Law

Like all software (or novels or paintings), open source software is only “free” to the extent that the copyright holders make the software “free.”

When distinguishing between, on the one hand, software that a company owns and, on the other hand, open source software that a company obtained from another source, lawyers and business people will often refer to software that a company owns as “proprietary” software. While this distinction is valid from the perspective of the company (i.e., the company does not own the open source software that it downloaded from a website), it is a mistake to infer from this that open source software is not owned by anyone or that it is in the public domain.

The developers of the open source software or their assignees own title to the copyright in the software automatically from its fixation in a tangible medium (e.g., a computer file). While such owners of the open source software may make the open source software available for anyone to use under the terms of the open source license that they have chosen, their ownership of the underlying copyright is what allows them to require that anyone using the software do so in accordance with the license.

76.2.2 Open Source License Terms

Generally speaking, open source software licenses fall into one of three categories: restrictive (also called “copyleft”), moderately restrictive (also called “copycenter”), and permissive. In theory, the number of possible licenses is unlimited because authors of open source software may select any license or create their own. However, the top 10 most common open source software licenses are used by probably the majority of all open source software modules and applications available. With the notable exception of the Affero variant of the GNU General Public License (the “GPL”), in most cases, these restrictions are only applicable or relevant if copies of the software will be provided to third parties and are not applicable or relevant when the software is only being used internally, which includes hosting the software in a software as a service (SaaS) arrangement for customers or using it to operate a customer-facing website. However, these definitions of “distribution” across different versions of the GPL are potentially subject to varying interpretations in different jurisdictions as will be discussed in the subsequent sections.

76.2.2.1 Restrictive

Certain open source software licenses, such as the GNU GPL, are considered “viral” licenses, because they generally require that proprietary software that is distributed with open source software be licensed under terms consistent with the open source software license (hence, like a virus, the license terms are passed on to other software).

Proprietary code distributed with or alongside GPL-licensed code as part of a larger program or application may in many cases be deemed a “covered work” along with the GPL-licensed code, such that the entire covered work (i.e., proprietary code and open source software) may only be distributed on terms compatible with the GPL license, including on the condition that the source code to the entire combined program (including developer’s proprietary code) be made available to recipients under the GPL-license terms. Unlike under the GNU Lesser General Public License (“LGPL”) and other moderately restrictive licenses discussed in the subsequent sections, maintaining the GPL-licensed code in separate source code and executable files (such as dynamically linked libraries [DLLs]) that only dynamically link to the proprietary code at run time does *not* necessarily prevent the proprietary code

distributed alongside GPL-licensed software from becoming a “covered work” under the GPL that may only be distributed subject to the terms of the GPL license.

An exception does exist for a compilation (called an “aggregate”) of the open source with other separate and independent works, which are not by their nature extensions of the covered work, and that are not combined with it such as to form a larger program, in or on a volume of a storage or distribution medium, if the compilation and its resulting copyright are not used to limit the access or legal rights of the compilation’s users beyond what the individual works permit. Inclusion of a covered work in such an aggregate does not require the license terms to the other parts (such as the company proprietary parts) of the aggregate be also licensed under the GPL. The GPL does not provide much clarity as to the distinction between when multiple components are deemed to be an aggregate (compilation) that is not a covered work and when deemed to be one larger program with multiple parts.* Many companies will not risk including GPL software in distributions of their software products unless the distribution clearly fits into the compilation exception (e.g., where the operating system software is licensed under the GPL and the application running on top of the operating system is commercially licensed).

76.2.2.2 Moderately Restrictive

Moderately restrictive licenses, such as GNU LGPL, may also have a viral effect on proprietary code depending upon the manner and form in which the open source software is used with the proprietary code. For example, if open source software licensed under the LGPL is statically linked into a proprietary software program (e.g., forming an .exe file out of both the LGPL and proprietary code), which is then distributed to customers or third parties, then compliance with the LGPL license would require that the entire executable (including the proprietary code) also be covered by terms compatible with the LGPL license and that, among other things, the source code to the proprietary software be made available to customers (in order to allow the customer to modify the LGPL source code and recompile the executable). On the other hand, distribution of the same LGPL-licensed software with proprietary software where the LGPL software is distributed as a standalone DLL file that is then dynamically linked to by the executable at run time is possible under the terms of the LGPL without requiring the proprietary executable file to be made available in source code form under terms compatible with the LGPL.

76.2.2.3 Permissive

Permissive licenses impose few if any restrictions. The restrictions (if any) are generally not considered to be burdensome (such as a requirement that certain copyright ownership and attribution notices be included with the distributed files), and the licenses are not “viral” as described earlier. Examples of permissive software licenses include the MIT license, the Apache license, and the Berkley Software Distribution license.

* The Free Software Foundation (the author of the GPL license) offers only:

“Where’s the line between two separate programs, and one program with two parts? This is a legal question, which ultimately judges will decide. We believe that a proper criterion depends both on the mechanism of communication (exec, pipes, rpc, function calls within a shared address space, etc.) and the semantics of the communication (what kinds of information are interchanged).”

“If the modules are included in the same executable file, they are definitely combined in one program. If modules are designed to run linked together in a shared address space, that almost surely means combining them into one program.”

“By contrast, pipes, sockets and command-line arguments are communication mechanisms normally used between two separate programs. So when they are used for communication, the modules normally are separate programs. But if the semantics of the communication are intimate enough, exchanging complex internal data structures, that too could be a basis to consider the two parts as combined into a larger program.”

“However, the exception would apply, for example, to a CD containing a collection of games where each game was a standalone game that did not rely on the inclusion of any other game to operate and did not link or pass data in any way to the other games. In this example, the CD could contain a mixture of GPL licensed and proprietary licensed games.”

76.2.3 Enforcement of Open Source Licenses

Copying, modifying, creating derivative works of, and distributing a work (such as software) that is protected under copyright requires either ownership of the copyright or a valid license from the owner or licensing agent of the copyright. Therefore, if a company distributes software that includes or is derived from open source software, and does not comply with the terms of the applicable license under which such open source software was made available, then such company is infringing the copyright in such software, breaching the terms of the license agreement, or both.

Most open source software modules are available for download and accessible without requiring the recipient to expressly assent to the license terms. For example, usually the recipient is not required by installation software to affirmatively click “I agree” to the terms before the relevant software is installed. However, but for a valid license, the recipient would likely be infringing the software’s copyright; therefore, taking the position that the recipient did not agree to the license terms will not usually be a viable option for a recipient.

76.2.3.1 Who Can Enforce an Alleged Open Source Violation?

Authors of open source software, often assisted by organizations formed to advance the enforcement of open source software licensing terms, have been increasingly active in enforcing such licenses. In other cases, commercial software companies that also make a less functional or older version of their proprietary software available under open source licenses, actively seek to enforce the terms of the open source license to ensure that users purchase commercial licenses when appropriate. It is important to note that only the owners of the open source software and their agents acting on their behalf have the right to assert a claim against a user of the open source software for violating the terms of the license or infringing the copyright.

76.2.3.2 Are Open Source Licenses Enforceable?

There is no longer any question that open source licenses are enforceable. The US Court of Appeals for the Federal Circuit, in a rare decision on a copyright matter,* ruled in 2008 in the *Jacobsen v. Katzer and Kamind Industries* case that the terms of the open source “Artistic License” are enforceable. The license covered software used to control model trains. Jacobsen claimed that Katzer/Kamind downloaded the open source software from Jacobsen’s website and incorporated it into another product without following the terms of the Artistic license.

Katzer/Kamind admitted that they copied, modified, and distributed the Jacobsen software. The issue for the court was whether these actions were within the scope of the Artistic license. If the actions were outside the scope, then Jacobsen could sue for copyright infringement. Otherwise, the lawsuit would be based on breach of contract.

The court concluded that the terms of the Artistic license that required a copyright notice and tracking of changes to the software were conditions to the license. That is, Katzer/Kamind were required to comply with these conditions to be granted the license to the software. Katzer/Kamind conceded that they did not comply with these conditions.

The court noted that on the facts of the case, Jacobsen made out a prima facie case of copyright infringement. More importantly, however, is that the court acknowledged that the terms of an open source license were enforceable. Therefore, it is likely that noncompliance with a properly drafted open source license, with terms construed as conditions to that license, would result in liability for copyright infringement.

* In the United States, the Court of Appeals for the Federal Circuit has jurisdiction over appeals concerning patent law, while the regional Courts of Appeal typically have jurisdiction over appeals concerning copyright law. The *Jacobsen* case included both copyright and patent law issues, so the Court of Appeals for the Federal Circuit had jurisdiction over the entire case.

76.2.3.3 Available Damages

In the case where, for example, a company distributes a program combining its proprietary software and GPL software and the company does not provide to its customers the source code to its proprietary software (or for that matter license it under the GPL), legal action taken against the company could take the form of a breach of contract claim and/or copyright infringement claim, with the most likely remedies being

- An injunction to prohibit further sale or license of the combined software and require cessation of use of the software by the company and its customers (until the open source software is removed)
- Impoundment and destruction of the combined software
- Monetary damages in the form of direct damages (often measured as copyright holder's lost profits or the price that someone would have been willing to pay) and, if the copyright of the open source software was registered, statutory damages
- Possibly attorney's fees if the copyright to the open source work was registered and the infringement is determined to have been willful

However, a court order forcing the company to "open source" its commercial software to comply with the terms of the GPL is *not* a realistic outcome or liability in this example (or any readily imaginable example). A court order for specific performance of this type is generally *not* available, especially when other remedies, such as monetary damages and court orders enjoining future distribution, afford an adequate equitable remedy.

76.2.4 Interactions between Open Source Licenses and Patent Law

Certain open source software licenses incorporate a provision that purports to cause any person modifying or contributing to the open source software to grant a non-exclusive patent license to recipients of the open source software with respect to any contributions made by such contributor to such open source software. In addition, some of the open source software licenses provide that if a user of the open source software brings a patent infringement claim against another user of the open source software, then the patent license (and, in some cases, also the copyright license) such party had to such open source software terminates. In case of the Mozilla Public License (MPL), a patent infringement claim against a contributor to the MPL licensed software, *regardless whether the patent infringement claim has anything to do with use of such MPL licensed software*, can result in retroactive loss of the MPL license. Because a user of open source software could lose rights to continue using certain open source software modules if it seeks to enforce its patent rights, and because licenses to its patents may be granted if it makes contributions, use of certain open source software licenses may need to be coordinated with decisions on patent strategy.

76.2.5 Commercial Off-the-Shelf

Commercial off-the-Shelf ("COTS") software is generally considered to be software that is widely sold to the general public. In other words, it is software that is not developed in connection with a specific contract or customer. Some advantages of using COTS software as part of a larger software package include decreased overall development time and potentially lower development cost. The reduced time usually means that the software package is delivered to the customer more quickly compared to software packages that consist entirely of custom code.

Although using COTS software may seem attractive, it is important to recognize that significant integration issues may arise, effectively erasing any projected reductions in development cost. Furthermore, the COTS software user has little or no control over the COTS software itself. That is, the manufacturer of the COTS software usually has absolute control over changes and other updates to it. If the changed COTS software is incorporated into the larger software package, it could render the latter inoperable without significant recoding of the package. In an extreme but not uncommon case, the COTS software manufacturer could discontinue the COTS software. In that instance, the COTS software user will likely

have no recourse other than to look for an alternative to the obsolete software, which may entail the creation of a custom piece of software as a replacement, retroactively eliminating a primary advantage of using the COTS software.

If a company is evaluating whether to incorporate COTS software into one or more of its released products, it is advisable to consider the inclusion of certain contractual provisions in its purchase orders for the COTS software. Such provisions would operate to protect the company in the event of alterations or obsolescence of the COTS software. For example, the company could require extended notice of planned changes to the COTS software or its availability. This would allow the company to plan effectively for such disruptions and minimize impact to its business and its customers.

76.3 Best Practices

76.3.1 Adopting an Open Source Policy

Having an open source policy that is adhered to is critical. Without such a policy, a company, for example, could find that it lacks the expected ownership and control over software that it just released because the software included certain open source code. The open source code may have been included inadvertently during development. It may have been a remnant of code included only for internal, debugging purposes and unknowingly left in the final, released version of the software. In either case, a company finding itself in such a situation will have significant problem on its hands that it might have avoided if it had a preexisting policy for dealing with open source software.

An open source policy should, at a minimum, include directives on the internal and external use (i.e., redistribution) of open source code, procedures for acquiring open source licenses and monitoring compliance with them, and a formal mechanism that tracks requests to use open source software. The policy should prohibit all use of open source software for which a request to use has not been made or approved.

76.3.1.1 General Philosophy on Open Source

Companies can follow one of two broad paths when setting a policy on the use of open source software. The first path involves an absolute prohibition on the use of open source software. The second path permits the use of open source software, at least to some extent (e.g., for internal use only and/or use in distributed software). Path number one can be easy to manage but will likely add to software developers' workloads and lengthen development time. Path number two may facilitate software development but will require attention to the various open source licenses to ensure compliance.

Irrespective of the path chosen, policing is required. In other words, a company must ensure that it has a complete understanding of its exposure to and use of open source software. Given that software can find its way into a company through unofficial routes, effective policing is necessary even if the company has chosen the first path and prohibited the use of open source material.

76.3.1.2 What Licenses Will the Company Accept?

There are many open source licenses that have been drafted over time and have achieved varying degrees of use by open source developers. As described earlier, these licenses can generally be categorized as restrictive, moderately restrictive, or permissive. One resource that maintains a catalog of these licenses is the open source initiative (opensource.org).

A company's decision as to which open source licenses to accept in connection with using open source software depends on the expected scope of that use. For example, if the expected scope is limited to internal use by the company, only those licenses (if any) that regulate such internal use should be evaluated. On the other hand, if the company intends to couple open source with its proprietary code, then the company needs to consider whether it will agree to license its proprietary code under the same terms as the open source software or seek an alternative license to avoid this requirement.

In view of the significant number of open source licenses in use, albeit in varying degrees, a company should approach a decision on which licenses to accept by first setting a policy regarding its proprietary software. That policy should include a position on the extent to which the company will license that proprietary software. That position will act as a filter and cause the company to reject certain open source licenses that are incompatible with its policy. Consequently, this would foreclose the use of any open source software that is subject to the rejected licenses.

76.3.1.3 Employee Education

An understanding of the benefits and risks of using open source software likely varies widely from employee to employee. Many experienced software developers will understand the relevant issues, while less experienced employees or those having jobs that do not involve coding may be largely unaware of these issues. The solution for dealing with this is having a comprehensive employee education program that covers the open source software landscape.

If a company has already decided to adopt a policy that prohibits the use of all open source software, the education program can focus on how to identify the open source and the risks associated with using it. This should provide the employees with a solid basis for the company's policy. If the employees fully understand that basis, it is more likely that they will follow the policy with minimal resistance.

If the company does not prohibit the use of open source software, it is important that employees be instructed to follow a procedure that ensures they formally request to use the open source. This allows the company to track the use of open source software and evaluate whether the applicable license terms are acceptable so as to authorize the use of the open source. Employees must be educated such that they follow this request-evaluate-approval process without fail.

Irrespective of the choice a company makes about using open source software, it is imperative that employees be able to recognize when they are using open source. This is necessary to guard against the inadvertent use of open source that, if left unchecked, could result in large-scale disruption of the business. If employees are sensitized to recognize open source, they can they take the necessary actions to purge the software or file a formal request to authorize its use.

76.3.1.4 Software Monitoring Tools

Tracking the use of open source software is a critical first step toward ensuring that one does not run afoul of the terms of an open source license. Open source that has worked its way into a company's released software package without the company's knowledge and approval can create major problems, including delaying the release of a software package until the open source is removed or its license terms agreed to.

In view of the complexity of large software engineering projects, it is typically impossible for the developers and their managers to ensure accurate tracking of the use of open source on an individual basis. Accordingly, tools have evolved that monitor the software development process and identify the existence of open source software. These tools are usually largely automated and can include additional features, such as tracking requests to use open source and the decisions made on those requests.

A company should consider the expected complexity of the software that it is developing and the number of developers that it will use and can reasonably monitor in connection with a decision on using an automated tool to police its use of open source.

76.3.2 Deciding Whether to Distribute Software under an Open Source License

76.3.2.1 Balancing Permissiveness with Competitive Concerns

A company that develops its own software for sale to customers should consider whether it will designate that software as open source. In other words, a company should evaluate whether to make its software

freely available to customers subject to the appropriate open source license. This contrasts with the company maintaining ownership and control over its software and granting licenses to its customers on terms that it sets.

The trade-off between maintaining software as proprietary versus releasing it as open source is clear: keeping the software proprietary allows a company to preserve the secrecy of its code. Customers who receive and use the software will generally be unable to determine the inner workings of the distributed software, and the company could include license terms that prohibit any type of reverse engineering of the software. In this scenario, the company's competitors will likely be unable to ascertain how the software works. This may be the proper approach when a company decides that it is imperative to protect its technology to the greatest extent possible.

On the other hand, by designating its software as open source, a company can potentially obtain a much larger base of users and customers, many of whom are drawn to the software initially because it would be freely available. Many of the users might exploit the open source nature by creating enhancements and other extensions to the software that could make it more attractive to use. Indeed, a community of user-developers could emerge from the customer base that propels the software toward wider adoption. An important point to keep in mind, however, is that a decision to designate software as open source should be accompanied by a plan to get revenue through alternative means. A different business model is needed because the distribution of the software will no longer generate the expected revenue. This is discussed in the following text.

76.3.2.2 Open Source Business Models

A business model for open source software needs to address how to generate revenue from software that is, by its very nature, distributed freely. Accordingly, business models must incorporate some value added aspect to justify a cost.

Providing proprietary software plugins to open source software is a common way to add value. Companies can offer these plugins, along with subscriptions for training and technical support, for a fee. Another alternative is to offer a stripped-down open source version of a software package for free and at the same time offer an enhanced commercial version for a fee. The theory behind this approach is that customers who are attracted initially to the free version would later want enhanced functionality and would purchase the commercial version.

A key to a successful business model is to identify a service relating to, or other proprietary element of, the product that end users consider sufficiently desirable or valuable such that they are willing to pay a reasonable fee to have access to it. Coming up with that service or other proprietary element is a function of the seller's creativity and knowledge of the marketplace.

76.4 Open Issues

76.4.1 What Constitutes Distribution in the Cloud Computing Environment?

Many websites, and providers of SaaS (where the software is centrally hosted by the provider or in the cloud and not distributed to the customer), make extensive use of open source software. This includes software licensed under the GPL in combination with their own proprietary software. In many cases, if copies of these combinations of open source and proprietary software solutions were distributed to end users as opposed to their functionality being made available under a SaaS model, then under the terms of the GPL or other similar restrictive open source licenses, the party distributing such software would have been required to make available the source code to both the proprietary software and the open source software (including any modifications). However, because the GPL-licensed open source software is hosted by the SaaS provider or website provider (on their own servers or in the cloud) and actual copies are not distributed to customers, the SaaS providers and websites are not required to make available the source

code to their own proprietary software or to their modifications to the GPL-licensed open source software (unless Affero GPL-licensed software is used as discussed in the next paragraph).*

The use of GPL-licensed open source software in this manner, without being required to disclose the source code of the modified open source software (and possibly the proprietary software too), was viewed by some to be an unintended or undesirable “loophole” in the GPL, the original versions of which were drafted before the wide adoption of SaaS and cloud computing (though not prior to previous incarnations of such business model, such as application service providers or ASPs). Therefore, in March 2002, the Free Software Foundation (the author of the GPL) published an Affero General Public License (“AGPL”), version 1, as an alternative to the then GPL, version 2. Subsequently, it published the AGPL, version 3, in November 2007, shortly after the publication of GPL, version 3. The AGPL redefines what a distribution is—with express wording that states that interaction over a computer network amounts to a distribution. The use of AGPL-licensed software with proprietary software is generally not compatible with a traditional SaaS model and will likely trigger an obligation to disclose source code. To date, the AGPL has had limited adoption in comparison to the GPL.

76.5 Summary

Open source software is a great resource and option for many companies desiring to supplement and extend the capabilities of their existing software and/or hardware products, allowing companies to focus internal development work on core proprietary functionality. However, as with any third party software that a company desires to embed or include with its own proprietary software, the applicable license terms must first be understood and carefully considered by the company.

The wide availability of open source code presents both great opportunities and risks to software developers. Companies should anticipate that programmers will have access to open source code and be proactive in creating and, more importantly, communicating, and implementing an open source policy so that decisions regarding use of open source software can be quickly made during software development instead of after the fact.

The following is a list of selected open source licenses by category—Permissive, Moderately Restrictive, and Restrictive—as described in Sections 76.2.2.1 through 76.2.2.3:

“Permissive” open source software licenses

- MIT license
- Berkeley Software Distribution (BSD) license
- Apache license

“Moderately restrictive” open source software licenses

- Common Development and Distribution license (CDDL)
- Common Public License (CPL) & Eclipse Public License (EPL)
- Mozilla Public License (MPL)
- Lesser General Public License (LGPL)

“Restrictive” open source software licenses

- General Public License (GPL)
- Affero General Public License (AGPL)

* GPL, version 3, states that mere interaction with a user through a computer network, with no transfer of a copy, is not a distribution.

Key Terms

- “Copyright” is a property right in an original work of authorship fixed in a tangible medium of expression that gives the copyright holder the exclusive right to reproduce, adapt, distribute, perform, and display the work. Black’s Law Dictionary 337 (7th edn., 1999). In the United States, copyrights are registered through the US Copyright Office (www.copyright.gov) and can be enforced through suit in the federal courts.
- A “license” is a permission to commit some act (e.g., reproducing, adapting, or distributing software code) that would be otherwise unlawful (e.g., due to a valid copyright). Black’s Law Dictionary 931 (7th edn., 1999).
- A “patent” is the exclusive right granted by a government to exclude others from taking certain actions such as making, using, or selling an invention. Patents differ from copyrights in several respects including the potential to protect the basic idea of the invention (as defined the claims of the patent), whereas copyright protection is limited to the particular expression of an idea (e.g., the particular source code used by the programmer). In the United States, patents are granted after examination by the US Patent and Trademark Office (www.uspto.gov) and are enforceable through suit in the federal courts.

77.1 Introduction

In this chapter, we first introduce the evidence-based paradigm, discuss its origins and use in a variety of disciplines, and consider how it can be used in software engineering. We then describe how a secondary study in the form of a systematic literature review (SLR) can be performed in software engineering. After that, we examine the profile of existing secondary studies and what they can tell us, as well as discussing some “gaps” that need to be addressed. Finally, we consider how the use of evidence-based studies might form the basis for *evidence-informed* software engineering practices.

77.1.1 Evidence-Based Paradigm

For centuries, the “traditional” view of *knowledge* in the sciences has been that this should be based on systematic observation and that such experiments should be *repeatable* by other scientists. Observations have led scientists to theorize and produce “models” (such as of gravitational attraction) that have then been tested against further observation. For sciences such as physics where it is usually possible to separate the observer from the experiment, as well as to isolate the key factors, this approach has been highly successful in developing understanding.

Where human beings become *participants* in the experimental situation, rather than simply observers, then issues of repeatability become both more difficult and also more important. Sometimes, the results have been powerfully evident (such as James Lind’s demonstration that vitamin C could prevent scurvy or the work of Louis Pasteur), at least to scientists. However, for many studies, the effects have been less pronounced, and because they could be masked by other factors, experiments using humans have not always been repeatable, to the extent that attempts at replication have sometimes produced conflicting results.

Until the last few decades, it was not unheard of for different groups of medical practitioners to advocate quite different treatments for a given problem, each appealing to empirical studies that supported that particular view. In particular, in reviewing existing studies an expert would be likely to “cherry-pick” the data by including only those studies that agreed with their ideas. It was this situation that spurred the noted epidemiologist Archie Cochrane to issue a challenge to clinical medicine that treatment should be based upon the best available evidence—and by implication, how was that evidence to be determined?

The approach that emerged has become known as *evidence-based medicine* (EBM) and with it the use of *secondary studies*, organized largely through the not-for-profit *Cochrane Collaboration*.^{*} A secondary study does not involve conducting any form of “experiment”; instead, it aims to aggregate the outcomes of many primary studies in an *objective* and *unbiased* manner. The process by which this is performed is known as a *systematic review*, although in software engineering we generally use the term *systematic literature review* (SLR) to distinguish it from inspection-style code reviews.

77.1.2 EBM to EBSE

We do not have space here to explore the impact of EBM (an informal but penetrating analysis is provided in [14]). However, the concept rapidly spread from clinical medicine to various other branches of healthcare, through to education and social science. En route there were some adaptations, in particular for the processes used to synthesize the outcomes from different studies. Most clinical studies, where the participants are *recipients* of a treatment, are organized as *randomized controlled trials* (RCTs), and the outcomes from these can be combined using powerful statistical techniques such as meta-analysis, enabling the secondary study to resolve potentially small effects with greater certainty. Education and other branches of healthcare have to deal with more complex forms of treatment and interaction of these with the participants and so have to use other forms for aggregating the outcomes of their studies.

The idea of employing this paradigm in software engineering was advocated by Kitchenham, Dybå, and Jørgensen in 2004 [26]. They suggested that with some adaptation to fit the nature of software engineering studies, this could be a valuable way of consolidating our empirical knowledge about what works, when, and where. From that point, *evidence-based software engineering* (EBSE) has evolved strongly, to the point where by the end of 2011, we could identify around 150 published secondary studies. We will discuss some of these later, but first we examine exactly how an SLR is performed.

77.2 Performing a Systematic Literature Review

We first examine some different reasons for conducting systematic reviews and then the form that an SLR takes in software engineering.

77.2.1 Why Conduct an SLR?

As indicated previously, we are likely to be motivated to undertake an SLR on a software engineering topic if we want to draw together the available knowledge about some phenomenon in some way. This might be to answer a specific research question about a technique, to identify the trends in research on a particular topic, or to find out what primary studies are available that investigate some particular model or technique.

^{*} <http://www.cochrane.org>

FIGURE 77.1 The role of secondary studies.

We usually term the last of these a *mapping study*, equating this to the *scoping review* described by Petticrew and Roberts [34]. However, we might usefully note that Booth et al. [5] do distinguish between these, characterizing a scoping review as one that identifies *what* primary studies are available, while a mapping study also *categorizes* them. Mapping studies can identify if there is scope to perform a fuller SLR or where new primary studies would be particularly useful [32].

The evidence-based paradigm, through the medium of the secondary study, therefore plays quite an important role in empirical research, as illustrated in Figure 77.1. There is the interaction with primary studies, by which a secondary study both draws upon the data from these and also identifies where new ones are needed (and how reporting standards can be improved). There is also interaction with practice and research, by providing recommendations for practice, for company policies, and for standards bodies. Finally, by identifying research trends (and dead ends), secondary studies may help with identifying where funding for new research might best be directed. Note too that for software engineering, we are potentially interested in a range of forms for primary studies (for simplicity, we have identified two here)—where there is a shortage of useful experiments, we might triangulate their findings with those from other forms of study such as case studies and observational studies [40].

77.2.2 Conducting and Reporting an SLR

In describing how evidence-based practice could be adapted for software engineering, Kitchenham et al. identified the following five steps:

1. Convert the need for information into an answerable question.
2. Find the best evidence with which to answer the question.
3. Critically appraise the evidence for its validity (how close it comes to the truth), its impact (the “size” of the effects observed), and its applicability (how useful it is likely to be).
4. Integrate the critical appraisal with software engineering expertise and stakeholders’ values.
5. Evaluate the effectiveness and efficiency in the previous steps 1 through 4, and seek ways to improve them.

Steps 1 through 3 are effectively the role of the SLR, for which the subsequent technical report by Kitchenham and Charters provides a set of guidelines as to how they can be performed in software engineering [30].

The *guidelines* (as we will refer to them in the rest of this chapter) describe a three-phase process for conducting a review.

Plan review. There are three steps involved in this:

1. *Specify the research question:* This is actually harder than it sounds, since this needs to be expressed in such a way as to form the basis for the search process and so may go through a number of refinement steps. Indeed, as indicated previously, it may only be practical to formulate this after conducting a wide-scope mapping study.
2. *Develop the review protocol:* We discuss the roles of protocols in Chapter 79. The protocol provides the plan that will be followed when conducting the study.
3. *Validate the review protocol:* This may be done by asking one or two experienced researchers to review it, as well as undertaking some prototyping activities for items such as the search strings, to ensure that these can find some known primary studies.

Conduct the review. This involves five major activities:

1. *Identify relevant research:* Searching for relevant papers using the search strings determined in the plan, with the literature sources also identified in the plan. While many SLRs are conducted using electronic searches of digital libraries, there are arguments for conducting manual searches [22]. These may be particularly appropriate where it has proved difficult to determine a sound set of search strings, perhaps because of wide variation in the vocabulary being used by researchers.
2. *Select primary studies:* This is quite a labor-intensive task that involves filtering the returns from the search for relevance, and it is common to perform this using two analysts working independently and then reporting and resolving differences, in order to help improve reliability. Common practice is to perform an initial sift based on the titles of the papers found, then on the abstracts, and finally on the full text of the remaining papers. Decisions are based upon the *inclusion/exclusion* criteria that form a key element in the protocol. The SLR on agile methods by Dybå and Dingsøyrr provides an excellent description of this process [12].
3. *Assess study quality:* This involves assessing how well the primary study was conducted and reported using a “quality instrument” such as a questionnaire. This is usually conducted with varying degrees of rigor, depending on need—mapping studies often omit this step.
4. *Extract required data:* One of the elements of the research protocol should be a *data extraction form* identifying what should be extracted from a primary study and, where appropriate, how this should be coded or parameterized. As with selection, it is normal to use two analysts for this task, comparing results and resolving differences. This is because primary studies do use very varied reporting styles—and since EBSE is a relatively recent development, few authors of primary studies organize their supporting data with the expectation that anyone will want to extract details from it, although there are indications that this is beginning to change. Again, for a mapping study, this will usually be a rather simpler task, depending chiefly upon how the studies are to be categorized.
5. *Synthesize the data:* This is a potentially challenging task. While in practice there is a range of possible forms for this, software engineers have so far tended to be rather conservative and limit themselves to tabulation and vote counting. Some useful guidance is available from [9].

Document the review. The writing of the methodological element of the final report can be largely based upon the research protocol. However, describing the outcomes, including any recommendations based upon the evidence, should also follow a systematic process.

As a final note on this, we should observe that an SLR might extend an earlier SLR. This may involve repeating the activities described in the protocol for a subsequent period and then synthesizing the

augmented set of primary studies. Or it could involve using extended search strings to widen the scope of the original study. An SLR does not necessarily have to begin with an empty sheet.

77.2.3 Realization

We have described some of our early experiences with performing SLRs in [6], and many of the observations made there are still relevant, with many later SLRs identifying very similar issues. So, what challenges do our environment and culture provide?

Specifying the *research question* is a significant issue. This forms the basis for the searching activity and, in particular, for determining the search strings to use. There should be a clear link between research question(s) and search strings, and an iterative process of refinement of these through prototyping of the search process may well be necessary.

Linked to this is the need to write a clear and full *protocol* for the study. SLRs usually involve a team of researchers, not least because we need two analysts for many elements. It is absolutely essential that everyone involved has a shared understanding of the goals of the study and of the criteria that are to be used for the various activities. Developing and discussing the protocol is an essential step in this process.

Another major issue is that of conducting the *search* for papers. Although various search engines are available, most notably the digital libraries from IEEE and ACM, as well as those such as Web of Science and Science Direct, together with indexing services such as Scopus, none have interfaces that are really optimized for our task. In addition, they tend to be organized differently, so that having identified a specific search string, the systematic reviewer then needs to interpret this for the forms used by each search engine.

An additional aspect to note about the searching activity is that electronic searches are rarely able to find all papers. However good our search strings, authors do not always use titles, or even keywords, that are “standard,” and so some relevant papers may well get missed. A technique commonly used to alleviate that is termed *snowballing*. This consists of going through the references of the studies found and selected from electronic searches, to identify any potentially relevant papers that they cite. The rule of thumb for this is that snowballing may well find up to around 10% of the final set of papers.

The task of *inclusion/exclusion* likewise offers many challenges, especially for the less experienced researcher. (We should note here that while our experiences suggest that mapping studies often provide a useful starting point for a research student [32], conducting a full SLR is a much more demanding exercise.) Ideally, performing as much as possible of this activity using the title and abstract of papers is far less time-consuming than reading full papers. However, the quality of abstracts in software engineering is often poor (we should observe that we are firm advocates of the use of *structured abstracts* as a means of alleviating this problem [8]), and so decisions have to be deferred. It is not uncommon to begin with 500–2000 “hits” from the searching process, so the scale of this task is also quite substantial.

Both *data extraction* and *synthesis* provide some domain-specific issues, and again it is essential to appreciate that some experience of the domain is really necessary. Indeed, this is one reason why we advocate the use of mapping studies rather than SLRs as a suitable form for postgraduate study.

Fortunately, although all of these are challenging, they can be overcome, and in the following sections, we examine some of the resulting outcomes.

77.3 What SLRs Do We Have?

In the rest of this chapter, we look at the activities that have been undertaken to catalogue the SLRs that address topics within the software engineering domain. We show the growth in numbers over the years since 2004 and summarize the topics that form the focus of studies to date. There are some indications that the cataloguing process has not resulted in the identification and indexing of all of the published studies in software engineering. We discuss the issue of completeness later.

77.3.1 Cataloguing SLRs

As indicated in Section 77.2, the SLR process can be used to map out the research in a particular area of interest. As well as mapping the research undertaken by primary studies, a mapping study can alternatively focus on secondary studies and be used to map out the SLRs undertaken across the whole software engineering domain (or across subareas of the domain). Such *tertiary studies* can provide a thorough overview of the breadth and quality of SLRs and form valuable resources for a range of stakeholders (such as educators, researchers, and practitioners). To date, three broad tertiary studies in software engineering have been published, which we refer to in the rest of this section, as TS1, TS2, and TS3, respectively [10,29,31]. Tertiary studies can also have a narrower focus. For example, a tertiary study of SLRs relating to global software development (GSD) has also been undertaken [39].

TS1, TS2, and TS3 addressed research questions across the broad software engineering domain in order to

- Identify SLR activities over a specific period
- Assess the quality of those studies located
- Identify the individuals and organizations most active in SLR- based research
- Determine the topics covered by the SLRs
- Map the topics covered to the Software Engineering 2004 Curriculum Guidelines for Undergraduate Degree Programs* and the Software Engineering Body of Knowledge (SWEBOK)† (TS2 and TS3 only)

The initial broad tertiary study, TS1, employed a manual search of 10 journals and 4 conference proceedings published between January 2004 and June 2007 (inclusive). From a total of 2506 papers, a set of 18 unique, relevant studies were selected. A further two studies were identified by asking researchers about current work [4] and by searching the Simula Research Laboratory website [21].

The second broad tertiary study, TS2, covered the period between January 2004 and June 2008 (inclusive) and used an automated search of four digital libraries and two indexing services: IEEE Computer Society Digital Library, ACM digital library, CiteSeer, SpringerLink, Web of Science, and Scopus. TS2 identified a further 14 studies in the period covered by TS1 and 19 studies published between July 2007 and June 2008 (inclusive).

The third broad tertiary study, TS3, used, as closely as possible, the protocol that was used for TS2 although it did incorporate manual as well as automated searches. TS3 covered the period July 2008 to December 2009 (inclusive) and identified a total of 67 unique relevant SLRs.

The more focused tertiary study of SLRs in GSD addressed a similar set of questions to those addressed by the three broad tertiary studies although the SLRs located were mapped against Abdullah and Verner's outsourcing risk framework [1] and the ISO 12207 framework [37] rather than the SE curriculum and the SWEBOK [39]. It used an automated search of seven digital libraries/indexing services, a manual search of selected conference proceedings plus snowballing. The study identified 24 SLRs addressing topics relating to GSD and published between 2005 and October 2011. Of these, three were published in the period covered by the broad tertiary studies but were not found by them, and 11 were published outside of the period covered by the broad tertiary studies (i.e., after December 2009).

77.3.2 Results from the Broad Tertiary Studies

Together, the three broad tertiary studies reported 120 SLRs on software engineering topics. The distribution of these reviews across the years from 2004 to 2009 is shown in Figure 77.2 that clearly indicates a growing number of studies through this period.

The topics covered by the studies are shown in Table 77.1, which maps the studies to the SWEBOK chapters.

In TS3, da Silva et al. [10] also reviewed the variation in quality of the SLRs over time and found a steady increase in the mean quality scores in every year except 2007. Over the 6 year period between 2004 and 2009, the increase in quality was 12.5%.

77.3.3 SLRs Not Indexed by the Broad Tertiary Reviews

Not surprisingly, given the year on year increase in published SLRs in software engineering, a substantial number of studies have been published since December 2009. We are not aware of any exhaustive systematic cataloguing of these; however, a manual search of the index pages of five major software engineering journals identified 24 SLRs between January 2010 and mid-2011 [7].

As noted at the beginning of this section, there are some indications that broad mapping studies may not be complete [28]. A study was undertaken to assess the completeness and reliability of a mapping study of research to compare the effectiveness of approaches to unit testing and regression testing [28]. The results indicate that the set of primary studies found by the search undertaken for the (broad) mapping study were less complete than other more focused studies. For example, Ali et al. [2,3] carried out an SLR on search-based test case generation and found 31 papers for the period covered by the mapping study. The mapping study identified only 4 of these papers, although it did find a further 6 papers that were missed by Ali et al. Similarly, in a focused SLR on regression testing, Engström et al. [13] found 24 papers for the period

covered by the mapping study; however, the broad mapping study found only 20 of these papers (although it did find a further five papers not found by Engström et al.). Having compared a broad mapping study with 6 more focused studies, Kitchenham et al. [28] conclude that relatively high-level automated search strings will almost certainly miss important papers that more focused searches are likely to find. The message, therefore, to researchers, practitioners, and teachers seeking relevant SLRs, is that although high-level mapping studies such as the broad tertiary studies TS1, TS2, and TS3 provide valuable catalogues of SLRs in the periods they cover, they will inevitably be incomplete. As the number of SLRs increases, we can expect the number of more focused tertiary studies (such as [39]) to increase too, and these will provide an additional source of pointers to relevant SLRs.

77.4 What Do SLRs Tell Us?

In this section, we look at what some of the key stakeholders can learn from existing SLRs. We look particularly at studies that make recommendations to software engineering educators and to practitioners.

77.4.1 Informing Educators

In a study to examine where the outcomes of SLRs can provide support for and inform SE teaching activities, 43 out of 143 candidate SLRs were classified as providing potentially useful teaching material [7]. The study classified the outcomes according to the body of knowledge that is appropriate for an undergraduate program in software engineering (SE2004). The knowledge is designated as the Software Engineering Education Knowledge (SEEK). The study is able to demonstrate that material is available to support all of the major knowledge areas (KAs) within the SEEK.

For the *professional practice* KA, there is evidence about the major challenges facing teams in the collaborative creation of graphical models of systems and also about why IT professionals change their jobs.

In the software *modeling and analysis* KA, evidence relates to the following topics:

- The use of cross-company and within-company data to build and apply management models
- Model-driven software engineering
- The technology acceptance model as a predictor of actual use of a technology
- The use of tools in domain analysis
- Requirements elicitation
- Use of SE models for creating textual requirements specifications

In the *software design* KA, only one study was identified as providing useful material for educators. This provides material about the strengths and weaknesses of aspect-oriented programming compared to other approaches.

Within the software *verification and validation* area, evidence was found across three of the subareas: review, testing, and problem analysis and reporting. Most of the evidence relates to testing and covers the following:

- The selection of unit testing techniques
- Automating acceptance testing
- Use of meta-heuristic search techniques to generate software tests
- Regression test selection

Two of the studies identified covered software evolution activities. These look at whether duplication of code affects system characteristics and how changes at the architecture level map to lower-level system characteristics.

Five studies were found that provide useful material relating to process implementations (falling within the *software process* KA). They focus on the Rational Unified Process, software reuse, pair programming, the use of scrum in GSD, and the challenges facing distributed development teams.

In the *software quality* KA, six studies provide material on topics relating to the following:

- The values of and motivation for adopting CMM for software process improvement (SPI)
- The use of SPI in small organizations
- Analysis of the causes of defects in code to aid product-based process improvement
- Use of coupling metrics as predictors of maintainability for aspect-oriented programming
- Techniques and models for predicting the maintainability of software

The largest proportion of studies (13 out of 43) provides material on topics within the *software management* KA. These cover project planning, project personnel, and organization and project control. For project planning, material was strongly focused on cost estimation and also covered project duration and quality, as well as risks and best practice in global/distributed software projects. For the other subtopics, studies provide material on what motivates and de-motivates developers, the reasons why software productivity varies across different contexts, and the effectiveness of different approaches to measuring and predicting productivity.

77.4.2 Recommendations for Practitioners

Although many of the results from SLRs will be relevant to software developers, projects managers, and other IT decision makers, many reviewers do not make specific recommendations for practitioners. The three broad tertiary studies do indicate which SLRs are or may be useful for practitioners or which specifically include practitioner guidelines. Based on the SLRs identified by the broad tertiary studies (TS1, TS2, and TS3) as potentially providing advice to practitioners, we summarize the recommendations and provide references to publications where more detailed information is available. We note, also, that many other SLRs may provide sufficient evidence from which recommendations for practitioners could be formulated.

From the 33 SLRs identified by TS1, TS2, and TS3 as potentially providing recommendations for practitioners, we were able to extract specific recommendations from 15 studies. The topics covered by these SLRs are shown in Table 77.2.

77.4.2.1 Cost Estimation

Two papers included in TS1 [15,21] use papers selected from a repository that was initially compiled by a mapping study of cost estimation studies [22]. In [15], the following guidelines for practitioners, researchers, and authors of textbooks are provided:

1. Do not mix estimation of most likely effort with planning, budgeting, or pricing.
2. When assessing estimation accuracy, make sure that the estimated and the actual effort are comparable.

Grimstad et al. [15] discuss the implications of these guidelines and indicate that they are based on their own experience as well as the textbook and papers included in the review.

TABLE 77.2 Topics Covered by SLRs That Provide Recommendations for Practitioners

Topic	No. of SLRs
Cost estimation	4

Jørgensen [21], who compares the use of expert judgement and formal models, provides the following advice to practitioners:

“The use of models, either alone or in combination with expert judgement, may be particularly useful when:

1. there are situational biases that are believed to lead to a strong bias towards over optimism;
2. the amount of contextual information possessed by the experts is low; and
3. the models are calibrated to the organization using them.”

Overall, the study concludes that models fail to systematically perform better than the experts when estimating the effort required to complete software development tasks. This is particularly the case when “models are not calibrated to the organization using them” and “experts possess important contextual information not included in the formal models and apply it efficiently”.

In an earlier study, Jørgensen [19] presents an evaluation of 12 best practice guidelines for expert cost estimation. He finds that “there is evidence supporting all these principles and, consequently, that software organizations should apply them.”

In another study, cost predictions from cross-company models are compared with predictions from within-company models [27]. Ten papers were included in the study and of these, seven present independent results, three of which found no significant difference, and four found cross-company models were significantly worse than within-company models. Companies are advised that they should consider how similar project data in the cross-company data set are to the projects undertaken within their own company and should consider the characteristics of their own company.

The focus of a further study on cost estimation is on how to improve the assessment of cost uncertainty of software projects [20]. The reviewer identifies a set of seven guidelines relating to cost uncertainty. Those considered as having the greatest level of supporting evidence are the following:

- Do not apply solely unaided, intuition-based processes.
- Apply structured and explicit judgement-based processes.

77.4.2.2 Distributed Software Development

The four studies on this topic focus on outsourcing [24,25], the use of Scrum [17], and mechanisms for improving distributed software development (DSD) processes [18].

The studies by Khan et al. [24,25] provide a number of suggestions about the following:

- The problems that outsourcing vendor organizations need to address in order to improve their capabilities
- The factors that influence outsourcing clients in their selection of vendor organizations

The study by Hossain et al. [17] focuses on identifying the challenges of using Scrum in GSD and the strategies used for dealing with those challenges. Hossain et al. provide a set of recommendations but also state that it is difficult to offer specific advice to practitioners based solely on their review and indicate that “the strength of evidence found in the literature about the identified strategies is very low.”

The remaining study relating to DSD aimed to identify procedures, models, and strategies for improving DSD processes [18]. Advice is presented as a set of success factors. The reviewers indicate that the evaluation of the results obtained from the proposed improvements is often based on studies in a single organization and sometimes only take into account the developers’ subjective perception. Supporting evidence for the recommendations is therefore limited.

77.4.2.3 Requirements Engineering and Elicitation

Guidelines for practitioners on techniques for requirements elicitation are provided by the study reported in [11]. The reviewers include 26 publications reporting 30 empirical studies that compare elicitation techniques. Studies are aggregated according to the techniques that are compared. This results in

a set of 35 ‘aggregations’, of the form *techniques A are better than techniques B* or *techniques A are similar to techniques B*, 17 of which are supported by several pieces of evidence. These 17 ‘conclusive’ aggregations can be considered as guidelines or advice for practitioners. The aggregations supported by more than one study and having no studies that contradict them are (taken from Table 8 in [11]):

- Structured interviews are better than unstructured interviews for eliciting customer needs
- Unstructured interviews are better than sorting techniques for eliciting information
- Hierarchical structuring techniques are better than sorting techniques for eliciting information
- Unstructured interviews are better than sorting technique regarding elicitation time
- Sorting techniques are better than hierarchical structuring techniques regarding total time
- Unstructured interviews are better than introspection and observation regarding completeness
- Introspection and observation are worse than sorting techniques regarding completeness
- Introspection and observation are worse than hierarchical structuring techniques regarding completeness

The reviewers point out that the evidence relates specifically to experienced elicitors and respondents and that for less experienced respondents a number of the techniques are equally effective. They also present a set of more complex guidelines developed through a process of combining the conclusive aggregations.

Also relating to requirements, the study by Nicolás and Toval [33] is concerned with the generation of textual requirements specifications from models. The advice given is embodied in a proposal for a general purpose tool that integrates graphical and textual models of a system.

77.4.2.4 Agile Development

Two studies addressing agile methods provide recommendations for practitioners. One takes a broad perspective with the aims of identifying what is currently known about the benefits and limitations of agile software development and determining the implications of the studies found for the software industry and the research communities [12]; the other focuses more narrowly on pair programming [16].

Dybå & Dingsøyr [12] are concerned with the benefits and limitations of agile methods and discuss the implications of the results of their review for both research and practice. The strongest evidence for practice is the need to focus on human and social factors and in particular on balancing individual autonomy with team autonomy and corporate responsibility. They also highlight the importance of practitioner confidence, good interpersonal skills and trust. Evidence suggests that traditional project management principles, such as state-gate project management models, should be combined with agile project management and that agile methods are not necessarily the best choice for large projects. The reviewers suggest that practitioners “carefully study their projects’ characteristics and compare them with the relevant agile methods’ required characteristics”. However, the reviewers consider that the strength of evidence is very low, making it difficult to offer specific advice to industry. Consequently, they advise practitioners to use the article as a map, to find and investigate relevant studies further and compare the settings in the studies to their own situation.

The study by Hannay et al. [16] offers the following advice about pair programming:

If you do not know the seniority or skill levels of your programmers, but do have a feeling for task complexity, then employ pair programming either when task complexity is low and time is of the essence, or when task complexity is high and correctness is important.

However, the reviewers note that pair programming is not universally beneficial or effective, inter-study variance is high, and publication bias may be an issue.

77.4.2.5 Software Process Improvement

The two studies on software process improvement (SPI) look at the approaches to SPI that have been applied to small- and medium-sized enterprises [35] and at establishing the state of the art in defect causal analysis (which is a means of product focused SPI) [23]. Pino et al [35] extracted practical advice

(success factors) from the primary studies that were included in their review. The factors were analysed and synthesised to provide a set of 11 guidelines however there is no indication of the strength of evidence relating to each guideline.

Kalinowski et al. [23] provide guidance to practitioners in the form of answers to the following seven questions:

1. Is my organization ready for defect causal analysis?
2. What approach should be followed?
3. What metrics should be collected?
4. How should defect causal analysis be integrated with statistical process control?
5. How should defects be categorized?
6. How should cause be categorized?
7. What are the expected costs and results of implementing defect causal analysis?

77.4.2.6 Testing

The study on testing focuses on defect detection, in particular looking at studies that compare testing and inspection techniques [36]. The authors suggest that there are no clear-cut answers about which defect detection method to choose; however, results suggest the following:

- “For requirements defects, no empirical evidence exists at all, but the fact that costs for requirements inspections are low compared to implementing incorrect requirements indicates that reviewers should look for requirements defects through inspection
- For design specification defects, the case studies and one experiment indicate that inspections are both more efficient and more effective than functional testing
- For code, functional or structural testing is ranked more effective or efficient than inspection in most studies. Some studies conclude that testing and inspection find different kinds of defects, so they’re complementary. Results differ when studying fault isolation and not just defect detection
- Verification’s effectiveness is low; reviewers find only 25%–50% of an artifact’s defects using inspection, and testers find 30%–60% using testing. This makes secondary defect detection important. The efficiency is in the magnitude of 1–2.5 defects per hour spent on inspection or testing.”

77.5 Conclusion

As we have demonstrated, research based upon EBSE is beginning to provide a better understanding of “what works, when, and where.” however, we offer a final word of caution. Employing empirical evidence needs this to be interpreted within a specific context, an activity termed Knowledge Translation (KT), and the outcomes of SLRs are rarely definitive. Hence, for use in teaching and practice, we prefer to use the term *evidence-informed* [7], to emphasize this.

78.1 Introduction and History

This chapter provides an overview of how the ideas and practices associated with empirical software engineering have evolved and also aims to supply some pointers toward the ideas that constitute current “best practice.” In doing so, we hope to aid the “would-be” empiricist to identify the most suitable form of study for a particular need and to provide enough background for software engineers in general to appreciate the strengths and limitations of empirical knowledge and practice.

78.1.1 Early History

The act of “measurement” is a key element of any empirical study and actually goes back quite a long way in software engineering. Measurement seeks to provide quantitative values for a particular *attribute* of some entity, while a *metric* provides a set of rules for generating those values. Much of the early work in software metrics, stimulated by developments such as Halstead’s *Software Science* [9] and McCabe’s ideas about control flow through his metric of *cyclomatic complexity* [17], addressed questions of how to measure both the attributes of software itself (usually at the level of code) and also those of the development processes (where prediction was, and is, an important need).

As a result, early empirical work in software engineering, particularly in the period 1970–2000, was concerned with gathering data about attributes related to code and to development practices and studying the effectiveness of these. Research into the extent to which the *lines of code* (LoC) and *cyclomatic complexity* metrics are correlated provided early examples of empirical studies that looked at actual code artifacts, comparing measures with expert assessments where necessary. (The book by Fenton and Pfleeger provides an authoritative review of how ideas about metrics have evolved [6].)

One of the consequences of these activities was the development of a wider realization that the values of these attributes, particularly those related to code, arose at least in part from the processes that led to their creation—and that experimentation was one way of exploring the cause–effect relationships implied by this. This in turn led to attempts to assess the effectiveness of development practices (encompassing the whole spectrum of software development), so that by the mid-1980s, ideas about experimentation (in the broader sense) began to emerge.

78.1.2 Experimentation

Initial thinking about empirical studies in software engineering was very much wedded to the “traditional” notion of the *experiment*—a controlled investigation of the relationship between two measures [3]. This domination of the controlled experiment was to continue until the end of the century [24,26]. This is not to say that other forms were completely neglected, particularly the use of *surveys*, although these were only used to a limited extent—but sometimes very effectively, particularly for process-related aspects [21]. Post-2000, other forms such as the *case study* [27] have come into greater use, as software engineers have realized the need to address deeper issues, especially “in the field,” as well as the *systematic literature review*, used to draw together the outcomes of many “primary” studies [13].

One reason for this broadening of the range of empirical forms used in software engineering has been that greater exposure to empirical thinking has made researchers aware of what was happening in other domains. Another influence has been the realization that our heavy dependence upon experiments that use human participants inevitably introduces new factors into our experiments and ones that cannot easily be controlled (or always measured). Indeed, even technology-based experiments have such factors too, such as the choice of software objects used in such studies. Underpinning this has been the nagging question as to how far a controlled experiment investigating the effectiveness of some “treatment” in a laboratory setting can really be a useful indication of its likely value to practice in everyday situations.

In the rest of this chapter, we first discuss a (simplified) model of empirical studies and the role of different forms in exploring questions in an experimental manner. We then go on to examine some of the main empirical forms currently employed in software engineering, offering some suggestions as to when each should be adopted and some examples of successful use. Finally, we suggest some practices that help ensure that these can be managed and used to best effect.

78.2 Scope of Empirical Knowledge

While basing decisions upon empirically based knowledge can confer greater authority upon our choices and actions, we also need to recognize that such knowledge is rarely definitive. In this section, we examine how such “knowledge” may evolve and what influences might limit its scope.

78.2.1 Models of Empirical Knowledge

Figure 78.1 provides a rather simplified description of how we gain knowledge through different forms of empirical interaction with the “real world” (well, simplified by the standards of philosophy).

So, how does this model imply that we gain knowledge about the elements of software engineering practice?

1. The first step is one of *informal observation* that some form of relationship seems to exist between the adoption of some systematic way of doing things and the qualities of the resulting software. As an example, this might be to note (say) that the practice of reading through our code or design with someone else seems to help find the faults more rapidly than working on our own.
2. This raises the question as to whether this might be a useful practice to adopt, so we might then perform some more *systematic observation*, probably involving some informal data collection for

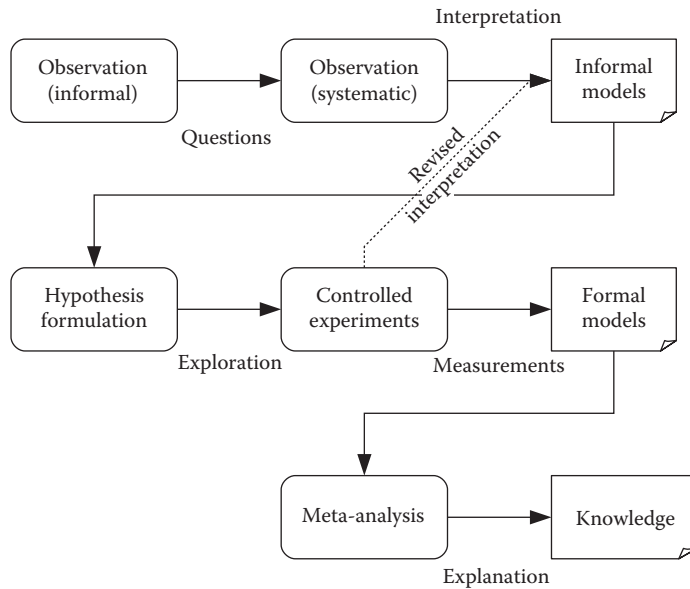

FIGURE 78.1 A simple model of knowledge acquisition.

a number of instances. If we conclude that this does seem to be useful, we can interpret this as meaning that this is a potentially useful practice for others too, and we now also have an informal model of how we can debug our code more effectively.

3. To test this model more rigorously, we can then use it to help formulate a hypothesis (“code inspection is more effective at finding errors than solo debugging”) and then perform a controlled laboratory experiment to test this hypothesis. If we conclude that the outcomes reliably support the hypothesis, then we now have a more formal model of how code might be debugged.
4. To give greater confidence in our results, we should repeat our experiment in a number of locations, perhaps involving programmers with different levels of experience, and by aggregating the outcomes, we begin to create some genuine knowledge about how well the technique works and what might limit its effectiveness. Even better, we might arrange that some of the studies we conduct are “field trials” to see if the same effects are still observed when undertaken as part of everyday working practice.

We should note that we have included the possibility that the experiments we perform do not support the hypothesis and that we might go back and revise our informal model. And there are of course many other issues that will *confound* our studies, obscuring the outcomes, since few issues in software engineering are simple cause–effect linkages.

Our purpose in using this rather simple model is to provide some context for discussion of some of the techniques that we will examine in the following sections, rather than to provide a comprehensive explanation of how knowledge is acquired.

78.2.2 Threats to Validity

While often associated with controlled experiments and quasi-experiments [22], perhaps because these lend themselves more to generalization than other forms, the concept of a *threat to validity* is an important issue for all empirical studies. A *threat* is basically a factor that could influence the outcomes of a study in some way. Reporting on the possible threats to validity affecting a study is now a fairly standard element of any empirical paper. Its particular value lies in that it provides an element of reflection from the people who are closest to the study and hence best able to assess the limitations of that study.

While threats to validity can take a number of forms, we describe the three most common ones (as those are the ones usually reported):

Construct validity. This is related to the questions as to how far the design of the study proved to be appropriate for answering the research question and whether the measures were valid measures of the construct that we are interested in. Assessment of this is concerned with such aspects as the tasks performed by participants in an experiment or with whether the “right” data were collected (e.g., quality measured by the number of defects found).

Internal validity. This is related to the actual conduct of the study and how far any problems with this (such as allocation of participants to groups and dropouts) might reduce confidence in the reliability of the outcomes.

External validity. More strongly related to experiments than other forms of study, this consists of an assessment of how far the outcomes generalize to a wider population. As an example, a study of design comprehension conducted using students might be well organized, so that we have confidence that the outcomes are reliable as regards that particular cohort of students, but we might have less confidence that they represent the outcomes that would result if using more experienced developers as the participants.

A realistic assessment of the threats to validity is an important contribution. It indicates possible limitations applying to any findings and helps future researchers with designing their studies. The complex nature of software engineering activities also means that these will always be present, and so they do need to be discussed.

78.3 Four Forms of Primary Study

In this section, we examine four of the major forms of primary study that we use in software engineering. (Anyone needing a rather wider review of empirical practices should note that the book by Oates [19] examines a much wider range of forms in a computing context.)

We should also explain what is meant by a “primary” study in this context. Basically, a primary study is one that directly collects data about the topic of interest, as opposed to a “secondary” study that does not directly collect data, but instead aggregates the data from multiple primary studies. We will examine secondary studies briefly in the next section, and they also form the topic of a separate chapter.

For each form described, we provide the following information:

- A basic description of how it is organized and key references
- A simple outline of the standard process where appropriate or a checklist of key activities
- A brief review of its limitations when used in software engineering
- A discussion of some common pitfalls to be avoided
- Pointers to some good examples of its use

78.3.1 Observational Studies

Sometimes labeled as “experience” or (mis)labeled as “case study” when reported in the literature, an observational study is one where the researcher performs little or no control of any processes, while recording their process in a systematic manner. Indeed, the value of such a study is likely to be proportionate to the degree to which records have been kept systematically, in order to ensure that the outcomes do not simply represent an unsubstantiated degree of “expert opinion.” An observational study may well be opportunistic rather than planned, created by the realization that what is being done merits the keeping of records so that others can learn from it. It may be conducted rigorously (such as in an ethnographical study) where the observer keeps firmly “outside” of the situation being observed, avoiding any form of intervention or, more informally, where the observer may be part of the situation.

An observational study may also use “historic” data, employing data mining techniques to analyze large repositories of information related to software. (A good example is the analysis of the records available for open-source software projects.)

Obviously there is no well-defined process for *conducting* such a study, but there are some key activities that relate to the way that the observations are made and recorded. In particular,

1. Be as objective as possible. As an example, if observing the progress of a project within an organization that is the first to use a new tool or technique, the observations are rendered more valuable if the observer can try to avoid being partisan about its success or otherwise.
2. Collect data systematically (e.g., at regular time intervals, or when particular events occur) and record as much as possible, bearing in mind that there is always scope to identify significant factors that were not initially recognized.
3. Wherever possible, collect data that are quantitative (number of faults uncovered, number of classes unchanged, etc.) since this makes it easier to detect trends. Obviously the data have to be relevant to the issue of interest (Basili’s *goal-question-metric* (GQM) approach [1,2] may be useful here).
4. Try to provide clear *cause-effect* linkages, in the sense of (say) recording the reasons why the development team believes that using some aspect of a technique might have led to a good (or poor) structure. Simply recording the views/outcomes is not enough without the rationale for these—something that is valuable, but easily forgotten if not recorded at the time.

Many of the *limitations* of this approach are self-evident. It depends upon someone realizing that it would be useful to keep a record of the process of interest and doing so in a systematic manner. The lack of advance planning means that there is a risk that the data itself may be of poor quality and its interpretation may also be open to bias.

The *pitfalls* are linked closely to the limitations. Any study of “experience” papers in the literature quickly reveals how few really provide adequate reasoning to link observations with conclusions. An observational study can easily degenerate into an “opinion piece.” Similarly, using historical data carries the risk that the larger the amount of data extracted that is related to an entity, the greater the risk of finding spurious relationships [4].

That said, there is real value in a well-conducted observational study, since it offers the opportunity to study actual practice in a manner that is rarely encountered. An excellent *example* of systematic and thoughtful reporting is provided in Peter Wendorff’s report of his experiences with maintaining software created with design patterns [25], not least because where problems were encountered, he probed more deeply to identify why particular patterns had been included in the original system.

78.3.2 Case Studies

A case study can also be considered as a form of observational study, at least inasmuch as it is also noninterventionist, but with the crucial difference that it is *planned*, sets out to answer a defined research question, and aims to collect data that are pertinent to that question in a systematic manner.

While case study research is a well-established practice in other research disciplines (including information systems), we should recognize that there are different views about its use. One camp views it from an *interpretivist* standpoint, whereby the outcomes from a case study can only be considered to be valid within that specific context and that there are multiple realities accessed through social constructs such as language. In contrast, there is also a *positivist* approach to interpretation, based upon the view that the phenomena being studied are subject to some general rules. Scientists and engineers are of course overwhelmingly positivists, so it perhaps not surprising that in embracing case studies, software engineers have tended to adopt this view, usually in the form as described by Robert Yin [27].

According to Yin, a case study is an empirical enquiry that

- Investigates a contemporary phenomenon within its real-life context (as we will see, an experiment removes it from its context into a controlled situation)
- Is particularly appropriate when the boundaries between the phenomenon of interest and its context are not clearly evident (as is often the case in software engineering)

He also observes that a case study

- Copes with the technically distinctive situation where there will be more variables of interest than data points (again, an experiment constrains the set of variables and seeks to measure their relationship across many values)
- Relies upon the use of multiple sources of evidence, seeking to achieve convergence through a process of *triangulation* (whereby we examine the different forms to see where they provide mutual support for a particular interpretation)
- Benefits from the prior development of theoretical *propositions* to guide the processes of data collection and analysis (where a proposition is usually a description of some form of relationship between variables that is less specific than a hypothesis)

As such, case studies are appropriate for situations where we cannot easily separate the object being studied from its context, usually because the *interconnection* of factors is an important element (again, experiments assume that the relationships between pairs of factors can be studied separately). A case study allows for study of a phenomenon in depth, and possibly over a long period of time—but one consequence of this is that it might be hard to generalize from case studies. For example, a case study examining why some development practice is particularly effective will be concerned with looking at the organizational context, the individual software developers, the systems developed with this practice, etc. Any conclusions will be based upon that context and not necessarily be easily translated into the context of a different organization.

Case studies can be used for different purposes. Yin suggests that there are three primary roles: *explanatory* studies (examining how some practice works and why it works successfully), *descriptive* studies providing a “rich and detailed analysis of a phenomenon and its context” but with less interpretation, and *exploratory* studies that help define the questions or scope for a subsequent study. There are also different forms of organization. For this, the primary distinction is between a *single-case* form (maybe involving a representative or extreme case) and a *multiple-case* form, replicating the study across different cases and comparing the outcomes in some way.

Yin identifies five major steps for *conducting* a case study:

1. *Determine the study questions.* These are the high-level concerns that motivate the study. For example, “investigate changes to the development process that arise from adopting the Scrum method in a given organisation.”
2. *Identify any propositions.* Examples here might be that “use of the Scrum method will reduce development time” or “use of the Scrum method will increase customer satisfaction.”
3. *Select the units of analysis.* This involves determining exactly what will constitute a *case*, such as a “typical” project and also what the *unit* of study will be (a group, division, etc.).
4. *Determine the logic that links the data to the propositions.* Essentially, this involves identifying the data that can be used to evaluate the propositions. An example might be the use of a semistructured interview with customers to assess “satisfaction” (and identification of what that will be considered to be).
5. *Define the criteria to be used for interpreting the findings.* Essentially, this is concerned with how we determine whether or not there is support for the proposition in the absence of being able to employ standard statistical tests. The criteria should be sufficient for the researcher to be able to reject other possible explanations of the outcomes.

A useful checklist approach for using case studies in software engineering is provided in [10].

Perhaps the main *limitation* of case study research is that it is difficult to generalize from one case study to other situations. Indeed, for single-case studies, it may even be difficult to generalize to other situations within the same organization.

What of the *pitfalls*? Perhaps the biggest risk is the relative lack of a well-defined structure, requiring some expertise upon the part of the researcher. Case study research can easily degenerate into something no better than a poorly conducted observational study if not approached in a systematic manner (we discuss the use of research protocols to help overcome this in a later section).

That said, there are a number of *examples* of the effective use of case study research in the software engineering literature. We suggest two contrasting examples here: The first, by Moe et al., examines the use of an agile development method within an organization, demonstrating the benefits of using a case study to study a phenomenon in its context [18]. The second is a study of our own, where we used case study research as an “envelope” to enable us to examine a research process, and hence demonstrates a rather different role for case study research [15].

78.3.3 Surveys

Surveys can also be regarded as a form of observational study. However, whereas a case study aims to probe deeply into a topic, using a small number of cases, a survey aims to do the opposite, probing to only a modest depth (in most cases), but using a large number of respondents. For a survey, the issue of *external validity* (how widely the conclusions can be applied) is particularly important. Essentially, a survey collects information from a sample of the relevant population and then seeks to identify patterns that can be generalized to the wider population.

Like observational studies, surveys can appear deceptively simple to conduct, while concealing some quite difficult design challenges. Perhaps more than the other forms discussed here, they are also difficult to repeat if things go wrong and so depend heavily upon careful planning.

Three common reasons for performing a survey are as follows:

- To use collective experiences in order to *describe* some phenomenon and its attributes. Here the questions being answered tend to be *what* its profile is and what the distribution of the particular attributes is. For example, we might conduct a survey of developers to find out their preferences from a defined list of programming languages, producing a ranking in terms of popularity.
- To make *explanations* about some phenomenon (the question then being *why* it has the form it has). For the example of preferences for programming languages, such a survey might probe into the question of why particular programming languages are preferred.
- To *explore* some issue, perhaps before conducting some other form of investigation (such as a case study), in order to identify the important factors and ensure that these are included in some way.

In software engineering, we tend to make only limited use of surveys. When we do so, it is apt to be in a rather focused manner, perhaps because it can be hard to identify and sample from larger groupings (populations) such as “all Java programmers” or “all users of the *Observer* design pattern” in any reliable manner. That said, surveys are used for both technical aspects and also organizational ones, although probably more for the latter (such as investigating the attitude of large software users to the use of open-source components).

A key issue when *conducting* a survey is to determine how the data will be collected. Within software engineering, we tend to make use of *questionnaires*, administered either on paper or online. However, a survey conducted through interviews is sometimes a more appropriate strategy to adopt (especially

for organizational issues where the presence of the interviewer can help with interpretation). Having decided on the format, some key decisions that need to be made are as follows:

- Organization of *data generation* in a form most suited to answering the research question. Issues to address will include the use of open or closed questions, whether to use “rating” questions (selecting a value from a list of options) or “ranking” questions (ordering a set of options or identifying the most/least important ones). This is a big decision and it is well beyond the scope of this chapter to discuss it in any detail.
- Identifying the *sampling frame*—the “population of interest” for our question. This might be the users of some software development tool, all Java programmers, managers of agile projects, etc.
- Determining the *sampling technique* by which we seek to obtain a representative sample from the sampling frame. Where possible, we seek to employ a *probabilistic* form for this to aid with later generalization, but sometimes we may not have the necessary control of how we sample and may have to settle for a *non-probabilistic* form (e.g., when we post our questionnaire on the web and invite responses).
- *Organizing* the actual survey process, including ensuring that we obtain an adequate *sample size*, usually by seeking to obtain a good *response rate*, perhaps by following up our original request for those who do not respond.

The general wisdom is that surveys often have quite low response rates (10% is generally regarded as the norm, although some surveys do achieve considerably better rates). As a rule of thumb, a survey needs at least 30 responses to enable reasonable analysis.

There is considerable expertise about the design and conduct of surveys in domains such as social science and psychology. A good reference work is the multivolume *Survey Kit*, edited by Arlene Fink, although for many purposes the first volume may be enough to guide initial design of a survey [7]. For use with software engineering issues, see [14].

When considering the *limitations* for software engineering, we have already previously mentioned a key one, which is that of access to an appropriate sample. For example, a sampling frame consisting of (say) developers who are design pattern users can be difficult to define and almost impossible to sample in a probabilistic manner. In addition, developers and others tend to be multiskilled, so that (to pick another example) the set of Java programmers will intersect with the set of C programmers, the set of Ada programmers, etc. Neither of these examples rules out the use of surveys, but they do have implications for their design and the degree to which are likely to accept the outcomes.

Perhaps the main *pitfall* to beware of with software engineering surveys lies in the sampling process mentioned previously. Many communities of interest may be difficult to identify or to access on a reliable basis, requiring considerable effort on the part of the researcher.

However, there are some good *examples* where surveys help to map out issues of importance. One of these is the survey of project managers to assess different risk factors for software development projects by Ropponen and Lyytinen [21]. This is discussed in the series of columns by Kitchenham and Pfleeger, published in *ACM Software Engineering Notes*, starting with [20] and ending with [16]. A good example of using a survey for exploratory purposes is that by Johnson and Hardgrave that examined which object-oriented design methods were actually being used by developers [11].

78.3.4 Experiments and Quasi-Experiments

For most branches of scientific study, the *experiment* is seen as the most authoritative form of empirical study, as indeed, we indicate in the knowledge acquisition model shown in Figure 78.1. However, one reason why we address this form last is because for a discipline such as software engineering, where the skills and knowledge of the individual play a major role, experiments can rarely be definitive in the way that they are for subjects such as physics. Indeed, building up understanding for software engineering may well need a potpourri of empirical forms.

To address the human element, we usually turn to the use of *randomization* in order to minimize bias, using this to help with such activities as allocating which participants in a study perform particular tasks and the order in which they do them. Where key elements of a study cannot be randomized, perhaps because their specific skills require some people to be allocated to particular groups or tasks or because of constraints in the availability of experimental material, then the experiment becomes a *quasi-experiment* and it becomes necessary to use further techniques to reduce bias [22]. Indeed, a study by Sjøberg et al. of reports of software engineering experiments conducted over a ten-year period suggests that many software engineering studies, despite being labeled as experiments, are actually quasi-experiments [23].

Designing and *conducting* an experiment is quite a complex task, so in this section, we can only discuss a few key aspects—for fuller discussion of empirical forms, we suggest consulting the book by Shadish et al. [22] and for software engineering issues, the book by Wohlin et al. [26].

Any experiment should set out to answer a *research question*. Based upon this, the plan for an experiment (more correctly referred to as the *protocol*—an aspect of study design that we will return to) should address at least the following:

A hypothesis: This is a testable assertion that is related to the research question and refers to the effect that the *treatment*, or the experimental condition, should have. A simple example might be that “the use of code inspection will find more faults than will be found by unit testing.” Accompanying this is a *null hypothesis* that effectively states the opposite (that in this case, there is no difference in the number of faults found, or even that unit testing would find more). Here the “treatment” being tested is the use of code inspection.

One problem with software engineering hypotheses is that they are often imprecise about both the treatment and the effect. Here, we might need to clarify the form of code inspection, as well as of unit testing involved, and also what we mean by “more faults.” There is also a statistical implication here that any improvement is significant enough to be distinguished from possible random fluctuations.

The independent and dependent variables: The *independent variables* are generally associated with the *cause* element of an experiment (X has the effect of causing Y to occur) and are under the control of the experimenter. While ideally we would only have one independent variable, it is not uncommon to have several. In the previous example, one independent variable is the treatment, that is, whether the participants will use code inspection or unit testing. In this case, where we might want to seed errors in the code to be tested, the forms of error seeded can also be a variable.

The *dependent variable(s)* corresponds to the *effect* element. While again we would like to have one variable, there may actually be several. Here, we might wish to measure the number of errors found within a fixed time (and we might also be interested to know which were found by each form).

The materials: Essentially these are the software objects that are used to test the cause and effect. In the example we are using, this would include the programs to be tested. Ideally these should be as “representative” as possible.

The experimental form: Two widely used ways to organize an experiment are as a *between-subjects* study or one that has a *within-subjects* form.

For a between-subjects study, participants take part in only one treatment. So for our example, they would be assigned to a group that used unit testing or code inspection, but not both. Where one of the treatments is what we might regard as “normal” practice, then we regard that group as a *control group* whose results can be compared with those arising from the treatment being used with the *treatment group*.

For a within-subjects study, participants take part in both treatments (or more than two). Since this may involve learning effects (performing one treatment first might influence the way that the second is performed), one way to organize this is as a *crossover* experiment. We divide the participants into two groups, A and B, and group A performs treatment 1 followed by treatment 2, while group B performs

treatment 2 followed by treatment 1. Since this often requires the use of two separate study objects (programs in this case), these also have to be permuted, so that we actually use four groups and orderings.

The allocation of participants to groups is related to this. The aim is to minimize the effect of any factors that might influence the dependent variable (the *confounding factors*), usually by using random allocation to “blocks” in order to avoid or limit any bias arising from having unequal experience or expertise in different groups. (Obviously this may not always be possible in quasi-experiments.)

Measurement plan: This addresses the question of how the dependent variable is to be measured.

It may also involve taking measurement before and after the study (pretest and posttest) and address such issues as how time is to be measured, how the number of defects is to be assessed.

Recruitment of participants: Again, this can form a potential source of bias. The participants in a software engineering study are a group of individuals who each bring their own unique past experiences and expertise with them. Some form of pre-study testing may well help assess key aspects of this and assist with such issues as training provision and assignment to groups.

As shown by this (not quite complete) list, conducting an experiment is a complicated exercise. To help assess how well we have planned an experiment, it is also wise to conduct a *dry run* in advance, using one or two “representative” participants in order to check out such aspects as participant training, the tasks allocated, adequacy of time allowed.

A major *limitation* of the controlled experiment is that isolating a relationship (cause–effect) so that we can study it then means that relationship loses its natural context that may well be important. Indeed, a weakness of experiments is that they do not readily allow us to study a phenomenon in truly realistic conditions.

Inevitably for so complex a study form, there are numerous possible *pitfalls* that can render the results of little value. One that should really be avoided is over-complication. A simple study design may well be more worthwhile than a complex one requiring advanced statistical analysis.

What are some good *examples* of well-conducted and well-reported experiments? We suggest two examples that provide particularly clear reporting of what was done and why. The first by Dzidek et al. is a controlled experiment that uses professional developers as participants and studies use of the UML in software maintenance [5]. The second by Güleşir et al. is part of a larger study, but again is particularly well reported in sections 9 through 12 [8]. These two papers provide both well-structured experiments and also excellent examples of how to report an experiment.

78.4 Secondary Studies

Since secondary studies have their own chapter, we will only touch briefly on them here, mainly to discuss their purpose and their role.

Secondary studies are widely used for what is termed *evidence-based* research, an approach pioneered in clinical medicine, but also subsequently adopted in many other disciplines such as education, various other branches of health and social care, and, more recently, software engineering.

A secondary study seeks to answer a research question by systematically locating all of the available primary studies that have relevant data and then *aggregating* that data in some form. While easily stated in this way, there are a number of challenges in performing such a study, not least ensuring that all relevant studies are included and that the analysis is objective. The key tool of evidence-based software engineering (EBSE) is the *systematic literature review* that provides the procedures for conducting an unbiased and objective secondary study [13].

Why have such studies become increasingly important? Well, one reason is that they provide a means of reducing the bias that might come from using expert judgment to select the primary studies. Aggregation also allows us to reduce the effect from local influences upon studies—a confounding factor may have a large influence on one study because of some local issues, but if it is not present in others,

then its overall effect will be small. Where statistical forms of aggregation can be used (meta-analysis), then it is also possible to detect smaller effects than can be recognized through a single study.

So why do we mention these studies in this chapter? Well, the reason is mainly because their existence (and effectiveness) depends upon the availability of a number of primary studies addressing relevant issues and also upon the quality of reporting of those studies. Prior to the development of evidence-based practices, each primary study was largely conducted and reported as an isolated item of research. However, this is no longer so, and so when we report our primary studies, we now need to consider how they might contribute to a much wider context.

78.5 Organizing Empirical Studies

For this last section, we examine two important elements for any empirical study: the first is linked to what happens *before* the study is undertaken, while the second is concerned with what we do with the results *after* performing the study.

78.5.1 Experimental Protocol

We have mentioned the *protocol* at various points in this chapter. The role of the protocol is to provide a plan for conducting the study by determining beforehand how all of the key activities will be performed. There is good reason for having a plan, particularly because it avoids the risk that we end up conducting a study that “fishes” for results by adapting the procedures in response to (apparent) observed outcomes. So, before we begin our study, we should have drawn up a complete protocol, which should then have been reviewed by experienced researchers to help identify any oversights (which happen to all of us) or flaws in the design (which unfortunately also tend to happen to all of us).

Studies that make use of human participants should also be subject to ethical approval. The form and procedures for this will vary according to where the study is being undertaken. For software engineering studies, obtaining ethical approval should not form too great a hurdle, since most of our studies involve the participants in performing fairly everyday tasks. They do not usually involve any form of risk nor involve any deceptions, but, particularly when using between-subject forms of study, there is always some possibility that one group will gain extra skills or knowledge simply from being allocated to that group. So, our plan should ensure that all participants should receive equal benefit from having taken part in our study.

Assuming that we have drafted a protocol, had it reviewed, updated it, and had it approved, what comes next? Well, basically the protocol then acts as a guide for conducting the study—and if we have to make changes while conducting the study, we should make careful note of these so that they can be reported as *deviations* from the plan. Finally, the protocol provides a useful starting point for reporting the study since it contains much of the detail about the study design that needs to form part of the final report [12].

The website www.ebse.org.uk provides a number of outline protocols for different forms of primary and secondary study that can be used and adapted by researchers.

78.5.2 Analysis

The analysis of empirical studies can take a wide range of forms, and the details of this are beyond the scope of this chapter. Indeed, this is one aspect where it is often useful to seek expert advice, particularly as regards appropriate statistical forms to employ. However, we do provide a short and simple overview here to indicate what might be appropriate in particular situations.

For any study, it is usually possible to provide some form of *descriptive* statistics. These often use familiar forms such as the *mean*, *median*, and *standard deviation* to describe the “shape” of the resulting data. Visually, data might be presented as a scatter plot (to see if any trends are recognizable) or as box plots

(to see how distorted the distribution is). Equally, we might provide counts for different categories in our results—for example, a survey might report how many of the respondents were in particular age brackets.

The descriptive statistics provide an opportunity to see if we can observe patterns (surveys and observational studies in general) or confirm relationships (case studies and experiments). In some cases, they may well be sufficient to enable us to answer our research question.

Where we do seem to observe patterns or trends, then we need to employ *inferential* statistics to confirm that these are truly so and not simply groupings or associations that could easily have occurred by chance. Inferential statistics enable us to answer the original research question with a much greater degree of confidence and are often required in order to decide between the hypothesis and null hypothesis.

78.6 Conclusions

This chapter has addressed a large and complex topic within software engineering and one that draws from many other *reference disciplines*. Indeed, if we are to make software engineering an “engineering” discipline, then its practices do need to be informed by evidence and that evidence needs to come from well-conducted empirical studies. Inevitably we have only been able to skim over many important issues in the space available. However, we hope that the material in this chapter will provide a useful starting point for anyone wanting to find out how empirical studies can be employed within software engineering or to understand their import.

79.1 Introduction

Software users have been suffering from quality problems for decades (Whittaker and Voas 2002). Quality is more and more often seen as a critical software attribute and a determinant of business success, which is as equally as important as the technology used in software products (Pralhad and Krishnan 1999). The absence of quality in software products and services results in dissatisfied users and financial loss, and may even endanger our lives (Peterson 1996).

Software process improvement (SPI) is a process-oriented approach to solve quality problems. SPI methodologies and concepts are inspired from the heritage of quality movements, such as total quality management (TQM), which have led to significant quality and productivity achievements in other engineering disciplines (Kemp 2006). A large body of software process knowledge has been made available to software organizations via process models and associated methods, such as Software Engineering Institute (SEI) Capability Maturity Model Integrated (CMMI) and ISO/IEC 15504. These have been used by software organizations for assessing and improving their processes systematically.

The basic premise of SPI is that quality of a software product or service is highly dependent on the quality of the process used to develop it. Therefore, an understanding of the concepts of quality, process, and their relationship is fundamental for understanding model-based SPI and evaluating their use. In this chapter, we aim to give an insight into the relation between software quality and model-based SPI. In Section 79.2, we first discuss the definitions for quality and address several characteristics of software products that are important while defining quality for software. Then, we overview the evolution of process-oriented

quality improvement paradigm (QIP) and interpret it for software development. We close the section with an analysis of the costs of software quality and relevant models, which are essential tools in managing process improvement programs and evaluating their results. In Section 79.3, we summarize CMMI and ISO/IEC 15504 models for SPI and review the results of their implementations. In the final section, we discuss several challenges in model-based SPI and address relevant future research prospects.

79.2 Underlying Principles

79.2.1 Quality

Quality has always been a difficult concept to define and agree, particularly much more difficult for software quality. As markets, customers and technology, and management paradigms change, the perception of software quality is getting more fluid, complex, and diverse.

Quality experts have brought different definitions of quality, which needs to be reconsidered while using them for software quality. Crosby (1979) defines quality as the “conformance to requirements.” The definition is based on the idea that requirements are testable. This brings several questions in mind: “Are software requirements complete and correct? Who determines the requirements?” “Can’t they ever change?” According to Juran et al. (1974) “Quality is the fitness for the intended use.” This definition accommodates the fact that software requirements may not be fully defined; however, it still needs the determination of who will decide whether it fits or not. Different users may have different definitions for fitness, for example, an expert user may desire a control of fine details on particular software where ease of use will be fit better to a novice user’s needs. Table 79.1 gives examples of different meanings of software quality for different stakeholders.

Weinberg (1991) “value to some person” definition of quality emphasizes the relativity of quality from an economic point of view. Weinberg argues that “the definition of quality is always political and emotional, because it always involves a series of decisions about whose opinions count, and how much they count relative to one another.”

In light of different definitions that emphasize certain aspects of quality, we can state that quality embodies numerous and various expectations. Garvin (1984) addresses this complexity and gives five approaches to defining quality as perceived from philosophy, economics, marketing, and operations management disciplines. These five perspectives can be outlined as follows:

Transcendental approach: The transcendent definition of quality implies an innate excellence or superiority. Quality cannot be defined precisely nor measured. It is an ideal to be strived for, but never can be completed perfectly, and we can only learn to recognize it through experience. It is this approach when we get the enigmatic answer “I know it when I see” and resort to prototyping to get customer feedback at

the early stages of development and understand the desired qualities of the software. Pirsig (1974) states that “Quality is neither mind nor matter, but a third entity independent of the two, even though Quality cannot be defined, you know what it is”. This philosophical definition is not found useful for modern business management since it is unanalyzable.

Product approach: The product-based definition presupposes that product quality is proportional to the quantity of internal attributes the product possesses and that the internal attributes are measurable. Therefore quality is precise, and the quality level of products is explained by quantifying the attributes and the products can thus be ranked objectively with respect to quality. As an example, consider a polar winter jacket. The grams per square meters of the polar cloth used is directly proportional to the degree of cold resistance the jacket provides. If it is 400 g/m², then it will keep us warmer in comparison to a 100 g/m² jacket. ISO 9126 software quality standard (ISO/IEC 2001) also supports this view, assuming a positive correlation between internal, external, and in-use attributes, for example, higher the degree of modularity, makes software testable and maintainable, and maintainability increases extensibility. However, there are considerable difficulties of software product measurement in regard to maturity of software measures and measurement models (Pfleeger et al. 1997). This approach has been found mostly useful for economic analysis purposes.

User approach: This approach assumes a highly personalized definition of quality. That is, an individual will call a good or service as high quality if it satisfies the person’s needs and preferences. Quality is perceived as highly subjective and in a manufacturing sense, it is “the fitness for use.” This definition is subject to open questions challenges when attempting to define quality for a particular market; for example, how should the subset of usability properties of a software product be selected in order to maximize satisfaction in an environment with customers having widely varying preferences and expectations? Uses of this approach have been observed mostly in marketing, economics, and operations management.

Manufacturing approach: Manufacturing perspective looks into the conformance of the products to stated requirements and industrial standard for assessing quality. The focus of quality is the manufacturing and engineering (design and supply) side in contrast to user view where the focus is the consumption (demand). Any deviation from the specifications is seen as reducing the quality of the product. The concept of process has a key role in the manufacturing view of quality. The approach assumes that organizations have imperfect processes and advocates the improvement of quality by improving processes. A focus on the processes and knowing how to do it, quality improvements are believed to result in prevention of non-conformities (defects) and reductions in rework, scrap, and total manufacturing costs. TQM, zero-defects, six-sigma are the noteworthy quality movements that follow this approach and they have the mantra of “do it right the first time” to express their focus on the processes. This view is found useful in contractual situations and is dominant in standards such as ISO 9000 series and models pertinent to software domain such as CMMI and ISO/IEC 15504. In the following sections, we will mostly refer to quality view of the manufacturing approach.

Value-based approach: This approach is based on the observation that the perception of quality change in relation to the price. That is, a product which is found to be excellent will not have an economical meaning if it is very expensive; it depends on how much a customer is willing to pay for a certain level of excellence. Therefore, the proposal is the definition of quality in terms of costs and prices. A quality product is one that provides a certain degree of performance at an acceptable price or a level of conformance at an acceptable cost.

From the endeavor for defining quality, we can infer that quality is a multifaceted term and it encompasses multiple attributes including value, conformance, fitness, and others. Defining quality is controversial, and it may be exceptionally difficult doing it for software, being an intangible, malleable, and pervasive product.

Recognizing the challenge of defining software quality, ISO published ISO/IEC 9126 (ISO/IEC 2001) series to help organizations define, communicate, and manage quality with respect to their needs.

FIGURE 79.1 Organization of the SQuaRE Series. (Adapted from ISO/IEC, *ISO/IEC 25000:2005 Software Engineering—Software Product Quality Requirements and Evaluation (SQuaRE)—Guide to SQuaRE*, International Standards Organization & International Electrotechnical Commission, 2005. With permission.)

The series include characteristics for software quality and a related taxonomy. The standard was inspired by similar software quality models (McCall et al. 1977, Boehm et al. 1979, Dromey 1995) and functionality, usability, reliability, performance, and supportability (Grady and Caswell 1987). The standard has four parts, which address a quality model, external quality metrics, internal quality metrics, and quality in use metrics. Quality model defines characteristics and sub-characteristics common for both external and internal quality aspects. Internal metrics are derived from static properties of the software, which do not rely on software execution. External metrics are derived from the behavior of running software and represent dynamic properties of the product. Quality in-use metrics is available when the final product is in use in a specific context. ISO/IEC 14598 (ISO/IEC 1999) Product evaluation standard series were published to be used in conjunction with ISO 9126 and to provide organizations with methods for measurement, assessment, and evaluation of software product quality.

Starting from 2005, ISO has begun publishing as Software Product Quality Requirements and Evaluation (SQuaRE) series as the next generation software quality standards (ISO/IEC 2005). The motivation for SQuaRE is to extend the scope to three complementary quality processes: requirements specification, measurement, and evaluation (Figure 79.1). Figure 79.2 shows the quality characteristics and their decomposition into sub-characteristics as defined in SQuaRE.

At the end of this section, we can conclude that each software product is unique in its definition of quality. Quality should be properly defined in such a way that it can be managed before, during, and after its development. Only with a good, usable, and communicated definition of quality we will be able to define our strategies, check whether it is built into a product, measure how much of it we have, and predict how much we will have.

79.2.2 Process and Quality

In its simplest sense, a process is what we do to create value for our stakeholders, such as our customers. We deliver value as software products and services. Quality is distinguished through an evaluation of the deliverables and is enjoyed by using them. More formal definitions of processes are as follows:

A series of actions or operations conducting to an end (Merriam-Webster online 2012).

A set of partially ordered steps intended to reach a goal (Feiler and Humphrey 1993).

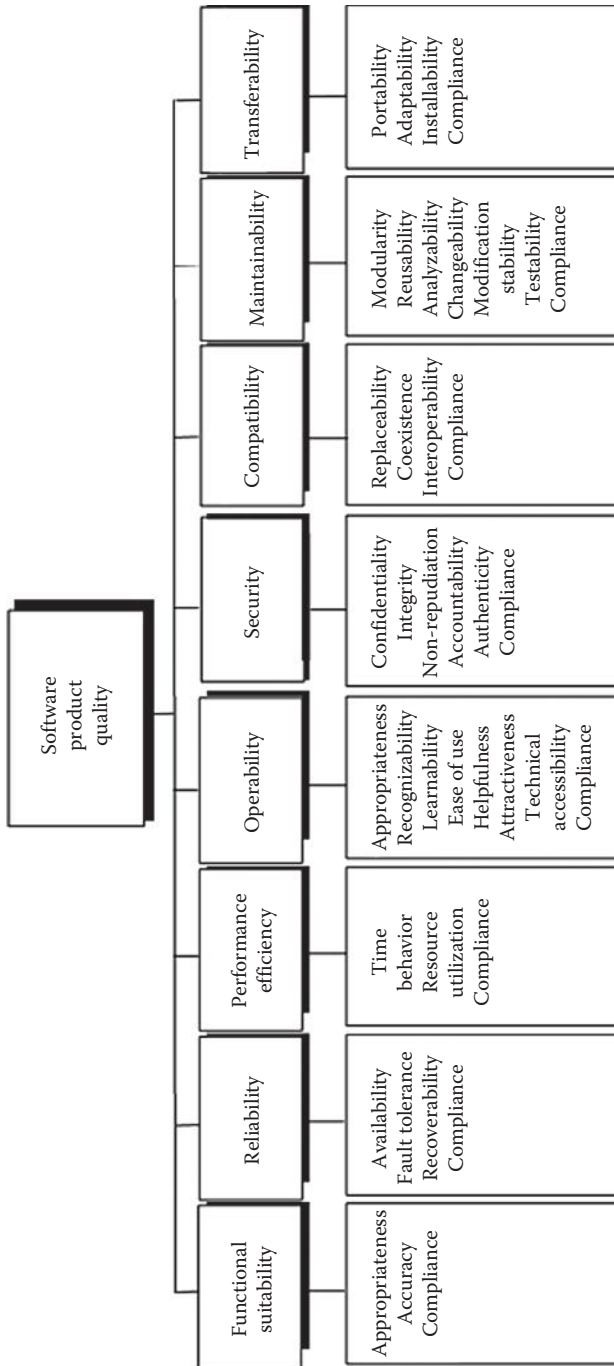

FIGURE 79.2 Software product quality model. (Adapted from ISO/IEC 25010:2005 Systems and Software Engineering—Systems and Software Quality Requirements and Evaluation (SQuaRE)—System and Software Quality Models Organization & International Electrotechnical Commission, 2011. With permission.)

A process is a set of tools, methods and practices used to produce a product (Humphrey 1989).

The set of activities, methods and transformations that people use to Develop and Maintain Software and the Associated Products, for example: product plans, design documents, code, test cases and user manuals (SEI 2010).

The concept of process has been widely appreciated as the proper ground for improving product quality and productivity. The applications of the approach dates back to late nineteenth century and the most influential works on “process focus” are attributed to F.W. Taylor and F.B. Gilbreth. Taylor’s approach was the application of scientific principles to improve the quality of tools and work processes in order to improve productivity and product quality. Following this principle, he made use of systematic observations, measurements, and experiments in standardizing and improving work processes and engineering practices. F.W. Taylor published his work in the book “The Principles of Scientific Management” in 1911 (Taylor 1911). Despite their criticisms on people factors of Taylorism, Gilbreth and his wife were advocates of scientific management, and they are known for their time motion studies where they sought for one the best ways to perform tasks by standardized hand motions (Gilbreth 1911). Gilbreth’s works included teaching managers with the need to continually question the workplace in order to improve. The works of F.W. Taylor and Gilbreth’s were later considered the genesis of the discipline of industrial engineering and making them known as pioneers of the discipline. Taylor’s and Gilbreth’s principles and approaches provided a foundation for the well-known quality approaches and related practices.

The process focus emphasizes that it is how the products are built that should be in question for improving quality; the investment and efforts for quality should not be driven by the motivation in getting the product out the door. Deming says “Quality comes not from inspection, but from improvement of the process” and he adds: “The old way: Inspect bad quality out. The new way: Build good quality in” (Walton 1986). Although there have been significant attempts to explain and promote the role of adhering to processes as a means of improving quality, the approach was not well respected, and the benefits were not recognized and realized before World War II (WW2). Convincing results were obtained later, leading to “quality movements” followed by organizations from various industries all around the world.

Before 1950s, the common practice for managing quality was “Quality Control.” The purpose of quality control (QC) was preventing unacceptable products from being delivered to the customer similar to the purpose of system or end-user testing we perform on our software products. The focus was on the finding the product defects by comparing product properties to a standard or by asking an experienced worker and scrapping the pieces with defects or fixing them later.

The practice was tightly coupled with a culture and management approach typical to mass production at the time. In a mass production environment with change resistant processes, no worker was appreciated nor allowed to stop the assembly line when she sees a quality problem. Solving quality problems were not rewarded. Workers were seen as the primary source of quality problems where they were controlled and forced not to repeat mistakes. Productivity and quality purposes were always seen conflicting targets and any initiative for the first have always won.

In 1930s, W. Shewhart have developed *statistical process control* (SPC) as a disciplined scientific management approach to improving product quality by focusing on the processes (Shewhart 1931). The premise of SPC was that when standard products are produced using standard processes and the processes are repeated, unusual process variations can be controlled using inspection data on work products and applying statistical techniques. As a result, the process performance can be monitored and quality problems can be detected and improvements can be measured. Today, SPC have evolved into a mature discipline and is also used for software processes (Florac and Carleton 1999).

Shewhart knew that without an understanding of the root causes of quality problems and fostering change, the information from process control would not be useful. Once a quality problem is identified, it should be analyzed, resolved, and the solutions should be built into the processes in order to prevent the process suffering from the problem again. In order to emphasize this essence of the taking actions to quality problems systematically, Shewhart developed an improvement approach called

plan-do-check-act (PDCA). PDCA cycle has been refined and applied successfully by Deming, Juran, Crosby, and many other quality experts after WW2. PDCA improvement cycles have constituted the basis for continuous process improvement in various quality methods and standards including ISO 9000 series. The description of PDCA cycle from ISO 9000 standard is as follows:

- Plan. Establish the objectives and processes necessary to deliver results in accordance with customer requirements and the organization's policies.
- Do. Implement the processes.
- Check. Monitor and measure processes and product against policies, objectives, and requirements for the product and report the results.
- Act. Take actions to continually improve process performance.

SEI IDEAL process improvement program model (McFeeley 1996) and QIP (Basili 1985) are examples that adapt continuous improvement approach to the software engineering domain and provide an outline of the steps necessary to establish a successful improvement program.

During WW2, the concentration on the processes critically increased with an aim to produce standard weapons and equipment without defects. Techniques relying on statistics and operations research were developed and used as the prevailing means of process control and optimizations for production and quality. After WW2, in the western world, the quality related practices have begun evolving from "Quality Control" to "Quality Assurance". *Quality assurance* (QA) has become a disciplined approach to quality extending quality practices from controlling the final products to the entire production process. QA primary function was ensuring compliance to organizational process and design standards and improving them. Doing so, defects can be prevented, detected and fixed earlier in the whole process. Although QA includes cross-departmental communication about quality, communication with vendors, it is usually established as an independent organizational function performed by a QA department. It has the potential for adversarial relationships and "Don't tell me my job" hassle between QA teams and employees, for example, between software testers and developers, which create inconsistencies and interruptions in the motivation to improve processes.

TQM was the first quality movement where the business value of improving quality through process improvement was appreciated and continuous improvement was achieved (Kemp 2006). The principles of the approach were established and successfully launched by Deming, Juran, Feigenbaum, Ishikawa, and other quality pioneers, see Hoyer and Hoyer (2001) in postwar Japan. TQM includes elements of improved SPC techniques, extension of quality practices organization-wide, and establishing quality as a continuous function.

The key factor of successful applications of TQM philosophy was managing the cultural change and the achievement of organizational and continuous motivation for quality (Kemp 2006). TQM did not distinguish managers, engineers, and workers; all people working for an organization were empowered with taking initiatives for improving processes and quality. Quality control and improvement was not seen as an isolated and independent function driven by a separate department. Instead, quality improvement was seen a shared responsibility and a cross-functional collaborative work with high involvement from top management. Stopping the assembly line and gathering others to understand the root cause of the problem was truly a desired action when a worker encounters a quality problem. TQM inspired many other quality movements such as Six-Sigma, zero-defects, and ISO 9000 quality standards and SEI CMMI. Today, the accumulated knowledge from the evolution in quality improvement is being studied under "Quality Engineering" (QE) discipline (Borror 2008). Quality engineering combines quality control and assurance techniques and practices whilst maintaining an emphasis on the cultural dimension of process change and continuous improvement. QE have gained good acceptance in software engineering, and "Software Quality Engineering" is now an emerging discipline.

Quality paradigms with a process focus have been effective in manufacturing domains such as automotive and electronics with proven pragmatic methods. They have been influential on

software engineering methods and many researchers and organizations have created models and methods that adopt TQM principles. Humphrey, one of the pioneers in SPI, points out “Dr. W.E. Deming, in his work with the Japanese after World War II applied the concepts of statistical process control to many of their industries. While there are important differences these concepts are just as applicable to software as they are to automobiles, cameras, wristwatches and steel” (Humphrey 1988). However, there exist peculiarities of software products and development that should be considered while adapting the methods, techniques, and tools of successful quality paradigms to the software domain.

Software products are intellectual artifacts. Software development is mostly analysis, design, and coding and it requires the integration of knowledge work. This makes software people the most valuable resource and the highest cost item. In contrast to traditional products, the manufacturing step, for example, copying it to CDs, creates an ignorable value. Once you design and implement it, you can create instances of it over and over again almost with no cost, in no time, and without defects. This is also different from large construction projects like stadiums, where you will need large amount of money and years to build every instance of the same design. Another feature that distinguishes software is that it does not deteriorate. It would not be exceptional if our laptop computers start overheating or its screen starts flickering after 3 years of use. However, once the software meets the requirements and defects are removed, an increased use will not cause any faults, and it would be operational as long as requirements do not change. Software products are malleable. When the malleability is exploited by following a disciplined approach, for example, automated regression testing after a change, it is very beneficial and desired since a critical bug can be fixed in hours. It also is the Achilles heel of software since rapid and frequent changes increase control risks and create challenges in avoiding code and fix development habits. The simplicity of software manufacturing increases utilization of software malleability in contrast to physical products. Another distinguishing characteristic of software products is that they change the expectations. Once software is operational, before long, the users start seeing further opportunities, for example, automations to jump to the next level of cost minimization, which can be realized through an enhanced version of the software or an entirely new design.

Adherence to “conformance to requirements” definition may have limitations for software quality. First, software requirements are usually hardly complete and correct and you will not be able to “do it right the first time” if you do not know the requirements. The acquirers and users also make mistakes in their requirements. Second, the requirements are usually considered as a means to an end, and the quality of the eventual product is also evaluated on the basis of how well software helps the users do their work. Although all stated requirements are fulfilled, there can still be a room to increase customer satisfaction and attain their loyalty by delighting them with software features that they did not anticipate but adds significant value to their business. A zero-defect aim can be realistic in a production process where use of automation, robotics, can be quite effective on producing physical products; however, this is not realistic for software, in particular, for the creative parts of software development such as requirements analysis, elicitation, and of software architecture design. A “good enough” software can be considered the optimal for all stakeholders (Yourdon 1996).

79.2.3 Cost of Quality

Customer value is determined by product quality, cost, and cycle time, which are the competitive factors of making business. From a traditional management view, their improvements are seen as conflicting objectives, that is, an improvement in any of them is only possible at the expense of others. For instance, if the objective is to develop software in shorter times, either we will need to work in larger teams of developers or do overtime work or we will deliver fewer features and skip some tests at a risk of low reliability.

From a continuous quality improvement point of view, it is possible to improve them simultaneously through changing processes and organizational culture. This view is based on the fact that not all

tasks we perform and time and effort we expend in order to develop software generates value for our stakeholders. The premise of continuous improvement is that an improved quality will decrease costs, improve productivity, and shorten delivery times, and in the long term any investment on quality will pay in terms of increased profits and competency.

Total costs of software production can be broken down as shown in Table 79.2. In a strict and ideal sense, the value-added tasks should change the product in some way, make the product more desirable to the stakeholders, and must be done right the first time. These criteria help us identify the proper targets for process improvement, that is, anything that is not value added is a suitable target for removal or improvement. Value streams analysis is also one of the indispensable tools of lean thinking quality approach that originated from Toyota production system and which attracts attention from agile software community (Poppendieck and Poppendieck 2003). Crosby (1979) points out “Quality is free. It’s not a gift, but it is free. What costs money are the unquality things—all the actions that involve not doing jobs right the first time.” Since our software processes are not perfect with respect to the value-added criteria, every process includes some essential non-value-added parts; they are necessary regarding the current methods of software product development, engineering domain knowledge, and in relation to the peculiarities of software. Non-value-added activities, software verification activities are of this type, that is, if the software design and implementation processes are perfect, verification tasks will not be needed. Quality improvement is also a non-value-added task; nevertheless, we need to invest in improving quality since we benefit from reducing total non-value-added cost.

Any investment decision on improving quality needs an understanding of the cost associated with achieving quality and the economic trade-offs involved in delivering good-quality software. A change to improve processes is justified roughly comparing the returns to the costs of the change. This challenging task involves the analysis, baselining, measurement, and prediction of all internal and external effects of the changes on business of the organization including repercussions on all interacting processes. It is best if the improvement can be represented in monetary units since it is the management language. Cost of Quality (CoQ) analysis and techniques have been developed in order to meet such requirements and have been in use for more than 50 years (Schiffauerova and Thomson 2006). Crosby’s CoQ model is one of the popular models in SPI literature. In line with the “conformance to requirements” definition of Crosby, total CoQ is divided into conformance and non-conformance costs (Figure 79.3). The former includes the costs of effort and resources we consume for improving quality (good quality) and the latter includes the costs we pay due to failing to achieve quality (bad quality). Prevention and appraisal costs are incurred to prevent and detect poor quality. Failure costs are further divided into external or internal costs with respect to occurrence of failure before or after product delivery.

Cost of software quality (CoSQ) techniques are the effective tools in feasibility analysis of SPI programs and the measurement and the evaluation of the program performance (Karg et al. 2010, Unterkalmsteiner et al. 2012). They are essential tools in convincing managers and technical staff that poor quality costs more than high quality in the long run, quality problems are serious, hence, it is worth fixing them.

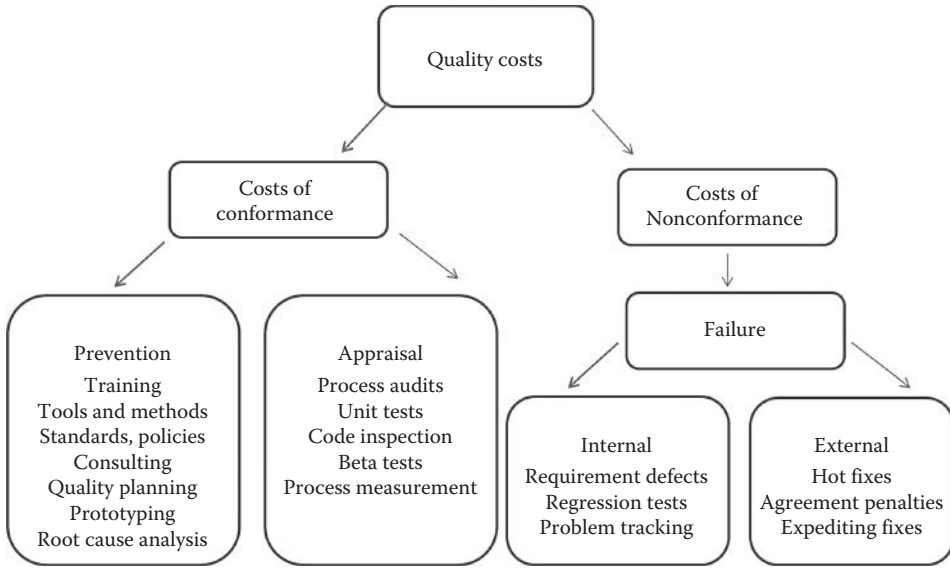

FIGURE 79.3 Costs of software quality.

Both theory and experience advise investing on prevention and appraisal to get the highest returns from the decreased costs of appraisal and failure. If we can prevent a requirements defect from happening, the defect will not cost us. If we detect the defect before design, it may only cost us some effort to update the specification document, but nothing more. If the defect is discovered from the analysis of a failure of the product in use, then a rework of the whole process may be needed. This view is addressed by two dominant views of CoQ theory (Schiffauerova and Thomson 2006). The advocates of the first theorize that there is an economics of quality, and there exists an optimal point where the costs of maintaining a quality above that point will exceed the benefits, where the others challenge the economics of quality and proposes the optimum is the perfect quality-zero defects (Figure 79.4). No matter where the optimum is, this relation is critical for software managers and drives the continuous improvement up-to the optimal, and CoQ analysis helps us decide which non-value-added costs to focus on and where to add non-value-added tasks (cost of conformance) to reduce net costs.

79.3 Best Practices

In the previous sections, we have discussed software quality, the relation between process improvement and quality, and explained how value and costs of quality analysis guide us in directing and evaluating our quality improvement efforts.

Today, SPI is being recognized as the core solution behind software development problems. Model-based improvement is a SPI methodology by which the performance of the software development organization's processes is improved on the basis of capability profiles provided by external process assessment models. A number of process models have been developed by people from research and industry that combine theoretical knowledge with practical experience (von Wangenheim et al. 2010). Process models are assumed as the most significant means for transferring process knowledge into process improvement. SPI models contain a set of goals, indicators, and associated best practices that adhere to processes and organized in a maturity context. The term "process quality" is sometimes used for addressing how well a process meets the defined goals that are measured in terms of indicators defined in the models.

In this section, we first discuss patterns of behavior that give us insights into the perception of quality and process by different organizational cultures. We explain how SPI models associate these patterns to the performance of individual processes and the whole process system in a maturity scale. Next, we briefly explain two most wide-spread assessment models used in model-based SPI and discuss the results of their implementations.

79.3.1 Software Process Maturity

During his quality studies in the organizations, Crosby (1979) observed quality management patterns, given as stages of maturity (uncertainty, awakening, enlightenment, wisdom, and certainty) in his quality management maturity grid (QMMG). The QMMG is based on the observation that the attitudes to quality imply certain cohesive characteristics of the elements of an organization. That is, the combination of certain types of product quality, processes, costs of quality, and the problems associated to these types of elements usually do not occur at random. Once the pattern that matches an organization is identified, then the practices, the quality of the products, and rates of CoQ can be predicted in that organization. Furthermore, the direction for improving quality would be the next maturity stage and referring to the target stage in the grid, the actions need to be taken for improvement can be understood. The maturity grid was first adapted to software development by Radice at IBM under the direction of Humphrey (Radice et al. 1985). In their work, they identified 12 software process stages (e.g., requirements, product-level design, and code) and rated them on a five-point ordinal scale. The scale consists of traditional, awareness, knowledge, skill and wisdom, and integrated management system points. Later, Humphrey et al. at SEI expanded the concept to provide the U.S. government with a method for assessing the capability of their software contractors (Humphrey 1988). In his model, Humphrey defined initial, repeatable, defined, managed, and optimized stages of software process maturity at the organizational level with a concentration on types of processes used in software development.

According to the model, at the *initial level*, the software processes are ad hoc, and occasionally chaotic. There is no or few understanding of the concept of process. Quality problems are repeated, deferred, or even forgotten rather than solved. As a consequence to poor planning, problems are discovered late and are usually solved by firefighting (Repenning 2001). The root causes of all problems are in poor management and success depends on individual efforts and heroics. At the *repeatable level*, earlier success on projects can be repeated with similar practices. The process concept is not embodied into engineering but project management practices. The scope, cost, and schedule of the projects are tracked. At the *defined level*, the management and engineering activities are represented as a set of standard software processes for the organization. All processes are documented, standardized, and integrated. The emphasis is on spreading and learning process definition and improvement to the whole organization. At the *managed level*, the emphasis is on measuring the processes, software artifacts,

TABLE 79.3 Comparison Table for Patterns of Software

Maturity Framework	—	Initial	Repeating	Defined	Managed	Optimized
Crosby	—	Uncertainty	Awakening	Enlightenment	Wisdom	Certainty
Weinberg	Oblivious	Variable	Routine	Steering	Anticipating	Congruent

and products. They are quantitatively understood and controlled, hence making quantitative management and prediction possible. At the *optimized level*, improvement is internalized and process performance improves incrementally and continually. The focus is on the overall organizational performance. The level was renamed to the optimizing level to correct the misperception that at level optimized, an organization has perfect processes and to emphasize the need that for continuous process improvement. These five progressive stages has constituted the structure of the formalized SEI-Software CMM model, published in 1991, with detailed descriptions of engineering and management practices (Paulk et al. 1991). The use of maturity models and levels has been popularized in software engineering models through SEI CMM.

In response to staged representation of patterns by Crosby and Humphrey, Weinberg gave patterns of subculture with an emphasis on the congruence between what people say and what they do in different parts of a software organization (Weinberg 1991). Although his subculture patterns largely overlap with observations of Crosby and Humphrey, Weinberg avoids the use of word “maturity” and explains that any subculture is not superior to another, thus, any pattern can be successful depending on the circumstances such as right product and customer.

While CMM was gaining popularity in the United States, in 1993, ISO has started an European initiative called Software Process Improvement and Capability dEtermination (SPICE), which has started working on the development of an assessment framework (later formalized as ISO/IEC 15504) and defined six capability levels for software processes. A table that roughly matches the patterns and the levels is given in Table 79.3.

It is also possible to roughly map the organizational competence to progressive patterns using the four stages of competence learning model used in psychology. In the model, the states involved in the process of progressing are expressed in terms of awareness and consciousness. Briefly, at the lowest stage, the organizations are incompetent and they are not aware of that situation. At middle stages, although they are not still considered competitive, the management awareness increases and the management realizes more and more for the need to improve to be competent in the business. As the organization progresses upper stages, the organization is competitive and is aware of it. At the highest stage, despite being competent, the organization gradually loses awareness on its competency since improvement is internalized as a continuous organizational function.

Today, the concept of maturity models and levels is implemented in popular models for SPI (von Wangenheim et al. 2010) and it has been adapted by a number of organizations including international research organizations such as ISO and professional framework governing bodies such as Project Management Institute and Information Systems Audit and Control Association (Grant and Pennypacker 2006).

79.3.2 Models for SPI

Among the models, CMMI and ISO/IEC 15504 framework models are prevalent and have been accepted worldwide (Pino et al. 2008; von Wangenheim et al. 2010). The essence of implementing CMMI and ISO/IEC 15504 models is the adherence to processes and achieving predefined goals set by the models in order to improve business in terms of quality, cost, and schedule. Both models consider quantitative

process management and continuous process improvement as the key factors of success in any realm of software business. Since their introduction, the models have evolved in response to theoretical and practical problems and suggestions from software community and emerging needs of the software business. Moreover, the models have influenced each other mutually. The similarities, differences, and compatibility between CMMI and ISO/IEC 15504 are among interesting topics of SPI research (Paulk 1999; Pino et al. 2010; Pardo et al. 2011).

Among many others, important models are BOOTSTRAP, software development capability evaluation (SDCE), and Trillium (von Wangenheim et al. 2010). BOOTSTRAP was developed under European Union (EU) information technologies program (Kuvaja 1999). Initially, it extended SEI Software Capability Maturity Model (SW-CMM) taking ISO 9000 and European Space Agency process standards into account. Later, it was updated to align with ISO 12207 and ISO/IEC 15504. Trillium is a telecommunications extension of SEI SW-CMM that combines it with ISO 9000 and relevant Malcolm Baldrige criteria (Coallier 1995). It was developed by Bell Canadian telecom companies. SDCE is a method for assessing an organization's ability to develop software for mission critical software-intensive systems development. It was developed by the U.S. Air Force to be used in system acquisitions (Babel 1997).

In this section, CMMI and ISO/IEC 15504 frameworks and software process models are summarized. Before proceeding, we would like to draw readers' attention to the following points to clarify possible sources of confusion. CMMI and ISO/IEC 15504 models are not models of software engineering domain knowledge. The models are not intended to define processes, procedures, or work practices for any given activity of an adopting organization. For example, when the software testing process is concerned in ISO/IEC 15504-5 model, defining a model compliant test process will not help if the tester does not know software testing. Having discussed the underlying concepts around process-oriented quality improvement in the preceding sections, we assume that reader has an understanding that the processes are not for the sake of processes. CMMI and ISO/IEC 15504 prescribe norms that processes should possess and a standardized system for measuring their capability. The practices included in the models are intended for improving the existing work practices of an organization.

79.3.2.1 CMMI

SEI published the original SW-CMM model in 1991 and later adapted the model to different domains such as systems engineering, software acquisition, and integrated product development (Paulk 2009). Starting from 2000, SEI combined maturity models into a single CMMI integration framework. CMMI for development (CMMI-DEV), CMMI for acquisition, and CMMI for services are the three flavors of the framework, called as "constellations," developed for the domains of software development, acquisition, and service, respectively.

CMMI-DEV model combines best practices and goals that help software development organizations improve their processes. The model has a process focus for improvement and follows the principle that "the quality of a system or product is highly influenced by the quality of the process used to develop and maintain it" (SEI 2010). The model defines processes as the concept that glues people, procedures and methods, and tools and equipment dimensions of developing software and constitutes the essential means to achieve the organizations business objectives. The conception and development of the capability maturity model was influenced by TQM principles and SPC (Paulk 2009). Humphrey (1988) points that "a truly effective process should be predictable" and explains that process control ensures the same results if we work the same way and when a process is under statistical control, it is possible to anticipate quality cost and schedule within their limits. CMMI model suggests that successive attainment of the goals and the institutionalization of the addressed practices across the software processes will improve software quality, schedule, and costs whilst decreasing costs of software quality. Figure 79.5 illustrates Knox's theoretical model for CoSQ where total CoQ gradually decreases as maturity increases.

CMMI-DEV model consists of process areas where each area encompasses goals and a cohesive set of practices to be fulfilled by organization's processes in order to make improvements in that area (Table 79.4, Figure 79.6). A set of goals, called "generic," apply to multiple process areas and they describe

the characteristics that must be exhibited for institutionalizing the processes that implement a process area. Subpractices are more concrete and detailed descriptions that help interpreting and implement specific and generic practice. Similarly, work products are supplied to complement practice definitions with typical activity inputs and outputs.

CMMI-DEV supports continuous and staged representations of processes and associates them with capability levels and maturity levels, respectively. Capability levels define goals to achieve improvement incrementally in an individually selected process area. Maturity levels address organizations improvement standing with respect to the attainment of goals in successive sets of predefined process areas. The levels can also be used to appraise the corresponding levels of process capability or organizational maturity of an organization. The model defines a “target profile” as the combination of process areas and capability levels selected for improvement. “Achievement profile” represents the actual progress for a combination. Capability evaluations are performed and ratings are given using SEI official appraisal method, standard CMMI appraisal method for process improvement (SCAMPI) (Team 2011). Successful type “A” appraisals are awarded with SEI certificates for the achieved level.

Personal software process and team software process are works of Humphrey that complement CMMI and operationalize the underlying principles of CMMI to individual developer(s) and development teams (Humphrey 2000a,b). These models were developed as a response to the early criticism on SW-CMM that process-orientation ignores human factors. The models have been reported to be successfully used independent from CMMI in companies including Microsoft, IBM, and governmental software organizations (Davis and Mullaney 2003).

CMMI models have been used by more than 5000 companies from over 70 countries. According to a recent maturity profiles report, which is updated regularly (Software Engineering Institute 2012), 4846 appraisals have been reported since 2006. More than 66% of appraised organizational units have a workforce less than 100 employees, and the majority of reported appraisals are maturity level 2 and 3.

79.3.2.2 ISO/IEC 15504

ISO/IEC 15504 Information technology—Process assessment, also known as SPICE is a multiple-part standards framework used for assessment and improvement of software and system processes (ISO/IEC 2004). Part 1 gives general information on the concepts of process assessment and its use in process improvement and process capability determination. It gives a top-view of the components of the framework, explains their relations, and provides guidance for the selection of parts and their use. It explains the requirements contained within ISO/IEC 15504 and their applicability to performing assessments. Part 2 is a normative part that sets out the minimum requirements for performing an assessment that ensure consistency and repeatability of the ratings. The process and capability dimensions of the process assessment model are described and assessment process is explained including inputs, outputs, and roles and responsibilities. Figure 79.7 illustrates the context ISO/IEC 15504 defines for the assessment process.

Parts 3 and 4 provide guidance on ensuring the requirements for performing an assessment have been met, and the results of a conformant assessment are properly utilized. Parts 5, 6, and 8 (part 8 is under development) are exemplar process assessment models that conform to the requirements given in Part 2. The domain of the exemplar models and lifecycle processes used in the process dimension are software engineering, system engineering, and IT service management and ISO/IEC 12207 (ISO/IEC 2008a), ISO/IEC 15288 (ISO/IEC 2008b), ISO/IEC 20000-4 (ISO/IEC 2010), respectively. Part 7 extends the framework by setting the norms for determining organizational maturity based upon the process capability profiles obtained from process assessments. Part 9 provides guidance for creating and using target process profiles that describe pairs of process and process capabilities with respect to a particular business need such as process improvement or supplier selection. Part 10 is a safety extension to the process assessment models given in Parts 5 and 6.

Figure 79.8 illustrates the core components of the framework. The measurement framework comprises six-capability levels and process attributes to be rated on a four-scale rating (Table 79.5). A process reference model (PRM) is a set of processes in a defined domain such as software development. A conformant reference model fulfills the requirements involving process descriptions, process purposes and outcomes, the descriptions of relations between the processes, the relation between the model, and its context of use and community of interest.

ISO/IEC 12207 software life cycle processes standard is a conformant PRM (ISO/IEC 2008a). The standard contains 48 processes and related activities, and tasks that are to be applied during the acquisition, development, operation, and maintenance of software products. It’s purpose is to provide a defined set of processes to facilitate communication among acquirers, suppliers, and other stakeholders in the life cycle of a software product.

A process assessment model (PAM) forms the basis for the collection of evidence and rating of process capability. It provides a two-dimensional view of process capability. The capability and process dimensions of a PAM are derived from the measurement framework and a reference model, respectively. A conformant PAM provides a mapping from the relevant elements of the model to the processes of the selected PRM and to the relevant process attributes of the measurement framework. The mappings are based a set of capability indicators that explicitly address the purposes and outcomes of the processes and demonstrate the achievement of the process attributes within the capability levels in the scope of the PAM.

In Part 2, a PAM is an abstract component of the assessment model; however, in practice, the exemplar PAM in Part 5 of the suite is frequently addressed in the assessments and ISO/IEC 15504-based SPI initiatives. The exemplar model takes all 12207 processes into its scope and defines capability indicators in terms of generic practices, generic work products, generic resources and base practices, and work products. ISO/IEC 15504 conformant PRM and PAM implementations are available for many business domains including automotive (Automotive SPICE), medical (Medi SPICE), space (SPICE 4 SPACE), banking (Banking SPICE), and component-based software development domains (OOSPICE) (von Wangenheim et al. 2010).

ISO/IEC 15504 is applicable by or on behalf of an organization with the objective of understanding any capability gap between the actual and the target capability profiles for the purpose of process improvement or determining the suitability of organization's processes or determining the suitability of another organization's processes for meeting particular requirements. ISO/IEC 15504 framework provide the means to determine process capabilities and can be used for setting improvement targets both at process entity (i.e., process area) and organizational levels.

79.3.3 Results from Implementations

CMMI-DEV and its predecessor SW-CMM have been the dominant models used in model-based SPI investments throughout the world. According to a 2008 literature review (Staples and Niazi 2008), reasons reported for CMM-based SPI includes "software quality" as the most common answer (65%–70%), followed by "development time" and "deployment costs" (around 55%), "productivity" (>40%), and "process visibility" (30%).

Substantial improvements in large companies in terms of software quality, development time, and productivity have been reported by individual and review studies (Agrawal and Chari 2007; Diaz and Sligo 1997; Gibson et al. 2006; Haley 1996; Herbsleb et al. 1997). In a SEI technical report, a survey of 61 assessments from different organizations was conducted, and the results of SEI report in 2006 (Gibson et al. 2006) summarized the empirical results of CMMI-based improvements from 35 organizations including small and mid-sized companies (Table 79.6). The organizations reported significant performance improvements after adopting CMMI, and they attributed their achievement to the model. The reporting organizations mostly defined quality measures as defects, and improvement in product quality is mostly measured by reductions in numbers of defects. Customer satisfaction was measured in terms of award fees and customer survey. Another study explored the relation between process maturity

TABLE 79.6 CMMI Performance Results

Cost	34%	29	3%	87%
Schedule	50%	22	2%	95%
Productivity	61%	20	11%	329%

and project performance using survey data from 154 experienced software project members (Jiang et al. 2004). The results of the analysis confirmed that software process management maturity is positively associated with project performance.

Evidently, not every organization that has attempted CMMI-based process improvement has succeeded. A group of problems were observed to be general and related to the management of change and underestimated costs and time frames that SPI initiatives typically encounter. Survey results include evidence where SPI efforts are overcome by crisis due to political struggles within the organizations or by an underestimated time and resource needs (Herbsleb et al. 1997; Dybå 2003, 2005; Pino et al. 2008). Another group of problems and risks are considered to stem from the characteristics of the CMM itself (Bollinger and McGowan 1991, 2009; Bach 1994; Staples et al. 2007). The model was found to be costly, heavy-weight, bureaucratic, and inherently infeasible for small scale organizations and projects. It was considered to overlook the people (creativity) dimension, not to provide adequate practical guidance on how to improve the process. SCAMPI appraisals were found inflexible with too much emphasis on statistical soundness and fairness. In addition to these causes for failure or inapplicability, the model was criticized to cause over expectations and not to be able to explain high maturity organizations with low performance and low maturity organizations dominating markets.

ISO/IEC 15504 is the second most used model after CMMI. A part of the difference in the usage share has been explained by the emergence of the standard much later than CMMI and continuous marketing of CMMI under the sponsorship of SEI and US Department of Defense. Nevertheless, the utilization of ISO/IEC 15504 standard has begun increasing in a wide-scale and a diversity of uses (Pino et al. 2008, von Wangenheim et al. 2010). This is mainly attributed to the fact that the model was found to be flexible, easy to use and understand. A frequent way of putting ISO/IEC 15504 into action have been through the development and use of conformant process assessment methods, particularly tailored for small and medium sized enterprises (SMEs) (von Wangenheim et al. 2005, 2006). Wangenheim et.al. and Montoni et al. separately reported the results of SPI that are based on ISO/IEC 15504-based conformant models developed to help Brazilian small companies. In von Wangenheim et al. (2006), according to results of a survey performed 1 year after the assessments, they found convincing evidence on the practice of systematic approaches to project management, measurement, customer-relations, software testing, and product installations. Besides, the assessment method for small software companies was found beneficial, because they were able to understand the strengths and weaknesses of their processes and focus on high-priority processes. Similarly, in Montoni et al. (2009), promising improvements were realized at reasonable costs. In the study, it was also reported that the use of a process-centered software engineering environment have catalyzed the improvements, reducing SPI costs up to 60% and amount of project rework up to 36%. Effective uses of ISO/IEC 15504 have been also materialized through the development of domain specific conformant models. For instance, the results from the trail implementations of the S4S model (Cass et al. 2004), which have been developed for space domain, indicate that the model is found useful for effective assessment and addressing paths for improvement. Individual studies on ISO/IEC 15504-based SPI programs also have reported encouraging results where the models were found to enable systematic improvements (Moreau et al. 2003; Truffley et al. 2004).

79.4 Research Issues

We conducted a brief systematic literature review (SLR) to further confirm outstanding research issues. For a more comprehensive SLR, the readers may refer to Unterkalmsteiner et.al. (2012). Our analysis identifies three important topics: SPI for small organizations and agile development, measurement, and automation and tools.

The software processes of organizations are characterized by a vast number of factors, that is, the business goals, the culture, accumulated knowledge and experience, the company size, the market and customer demands, the software domain and environmental and regulatory constraints, etc. Moreover, each execution of an organization's software process is unique as it is dominated by creative human activities.

SPI is challenged by this process diversity issue, and there is no generic reference process model that suits for all software development projects and organizations (Lindvall and Rus 2000). However, SPI models are intended to provide the organizations with a systematic approach and relevant tools for managing the complexity of these factors, increasing their performance; thus, to implement “process-thinking” (Dybå 2005). Organizations increasingly recognize the importance of software processes and model-based SPI is regarded as one of safe paths to improve their business and to survive in the market. In parallel to endeavors for adopting SPI models, SE research has been evaluating the theoretical soundness of SPI models and their validity in practice and proposing improvements to these models. Based on the current trends and analysis of available literature, we address the following issues for future SPI research.

79.4.1 SPI for Small Organizations and Agile Development

SMEs have a growing impact in software development industry. In some countries, the majority of software project development is realized by SMEs. While empirical results have indicated that successful implementation of SPI models were mostly possible in large organizations, SPI research has identified various challenges that make model-based SPI infeasible or risky for SMEs (Emam 2006; Staples et al. 2007; Mishra and Mishra 2008; Pino, García, and Piattini 2008).

A group of factors poses limitations on SMEs such as budget, time, subject-matter expert staff constraints and inadequate guidance. Others are related to structure of the models and their validity in SME business context. Most literature works consensually agree that adopting an SPI model is not just a matter of using the scaled-down versions of the models, and SMEs have highly variable priorities and motivations for doing business when compared to large organizations (Richardson 2001; Mishra and Mishra 2008). Nevertheless, there have been successful SME implementations of the SPI models (Dybå 2003; Gibson et al. 2006). Several factors have been found to be critical in SMEs success with model-based SPI such as model flexibility, improvement paths: continuous or staged, software development team members involvement, involved people’s prior experience in the field, existence of tools for self-assessment, and learning strategy (Dybå 2005; Mishra and Mishra 2008; Pino et al. 2008). The problem is increasingly attracting attention from researchers and studies have begun investigating model-based SPI in SME context and collecting evidence on particular requirements and factors of SPI success (Pino et al. 2008). Empirical validation studies and systematic review indicate increasing number of publications on the subject and encourage more empirical results of SPI implementations (Pino et al. 2008; Staples and Niazi 2008).

In addition to proposals for new or tailored models for SMEs, possibilities for harmonizing other software development approaches are being explored (von Wangenheim et al. 2010). Among them, agile methods have been favored in SMEs due to its inherent suitability for small team settings (Dybå and Dingsoyr 2008). Agile methods have also attracted interests of large-scale companies, and attempts have been made to adopt agile practices to large organizations (Auvinen et al. 2005). In agile models, people are in focus, where in SPI models the processes are. Despite this difference, there is a growing discussion on harmonization of model-based SPI and agile practices (Boehm 2002; Nerur et al. 2005; McCaffery et al. 2008; Lami and Falcini 2009). We expect that SPI research will continue to study the context for model-based SPI success for SMEs and agile environments. In the near future, we may expect a separation of SPI models and standards for the SMEs and more emphasis on people and organizational learning factors.

79.4.2 Measurement and Using Statistical Process Control

Clearly, measurement has a crucial role in SPI as it does in any engineering area (Kitchenham 1996; Dybå 2005). There is a vast diversity of measurement related issues for current and future SPI research that seeks to address and eliminate barriers in the effective use of measurement and in making progress through capability levels while implementing process models. However, we believe the following measurement issues will be influential in model-based SPI.

The success and continuity of SPI programs and decisions rely on a well-established measurement program since the benefits from SPI efforts can be justified using proper measures. Software organizations need well-defined and valid SPI measures, measurement methods, performance baselines, and relevant guidance that are applicable even at low maturity levels (Dybå 2005; Unterkalmsteiner et al. 2010). SPI change measurement is a promising topic for future research where means for supporting organizations in measuring, evaluating, benchmarking, and communicating the impact of improvement initiatives can be derived and SPI implementations can be encouraged.

A CMMI compliant organization is required to develop capabilities (e.g., achieve measurement and analysis process area goals) for product, project, and process measurement at starting at lower maturity levels (repeatable and defined). Starting from managed level and measurement becomes a critical capability in order to implement process areas effectively. Similarly, ISO/IEC 15504 defines a measurement process in the assessment model and proposes many other measurement practices in the whole process system. ISO/IEC 15504 model also requires processes to fulfill process measurement process attribute at predictable process capability level (level 5) and higher. SPC is a very powerful tool in process management and improvement, and SPI models direct SPI efforts to apply SPC techniques. However, despite the models exhort organizations to do measurement, the existence of SPC-enabling requirements at high maturity levels (level 4 and above) and the common sense belief that SPC can only be performed after achieving level 4 almost prohibits organizations implementing SPC techniques earlier (Sargut and Demirörs 2006). It normally takes up to 5–10 years to achieve level 4 for an emergent company, which implies that the company will not benefit from SPC techniques before level 4. Several case studies and experience reports demonstrate evidence that SPC can be used at lower levels provided that processes are stabilized and measurements capability and reliable data are available. Another challenge that organizations encounter is the selection of which processes to apply SPC (Sargut and Demirörs 2006; Boffoli et al. 2008) and lack of tools for assessing processes for quantitative management (Tarhan and Demirörs 2012). SPC might not be applicable to all software processes and critical processes in a software organization should be considered for SPC, although all SPC techniques seem to be applicable. Therefore, organizations need methods to systematically assess their processes and apply quantitative techniques to understand their potential for improvement. There is limited research on this issue where further research output can increase effective application of techniques such as SPC and Six-Sigma, shorten SPI cycles, and decrease development costs.

Another issue that undermines SPI initiatives, and can be generalized to software engineering, is related to use of software measures and metrics that lack theoretical rigor and validity. Despite the progress in software measurement research and international standardization efforts (e.g., ISO/IEC 14143), there is a lag between research and practice (Pfleeger et al. 1997). Research for defining and validating software measures and developing measurement methods is expected to continue together with further standardization and communication.

79.4.3 Automation/Tools

Process definitions are central for both CMMI defined and ISO/IEC 15504 established levels. In model-based SPI, they also provide the comprehensive and efficient means to describe an organization's processes and compare them to prescriptive process libraries of an SPI model. Therefore, integrating process modeling with process improvement activities can enhance the efficiency of SPI initiatives (Makinen et al. 2007). Tool support is essential for modeling processes enabling formalism in descriptions and other facilities for process automation, error checking, integration, and simulation. However, the relation between process modeling and process improvement has not been examined in the literature thoroughly.

Another challenge in SPI is the use of automated tools at large scale and in integration. For example, a CMM-adopting organization improvement focus extends from individual project performance to multiple projects and then to organizational performance as the organization progresses to upper levels.

This implies the use of integrated tools such as measurement, process modeling, workflow, and document management tools used organization-wide (Sharp and McDermott 2009). Although large companies can afford the burden to develop or acquire custom solutions, the problem challenges the SMEs requiring more resources and subject matter expertise (Montoni et al. 2009). SPI tools are among the important topics of future SPI research.

79.5 Summary

In this chapter, we introduced software quality and model-based process improvement. Quality is more and more often seen as a critical software attribute and a determinant of business success. The absence of quality in software products and services results in dissatisfied users, financial loss, and may even endanger to our lives. SPI is a process-oriented approach to address quality problems.

We presented underlying principles by focusing on quality, process and quality, and the CoQ. We explained quality using different defining approaches, such as transcendental, product, user, manufacturing, and value-based approaches.

We then defined process and quality starting with the concept of process as widely appreciated as the proper ground for improving product quality and productivity. We highlighted the importance of SPC, plan do check act, and TQM.

We also explained CoQ. CoQ analysis and techniques have been in use for more than 50 years and there are multiple models for CoQ. These models are the effective tools in feasibility analysis of SPI programs and the measurement and evaluation of the program performance. Both theory and experience advise investing on prevention and appraisal costs to get the highest returns from the decreased costs of appraisal and failure.

In terms of best practices, we focused on software process maturity, models for SPI, and results from implementations. The use of maturity models has been popularized in software engineering through the SEI software-CMM, which was published in 1991. In 1993, in Europe, ISO started the SPICE initiative. Both these models define capability levels for software processes and corresponding key process areas. Not every organization that has attempted model-based process improvement has succeeded. A group of problems were observed to be general and related to the management of change and to underestimated costs and timeframes. Survey results also included evidence that SPI efforts were overcome by crisis due political struggles within the organizations.

Software processes are characterized by a vast number of factors, that is, business goals, organizational culture, accumulated knowledge and experience, company size, the market, domain and environmental and regulatory constraints, etc. SPI is thus challenged by this process diversity, and there is no generic reference model that suits all software development projects and organizations. Furthermore, our analysis showed that the main areas of future research should focus on SPI for small organizations and agile development, measurement, and using SPC and automation/tools.

Key Terms

Capability maturity model integration (CMMI): An approach to process improvement that provides organizations with models that consist of the essential elements of effective processes. CMMI models define a number of levels of process maturity in terms of the key processes undertaken at these levels.

Cost of quality (CoQ): Any cost that would not have been expended if the quality was perfect such that there were no possibility of substandard service, failure of products, or defects in their manufacture or development.

FURPS: An acronym representing a model for classifying software quality attributes: Functionality, usability, reliability, performance, and supportability. The model was proposed by Robert Grady and Hewlett Packard in 1987 (Grady and Caswell 1987).

ISO/IEC 15504: A generic framework for the assessment of software and system processes published as an international standard. Used most widely by software and systems development organizations in process improvement and capability determination contexts. Also known as SPICE.

Model-based software process improvement: An approach to software process improvement where collections of best practices are organized into reference process models (e.g., CMMI models and ISO 15504-15505) that help organizations improve their processes.)

Plan-do-act-check cycle: An iterative four-step management method used for continuous improvement of processes and products. Also known as Deming or Shewart cycle.

Six-Sigma: Six Sigma is a data-driven quality improvement strategy that values defect prevention over defect detection. It has a focus on the control and the reduction of process variation through the application of statistical methods.

Small and medium sized enterprise (SME): The organizations whose number of employees falls below certain limits. The defined limits vary across countries and organizations.

Software quality requirements and evaluation (SQuaRE): The second-generation software quality standards being published by ISO and aims to harmonize ISO 9106 (product quality) and ISO 14598 (product evaluation).

Total quality management (TQM): An integrated system of principles and procedures whose goal is to improve the quality of an organization's goods and services.

Further Information

As a sequel to book by Humphrey (1989), Software Engineering Institute (1995) provides a description and technical overview of the capability maturity model for software process management, along with guidelines for improving software process management. Hunter et al. (2001) summarizes the best practices for software process improvement (SPI) and related international standards and provides the reader with a collection of republished papers from journals in SPI and papers from international experts in the field. Emam et al. (1997) covers both the theory of SPICE (ISO 15504) and its practical applications, including the lessons learned from the SPICE trials. Kan (2003) gives a thoroughly updated overview and implementation guide for metrics and models used in software quality engineering, which are essential in support of process improvement. In his book, Kemp (2006) gives a general and practical guide to the basic terms, concepts, and tools for defining, measuring, and managing quality as well as giving an insight into history of quality movements. In particular, part 3 of Kemp's book addresses software quality and process improvement. Similarly, two handbooks published by American Society for Quality are two comprehensive guides to Software Quality Engineering discipline, which includes quite valuable information for achieving quality through process improvement (Borror 2008, Westfall 2009).

Research articles on process and quality improvement regularly appear in the following journals, among others: *Journal of Software: Evolution and Process*, *Software Quality Journal*, *IEEE Software*, *IET Software*, *IEEE Transactions on Software Engineering*, *Information Technology Journal*, and *Journal of Systems and Software*.

80.1 Introduction

Software measurement gained momentum as a field of study in the 1970s as researchers began to investigate factors that were thought to influence software development and the performance of software applications. Over time, the scope of software measurement grew, and it took on a critical role in software engineering. In *A Framework of Software Measurement*, Horst Zuse observed, “From a management perspective, measures support up-front estimation of time, resources, and quality, provide true status of projects to permit early insight into potential problems, enable the correction of problems before the consequences consume you, guide decisions on resources, priority adjustments, and schedule stability based on data, not best guesses, and provide hard data on which process can be improved and where to improve them” (Zuse 1998). Software measurement is not a passive field of inquiry; it is an action-oriented activity that supports informed decision making.

80.2 Principles

What are now considered the foundational principles of software measurement have emerged from years of experience and research. The field has evolved as challenges of implementation, adaptation to new methods of software development, and the scale and pervasiveness of software have increased. While some degree of software measurement is frequently employed in practice, overarching theories,

systematic applications, and empirically validated results have taken longer to emerge. A 1997 article on the state of software measurement by Shari Pfleeger noted that while measurement theory was receiving considerable attention from researchers, the theoretical underpinnings of software measurement were largely ignored by the practitioners and customers (Pfleeger et al. 1997). Rather, they seemed to be solely concerned with a metric's utility in practice regardless of its scientific grounding. Indeed, Grady Booch has noted regarding his method of measuring architectural complexity, "In practice, I've found these rules of thumb sufficient for distinguishing relative complexity. They're woefully inadequate for measuring absolute complexity; they're also woefully under-tested. And yet, for my purposes they work" (Booch 2008). Shari Pfleeger and her colleagues went on to identify the lack of models in software engineering as symptomatic of a much larger problem: a lack of focus on software engineering as a systematic set of connected activities (Pfleeger et al. 1997).

More recently, Pfleeger highlighted new challenges in her article "Software metrics: Progress after 25 Years?" (Pfleeger 2008). The first challenge, Pfleeger says, is dealing with uncertainty: "[W]hen we use models developed in the research community, we rarely see the assumptions expressed explicitly, let alone evaluate whether they apply to our particular situation. This disconnect is especially true when we apply economic models for cost estimation or trade-off analysis." Another challenge is measuring "soft" characteristics, such as context, experience, and expertise. Involving social scientists in measurement research could be helpful in developing useful measures for how these characteristics affect product and process outcomes. Finally, anticipating change and developing heuristics are identified as additional challenges that need to be addressed to enable progress in software measurement. Together, these articles establish a set of principles around which best practices are defined. These principles include

- Increasing and demonstrating the value provided by measurement
- Consistently capturing product and development context and other metadata
- Understanding variation and explicitly reflecting uncertainty
- Developing validated measures, especially for quality attributes
- Providing predictive models and indicators
- Developing validated benchmarks and heuristics
- Understanding and improving data quality

There is a continuing need for ensuring and demonstrating the value provided by software measurement and making its practice cost effective. For software measures to truly be useful and actionable, they must be based on sound principles, valid, and take the product and development context into account. As noted by Pfleeger, models and analyses also need to explicitly reflect uncertainty.

In recent years, software systems have been expected to possess a growing numbers of qualities such as security, interoperability, and usability. Before we can understand exactly what is meant by these qualities and how well they are implemented, the field of software measurement needs to develop, validate, and agree on measures for these qualities. Additionally, measurement cannot be truly effective if it only reflects what has been. It must provide models and analyses that enable us to foresee problems and take actions to avoid or minimize adverse effects. Finally, given the increasing volume of information that can confront managers and other decision makers, evaluating it and using it to make decisions can be quite difficult. Heuristics and guidelines need to be developed and validated to help people make sense of the information provided.

The area of data quality, although not explicitly identified as an issue in the software measurement literature, also needs attention (Kasunic et al. 2011). Poor-quality data are a problem from multiple perspectives. While the most common understanding relates to the quality of data in a database (such as information about customers), the same principles and techniques can be applied to assess the quality of the data related to software projects and software engineering.

In the following sections, we describe best practices and frameworks related to each of the seven principles noted earlier.

80.3 Best Practices

80.3.1 Increasing and Demonstrating the Value of Software Measurement

80.3.1.1 Software Measurement Standards

The International Organization for Standardization (ISO) defines a standard as “a document that provides requirements, specifications, guidelines, or characteristics that can be used consistently to ensure that materials, products, processes, and services are fit for their purpose” (ISO 2012). Among those standards having an impact in the field of software measurement are ISO/IEC 15939 (ISO 2007a) for software and systems engineering measurement, and the ISO/IEC 25000 series for software quality measurement (ISO 2005). These standards embody principles and best practices as defined and codified by experts in the field.

ISO/IEC 15939 defines a general measurement and analysis set of practices and framework for software. It has made a couple of important contributions to the field in addition to laying out practices related to the measurement and analysis process. First, it standardizes the terminology for the key concepts associated with software measurement. Second, it defines an information model, shown in Figure 80.1, which links the base measure and the method for collecting it to the decision that the measure should inform.

This standard is important because, as Vic Basili noted, the interpretation of a measure and the information that it conveys depends on the context in which it was gathered and the context in which it will be used (Basili et al. 1994). Understanding and sharing the context is vital to the intelligent use of measures from a practical perspective and to validation of the purported utility of the measures by researchers.

To fully understand a measure, it is useful to think about the process that produces the information on which we base our decisions. Various depictions have been used to illustrate the process and the issues associated with producing highly quality data and analysis that supports informed decisions. As depicted in Figure 80.1, the ultimate purpose of the measurement and analysis process is to meet an information need. A measurement product, such as a report, graph, table, or dashboard, is created in this process to represent the interpretation of the analyses performed on the data that have been collected. Continuing to move down the diagram in Figure 80.1, you will notice the concept of a derived measure. This is a measure that is the result of combining two or more base measures, for example, productivity. Common measures for productivity include lines of code or function points per effort hour or effort month. The manner in which the base measures are combined is the measurement function. These functions could include addition, multiplication, division, or a more complex formula.

Further down are the base measures. This is where the raw data collection occurs. As Figure 80.1 indicates, base measures result from applying a measurement method to one attribute of an entity. In software engineering, there are many entities, each with a multitude of attributes, from which to choose. For example, consider an application or file as an entity. Attributes commonly of interest include its size, quality, and cost or effort to produce. Assuming we want to measure its size, we can choose among several measurement methods, such as counting lines of code or function points. Even at this point, there are variants and decisions to make about the specific counting details. For value to be delivered to the organization, choices need to be made and aligned with the information need to be served, not only at this point in the process but also at many other points in the measurement and analysis life cycle.

Several approaches can be taken to implement measurement. The Capability Maturity Model Integration (CMMI) Measurement and Analysis (M&A) process area provides a complete, high-level framework describing what is needed to implement measurement (CMMI 2010). The M&A process area describes important practices needed to institutionalize measurement and analysis, including providing the resources needed to implement it, training those involved, and verifying that the process is being performed. Specific practices for implementation address planning and defining what to measure, how to measure (including instrumentation, tools, and procedures), what types of analyses to perform, and how results will be reported and to whom.

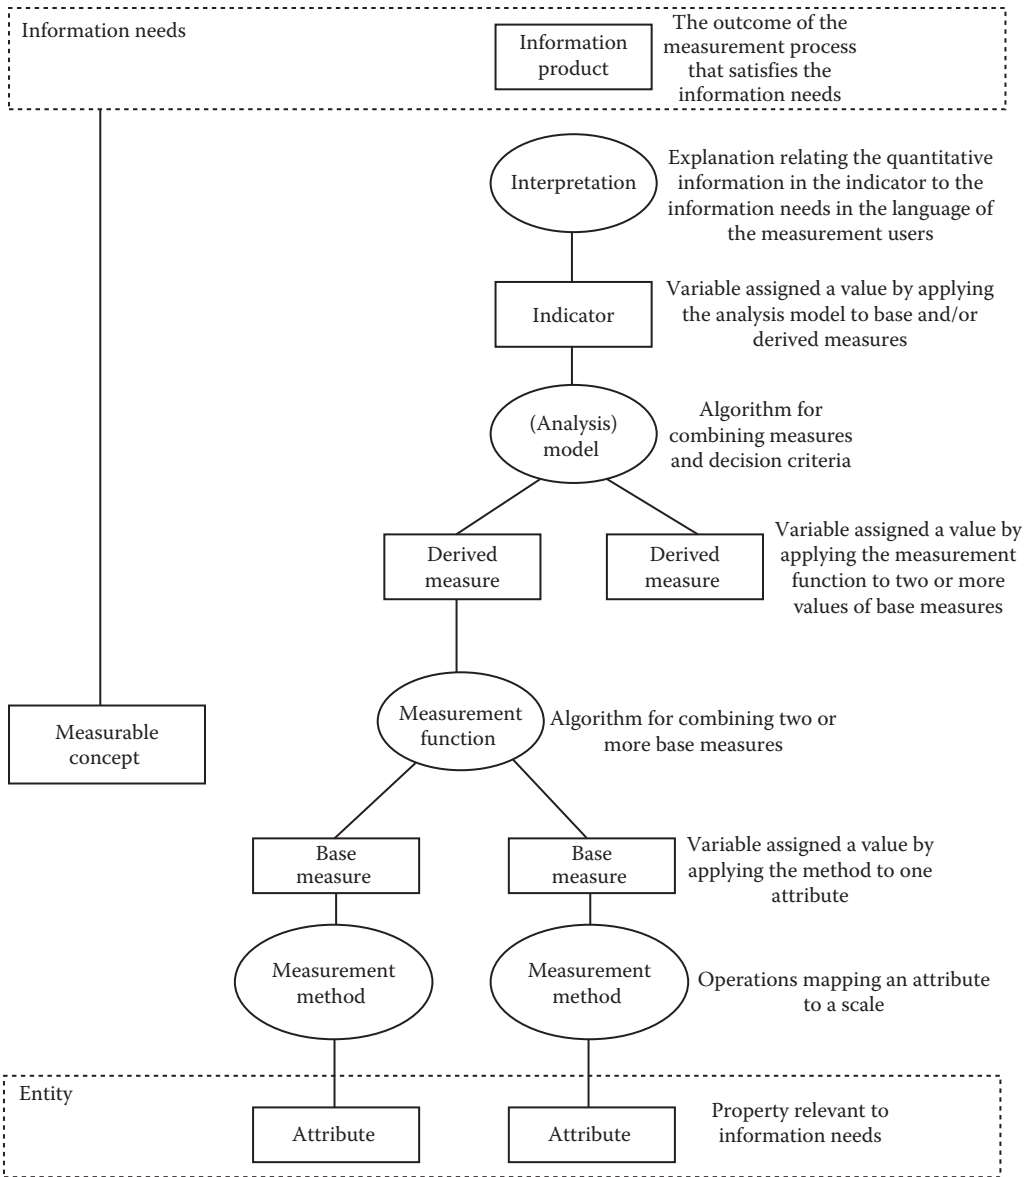

FIGURE 80.1 The ISO 15939 information model.

Organizations can use the Measurement and Analysis Infrastructure Diagnostic (MAID) method to help detect and evaluate shortfalls in the performance of their measurement and analysis process (Kasunic 2010). MAID structures criteria from several sources of best practices into an assessment method. Sources include CMMI, ISO standards, Practical Software and Systems Measurement (McGarry et al. 2001), and the works of leading practitioners in various areas of the measurement and analysis process, including information design, data analysis, and measurement technology (SEMA 2009). Another useful tool for implementing measurement processes is the indicator template (Goethert and Siviy 2004). Building upon the GQM work of Basili et al. (1994), the GQIM approach adds an “indicator” step (Zubrow 1998). In this approach, a sketch of the output of the measurement process, such as a chart, table, or report, serves two purposes. First, it can be analyzed to make sure that it addresses

the identified information need prior to implementing the measurement process. Evaluating a sketch of the output helps determine if the data, as analyzed and displayed, will provide the information needed. Second, it specifies the data needed to build the indicator and serves as input for planning its implementation. The rationale and specification for the indicator can be recorded in the indicator template (Goethert and Siviy 2004).

Another notable series of standards, the ISO/IEC 25000 series, relates to the definition and measurement of software qualities. The standard was originally identified as the ISO/IEC 9126 series. The 9126 series and ISO 14598 are being integrated and updated as the ISO/IEC 25000 series (ISO 2005). This series focuses on software quality, with standards addressing requirements development, software evaluation, quality models, and measurement. Within the 25000 series, the measurement set of standards, 25020–25024, includes a general measurement process building on ISO 15939 and catalogs of measures related to the quality characteristics listed in the quality model. The overall software quality model, ISO/IEC 25010, is actually composed of a quality in use model and a product quality model (ISO 2011). Each model lists several quality characteristics and subcharacteristics. The quality in use model is shown in Figure 80.2 and the product quality model is shown in Figure 80.3.

ISO/IEC 25020 builds on the information model from ISO 15939 to show the relationship between the conceptual models depicted in Figures 80.2 and 80.3 and the operationalized measures of those qualities (ISO 2007b). Figure 80.4 shows this relationship.

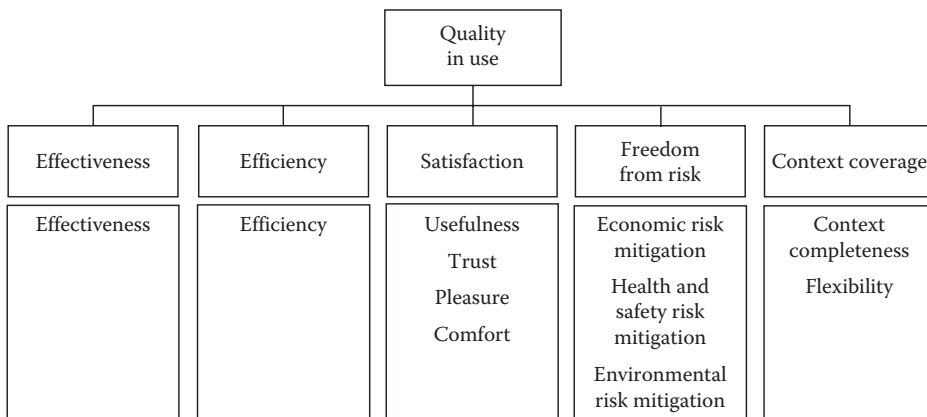

FIGURE 80.2 The ISO 25010 quality in use model.

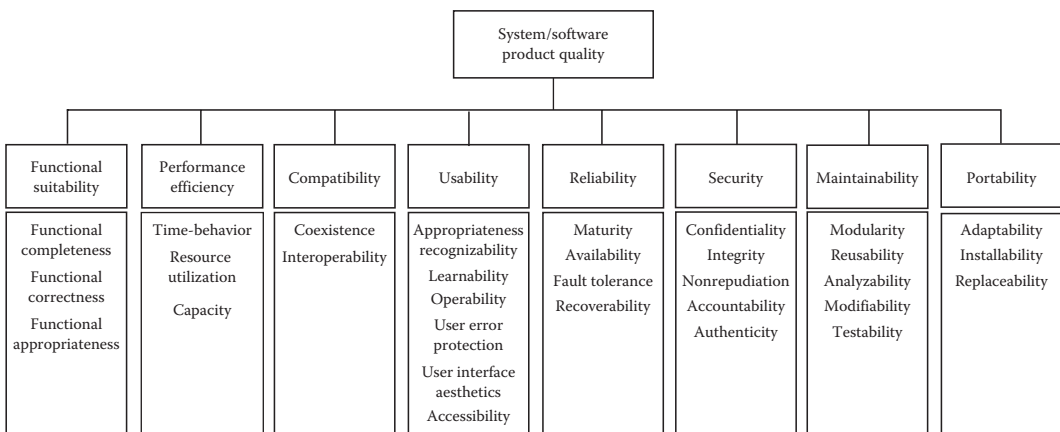

FIGURE 80.3 The ISO 25010 product quality model.

FIGURE 80.4 The ISO 25020 software product quality measurement reference model.

Measures for these quality characteristics can take a number of forms. For example, measures of the quality in use characteristics may be based on financial and sales information, end-user feedback, or surveys. Alternatively, measures of the product quality characteristics are likely to be based on static and dynamic measurement methods applied to software artifacts and work products. Examples of methods and data to measure product quality characteristics include software inspection, static analysis, and test results. Kasunic and colleagues developed a data specification for software project performance following the approach described in ISO 15939 (Kasunic 2008b). The specification defines measures for project effort, productivity, project duration, schedule predictability, requirements completion ratio, and postrelease defect density. Furthermore, it defines measures for project influence factors. These are factors that influence project performance measures that may or may not be under the control of the project.

80.3.1.2 Understanding Value

A general principle for software measurement is to return more value to the organization than the expense the organization incurs to collect, store, and analyze the data. That is, the value of software measurement is directly tied to the use of the information generated versus the cost of collecting and analyzing the software measurement data. To help generate value, the right information needs to be provided to the right decision maker at the right time. To accomplish this, it is important to understand the decision to be made, the information needed to support the decision, and how that information should be displayed. As noted earlier, the Software Engineering Institute (SEI) indicator template is a useful tool to ensure the purpose and uses for data to be collected is understood and agreed upon prior to initiating data collection. While we want to maximize the value returned, it is also worthwhile to think about minimizing costs. One way costs can be minimized is by ensuring that only information that will be used is collected. If there is not an identifiable purpose and stakeholder for the information, then perhaps the data collection need not be done and overall measure expense can be reduced. A second strategy for increasing value is to integrate the collection into the work processes performed to develop the software. The measurement framework integrated into the Team Software Process is a good example of this (Humphrey 1999).

80.3.1.3 Measurement and Analysis Tools

A variety of tools are available to automate the collection and analysis of data. These tools support measurement and analysis practitioners performing tasks such as data collection, storage, analysis, and reporting. Tools can now automate many of the activities involved in measurement and analysis and offer interfaces to engineering and management applications such as requirements management repositories,

earned value management systems, and defect tracking systems. These tools ease the burden of collecting data by utilizing the data generated as a natural by-product of performing engineering activities. They can also be used to create a repository where data from multiple sources are stored, which facilitates analyses and reporting for a variety of data types. A common product of this work is a project dashboard or balanced scorecard that reports cost, schedule, requirements, technical progress, risk and dependencies, and quality (Kaplan and Norton 1992, Few 2006).

Organizations today are using a wide variety of analyses to gain insight into and manage their engineering activities and projects. Some of these techniques include modeling and simulation using discrete event simulation, dynamic simulation, and Monte Carlo methods. Discrete event simulation, for instance, can be used to analyze proposed process changes (Raffo et al. 2007), while Monte Carlo simulation can be used to improve schedule analyses by characterizing activities by best, worst, and most likely case distributions and running thousands of combinations to come up with an overall schedule distribution.

General statistics packages and specialized programming languages provide access to an enormous number of parametric and nonparametric multivariate techniques that can prove beneficial, including analysis of variance (ANOVA), regression analysis, correlation analysis, and chi-square analysis. As in any field, formal statistical analysis guards against being fooled by relationships that could be the result of chance and enables the detection of relationships that may be too complex or subtle to perceive through less sophisticated analytical techniques or visual inspections of the data. Software packages now include the ability to conduct more specialized analyses, such as statistical process control (SPC), that were once found in separate, specialized packages. Statistics packages can also provide a full gallery of displays for visualizing raw data. Other special analyses for specific investigations include cost estimation, reliability growth modeling, Bayesian analysis, machine learning, and data mining applications. Finally, there are tools that will perform specified analyses and format and assemble the results in a report or in the form of a dashboard. These tools save much effort and time. However, users should be knowledgeable about their configuration and the business rules they use for aggregating and summarizing results. This is especially true when the dashboard reduces the data to a stoplight chart and the thresholds used to assign red, yellow, and green values are not readily evident.

80.3.2 Capturing Context: The Importance of Metadata

Collecting data about measured values such as size, effort, and quality is useful for analysis and decision making, but metadata and contextual information also need to be captured and included with the analysis to get the most value from the data. Metadata provide context for understanding and interpreting the measured data. Imagine the following scenario: You are asked to develop an estimate for the next project that your team will be performing. You think it would be useful to have a productivity figure to use as input to computing the estimate and look to the web to find an average productivity value. As you think about it, you might decide that you would like a figure based on projects that are similar to the one you will be conducting. Part of this context might include: the project's type, size, when it was executed, the methodology used, characteristics of the team, the customer for the project, whether it was the initial or a subsequent release, the country where it was performed, and so on. This contextual information is considered metadata, although it might be referred to by other names. In the data specification for project performance measures described earlier, the project influence factors are examples of metadata.

The aspects of the context that you capture are driven by your understanding and anticipation of how the measures will be used. Often, the data are being generated and used in a specific project, so much of the context is implicit. A rich set of contextual information, or attributes, about measures enables analyses that span projects, processes, domains, and organizations. It also allows data to be segmented into groups that may exhibit patterns and predictability that are not apparent in the total aggregated data set. One way of identifying useful contextual attributes is by imagining the types of questions you want answered and analyses you might perform. Another technique is to sketch out any charts or reports to be produced and note the breakdowns that are needed.

80.3.3 Understanding Variation and Explicitly Reflecting Uncertainty

Understanding variation in measures is important for making the information as useful as possible for informing decisions (Wheeler 2000). As measures are collected, they combine to form a distribution. For example, the average productivity within an organization might be 3 LoC/h. However, productivity might range from a minimum of 0.5 to a maximum of 5. The distribution reflects the degree to which productivity on projects varies within the organization. Rather than always using the average productivity, decision makers can select a value from the distribution that reflects their risk tolerance. If they want to be sure that the project has adequate resources and time to execute, they can select a value from the lower end of the productivity distribution. The distribution provides much more insight and information for making decisions and allows consideration of uncertainty to be included in the decisions made.

Statistical process control is the most common type of analysis used to understand variation and is often represented by a control chart. The basic elements of a control chart include a center line, upper and lower control limits, and the plotted data in a time-ordered sequence. The center line represents the average performance of the process, while the distance to the control limits represents the variation in process performance and the magnitude of uncertainty associated with future performance. In *Measuring the Software Process*, Florac and Carleton discuss how to appropriately and effectively apply this method of analysis to software engineering processes (Florac and Carleton 1999).

Understanding variation and uncertainty can improve the nature of commitments and management decisions. For instance, when committing to a delivery date or budget, it might be wise to pick a point from the relevant distribution where previous performance suggests a 90% chance of being successful. Note that this is very different than basing the decision on average performance and requires detailed knowledge of the distribution of the relevant performance data.

80.3.4 Validating Measures: The Case of Quality Attributes

Validation in software measurement means the extent to which the measure meets its intended purpose or measures the concept that it is intended to measure. In the field of measurement, validity is not an all-or-nothing concept; rather, measures can have varying degrees of validity that are influenced by the reliability associated with their measurement method. The two concepts, validity and reliability, are inextricably linked. The practice of measurement system evaluation offers techniques for examining the degree to which measures are valid and reliable.

Measurement reliability is defined as the extent to which a measurement method produces the same value when applied to the same object. One way to effectively increase measurement reliability is to have clear and detailed operational definitions of software measures.

The lack of precision in operational definitions of measures was addressed by a series of technical reports by the SEI in 1992 (Carleton et al. 1992). These reports provided a means for communicating exactly what is to be included and excluded in a measure. One example of the lack of common interpretation can be seen in the wide range found when counting the number of lines of code in a small function. Interpretation problems such as this have existed for years, and the problem of definition continues to plague the field as it addresses quality attributes such as security, interoperability, usability, and others. As software becomes more pervasive, an increasing number of these quality attributes are assigned to it. Recently, these attributes have been codified in ISO 25010, which is an update of its predecessor, ISO 9126. The standard is structured into six main characteristics, each of which includes multiple subcharacteristics. These characteristics reflect an increasingly important challenge to the field of software measurement: many measures are proposed but few have been empirically validated. Validating the relationship between the conceptual definition and interpretation of an attribute (the upper part of the 15939 information model) and its operational definition in terms of a specific measurement method (the lower part of the 15939 information model) has rarely been done. Rather, the field has tended to rely on logical rather than empirical validation. This may seem to be a theoretical point, but it is not.

Decisions and actions are taken based on the conceptual model meaning: security is low or maintainability is high, but assignment of the value, low or high, is based on the specific measurement employed.

This bleak assessment is a general, not universal, characterization. Current research is being done in this area and validation studies are being conducted. For instance, many studies in the journal *Empirical Software Engineering* include a description of how their results were validated. However, the generalizability of the results remains questionable. Among the obstacles are the lack of a good reference database against which validation analyses might be conducted, the difficulty developing samples from a reference population, and the general reluctance of organizations to collect and share data. To overcome these obstacles, researchers have become resourceful. They use data from public repositories and open sources, conduct experiments with students, and find industrial organizations with which to collaborate. However, this makes the process of transition into practice slow and uncertain. This type of evidence often does not sway an organization to adopt a new measure; it does not overcome an organization's preference for "what seems to work for them" (Pfleeger et al. 1997, Booch 2008). While the decisions made might be right for individual organizations, they ground the field in local empiricism and slow scientific progression.

A related problem occurs when measures are used without explicit conceptual definitions. This can happen when measures are collected in an ad hoc manner in a repository and then used with assumptions placed on them by the analyst with no real knowledge of the details of measurement and collection. In these instances, there is often misunderstanding and ambiguity as differing interpretations, purposes, and meanings are assumed for a specific measure. This is often the case when measuring lines of code. Lines of code is often considered a needed and important measure, but the reason why is rarely explicitly stated. From a research and community view, the lack of details and metadata diminishes the contribution the measure can make to the community as a whole. Good practice would establish the validity of the measure in four ways corresponding to various forms of validation (Ghiselli et al. 1981). First, the measure would logically relate to what it purports or is intended to measure. Second, the way it is measured—that is, by counting something, by asking experts to provide a rating, or via some testing mechanism—should also make logical sense. Third, the measure should correlate with an independent measure of the same quality attribute. Finally, there should be evidence that the measure is providing value to the user.

80.3.5 Providing Predictive Models and Indicators

Measurement should not be used only to reflect the current state of a product or past performance but also to provide insight into what will be in the future. In order to do this, predictive models must be developed. As an analogy, think of a gas gauge. As a measure, it indicates the amount of fuel remaining in the tank. However, as the fuel level decreases, most drivers and cars can now predict the number of miles they can go before running out of gas. This information can then be used to decide when to go to a fueling station. The number of miles that can be driven before running out of fuel is based on a predictive model.

Predictive models play many roles and inform many decisions in software engineering. For instance, a manager might want to know whether a project will meet its delivery date. The answer is often based on a predictive model, for example, a model that uses productivity to date to predict when the work will be completed. There are a variety of assumptions with such a simple model and they need to be explicitly assessed for their reasonableness and applicability. Furthermore, the model needs to be validated. While there are a variety of ways to demonstrate the validity of a model, the most direct is to measure the difference between the model's predictions and the actual outcomes—that is, its accuracy. Accuracy is not an absolute characteristic but rather a measured amount. Having a measure of accuracy informs those using the model about the level of confidence that can be placed in its predictions. The downside of this is that it requires future data. During the development of the model, there are alternative statistical techniques that can be employed to assess its accuracy or goodness of fit.

Developing a predictive model requires good data representing the quantity, class, or state to be predicted and data representing the variable or variables that the prediction will be based on.

80.3.6 Developing Benchmarks and Heuristics

Although it has been said that “the data speak for themselves,” this is rarely the case. There is always some ambiguity and possibility for misinterpretation. The principal purpose for measuring is to use the results to guide decision making and action. This generally requires some expectation about what is good, which often comes from a comparison against past performance, the performance of others, or customer expectations. Useful benchmark values have been published by Caper Jones (2000), the International Software Benchmarking Standards Group (ISBSG) (ISBSG 2012), software cost estimation tool vendors, and others. However, users of this information should take care to understand the provenance and limitations of the underlying data.

80.3.7 Understanding and Improving Data Quality

Software measurement and analysis depends on data, yet there has been relatively little written regarding the methods and practices for assessing and improving the quality of software measurement data. Much more attention in the commercial world has been focused on customer facing data in IT systems (English 2004). The research community has focused its attention on experimental methods, design, and instrumentation, with a relative lack of attention on data quality in practice (Kasunic 2008a). Some progress was made with the recent publication of the ISO/IEC 25012 standard (ISO 2008), a standard similar to ISO/IEC 25010. It contains a data quality model and defines a set of characteristics for data quality. In general, though, data quality is still an area in need of greater attention in terms of research and practice.

It is good practice to first check the data to be analyzed when performing an analysis of organizational, project, or product data (Tabachnick and Fidell 2013). Invariably, checks for data integrity and quality reveal errors and issues in the data. Errors can take the form of missing data, invalid data, and inaccurate data. Missing data occur when a desired piece of data is not available. This is fairly common if the data collection mechanism does not enforce the submission or collection of complete data. There are a number of methods for dealing with missing data that range from ignoring them to estimating the data value. How missing data are best handled depends on the particular circumstance. For instance, a simple solution is to replace missing data with the mean value. This can be reasonable if there are many cases and relatively little missing data. However, it can unduly influence the distribution of a variable if there are many instances of missing data. In those circumstances, it is better to use a method that creates appropriate variation in the missing values. This can be done by building an algorithm to estimate the missing value based on data available for that specific record. Another option is to sample from a distribution based on the present data.

Invalid data can occur when measured data are collected but they are not within the bounds of the valid range for that particular measure or are inaccurate. An example of a problem with measured data would be negative numbers for counts such as lines of code, requirements, and defects. Also, if there is a defined valid range, then numbers outside of the range would be invalid. For example, if a total is supposed to be 100%, then no individual value should be greater than 100% assuming that there can be no negative numbers. This can happen with categorical data in addition to measured values. Examples of problems with categorical data include nonexistent release identifiers, wrong codes for defect types, and status codes for change requests.

While missing data and invalid data are relatively easy to detect and prevent, inaccurate data are not so easy. A typical strategy is to use other information to develop integrity checks that bound the range of likely accurate data. For instance, historical data might inform the likely upper and lower bounds for certain measures thereby identifying outliers that might be errors. Knowing the distribution for

defect counts, requirements changes, earned value, and other measures can help detect inaccurate data. Techniques such as use of the Benford distribution can help identify data that have been fabricated or “chunked” (rounded to the nearest 5 or 0 value for instance) when in fact they were supposed to be actual measurements. Also, business rules representing known relationships among the data can be used. For example, it is often expected that the defect density of software will decrease as it progresses through different levels of testing (such as from integration to system testing). Should this expected trend not occur, reviewing the data for any errors is warranted before reviewing the development process.

80.4 Conclusions and Observations

While software measurement has long been a topic of interest and has provided measured benefits, much work remains. Increasing and demonstrating the value of measurement will encourage adoption. As tools and technology mature, they provide an increasing amount of support for measurement activities and can increase the value they provide. Additionally, measures need to be carefully defined, contextual data recorded, information about uncertainty explicitly provided, and greater recognition brought to measurement reliability and validity. Models related to current software engineering methods and products need to be developed.

High-quality data are integral to effective modeling and analysis in support of making decisions related to software engineering. Data quality is directly related to the validity of the data used. Therefore, developing validated measures of quality attributes is also important. Creativity in developing measures of these attributes, as well as measures of progress and the quality of work products, should be encouraged. However, we should also demand evidence of validation and the utility of the measures before adopting and deploying them.

Current trends in software measurement and analysis include a greater focus on analysis, prediction, and integration of measurement with decision making. Better analysis could be done if the data for both dependent and independent variables in models of software engineering are collected. In data mining, this allows us to do supervised learning. While some of this occurred in previous years, it is explicitly included as part of best practice models and standards as well as the design of measurement systems. Software measurement is required to quantify quality and performance and to provide an empirical and objective foundation for decision making—a foundation that is a necessary element if software engineering is truly to be a disciplined field of engineering.

Glossary

Unless otherwise noted, all definitions are from ISO/IEC 15939.

Attribute: Property or characteristic of an entity that can be distinguished quantitatively or qualitatively by human or automated means

Base measure: Measure defined in terms of an attribute and the method for quantifying it

Derived measure: Measure that is defined as a function of two or more values of base measures

Entity: Object that is to be characterized by measuring its attributes

Indicator: Measure that provides an estimate or evaluation of specified attributes derived from a model with respect to defined information needs

Information model: Structure linking information needs to the relevant entities and attributes of concern software quality

Process: Set of interrelated or interacting activities that transforms inputs into outputs

Software product: Set of computer programs, procedures, and possibly associated documentation and data (ISO/IEC 25000:2005)

Software quality characteristic: Category of software quality attributes that bears on software quality.
Note: Software quality characteristics can be refined into multiple levels of subcharacteristics and finally into software quality attributes (ISO/IEC 25000:2005).

Work product: A useful result of a process (CMMI v1.3)

The persistence of similar problems in software development since the 1960s, as well as common observations that the vast majority of software projects are typically late and overbudget, suggests that the field of software engineering has not made much progress. But any close look at the complexity, quality, and breadth of software systems available today, for devices ranging from supercomputers to smartphones, demonstrates that software engineering has indeed made remarkable advances. In addition to much more sophisticated and easy to use software applications for various devices as well as the Internet, there are now far better programming languages, code libraries and other reusable modules, and support tools available. In addition, we know a lot more today than we did in the past about how to run software projects and software businesses.

Nevertheless, software development remains very much dependent on individual talents for problem solving, design, and creativity, leaving considerable room for managerial discretion. Moreover, not all individual programmers or software project managers incorporate best practices. The development challenge is often further complicated in that many users do not know what they want until they see part of a working system or a prototype. Consequently, software managers and individual

engineers still need to think about how to manage the *process* of software development and how software engineering skills can contribute to organizational success.

One reason why software projects do not always apply best practices seems due to ongoing disagreements about what approaches are most effective in different contexts. Some projects require more invention and innovation, as well as trial and error. Invention and innovation are usually more difficult to manage and predict compared to routine work. Some customers have mission-critical reliability requirements, and others do not. But, whatever the situation, in order to be more systematic, software managers and engineers need to avoid treating all software projects as unique events.

At the same time, even though many projects may have much in common, the reality is that software developers still need to adapt their techniques and processes to the needs of different contexts. For example, companies that offer mass-market products or Internet services like Microsoft, Adobe, Google, and Salesforce.com need to anticipate general user needs and release products or features relatively quickly. Professional services companies like IBM, Accenture, and Infosys, whether they are building or enhancing custom systems or hybrid solutions, have to work closely with individual clients and understand these distinct relationships as well as their customers' technical and business requirements. Other kinds of software producers, such as those creating complex, real-time systems for defense or space applications, may have to invent as they go along and try to schedule what truly is rocket science.

In short, this chapter argues that there is no one best way to develop software and manage projects for all kinds of applications and contexts. It is, therefore, natural that the field of software engineering has generated disagreements over what is the best way to manage the development process. Be that as it may, some basic principles are useful to apply to a variety of projects: the need to have strategies for high-level process management, innovation and design, system architecture, team management, project management, and quality assurance. The focus of this chapter is on these general principles, through the lens of my personal experience as a researcher, teacher, and consultant.*

81.1 High-Level Process Concepts

When beginning a software project, rather than trying to plan out schedules and features in detail, managers and engineers should begin by deciding what process is most appropriate for their particular development effort (Cusumano et al. 2009). When making this decision, I have found three observations to be particularly useful. One is the recognition that all projects of more than a handful of people need some well-defined structure to keep everyone in synch (such as how and when to check in components, add features, fix bugs, or ship to the customer). This structure should be repeatable as well as adjustable across different phases or milestones of the same project and across multiple similar projects. Second, the structure should fit the particular technical characteristics and requirements of the product or system being built. This requires some extensive conversations with the customer or customer representatives as well as an understanding of the experience of the team. Third, the structure should fit the market and the business context of the project. This requires understanding the technology and competition as well as customer needs and goals.

81.1.1 No “One Best Process”

Many companies have tried to define a standard development process for their entire organization in an attempt to improve quality, predictability, and perhaps productivity or cost control. One approach should make it easier to introduce a repeatable process, which the Software Engineering Institute (SEI) at Carnegie Mellon University has emphasized since the mid-1980s (Humphrey 1989). While a repeatable process is highly desirable, however, one process for every project or department is usually not. Again, software products and custom (bespoke) projects can differ greatly according to the application and the

* This chapter adapts and updates material originally published in Cusumano (2004, pp. 128–185).

market and due to unique customer requirements. It follows that software development projects even within a single organization need to define different processes or variations for their different needs.

The market and business strategy introduces complexity into process choices, though we can map these out across two dimensions: the level of uncertainty in requirements and thus the need for feedback during development versus the number of releases (i.e., chances to get it right) the team can expect in the future (Figure 81.1). For example, we have new applications where developers know little about what customers want and so feedback from early prototypes or other mechanisms is critical during development. In some cases, rapid prototyping, where engineers evolve the requirements and an actual working system side by side with the customer, may be the best approach. However, if user requirements are well understood, as in the case where a team has built several similar systems before, and managers do not expect there will be multiple releases in the future where engineers can gradually improve the system (such as in embedded satellite software where uploads of new software are difficult), then a carefully documented “waterfall” approach may be best. In a waterfall type of process, development generally proceeds in careful, documented, sequential phases, from concept to detailed design to coding and then to multiple levels and cycles of testing and debugging. In other contexts, again depending on the level of uncertainty in requirements and the number of expected releases in the future, different styles of “agile” or “iterative” development seem most appropriate (Boehm 1988; McConnell 1996; Larman and Basili 2003). In these kinds of projects, developers add functionality in small increments as well as over multiple versions of the system.

81.1.2 What to Emphasize Most

It follows that depending on a company’s business objectives (or organizational goals in the case of a non-commercial entity, such as a government department), as well as the familiarity with the application domain and customer requirements, software managers need a different high-level process strategy that leads to different development approaches. The process should vary in terms of how much emphasis to place on practices like writing as complete a spec as possible before coding or applying a “full-court press” in quality assurance (such as intensive design reviews, formal code reviews, and rigorous testing at multiple levels and stages of the project). In mission-critical projects with extremely high reliability requirements, projects generally need extensive specification and architecture work before coding, though still leaving room for feedback and evolution of the spec, such as in the user interface (Fagan 1976; Gilb 1988; Humphrey 1989).

In some cases, such as for mass-market consumer applications, speed to market and innovation may be more important than product reliability. If a firm waits to deploy the latest technology or create a

zero-defect product, it may never deliver in time to beat the competition. On the other hand, if a firm targets the mass market, whether the users are enterprises or individual consumers, then quality in the sense of reliability will eventually become more important (Cusumano and Yoffie 1999).

In summary, if minimizing defects is important, research and anecdotal evidence suggests that project managers should insist on design and code reviews, continuous builds and testing of the evolving software, and careful documentation of the design (including changes) as well as the code and code changes and fixes. They should make sure teams have debugged features as thoroughly as possible before moving on to the next feature, function, or project milestone—otherwise, apparent progress will not be the real level of progress. Problems or unfinished work will accumulate and delay the project, result in serious quality problems, and eventually prevent shipping or releasing to the customer on time and on budget. Managers should also collect product and process data during and after a project and invest in some sort of formal or informal process review (postmortems) to figure out how to do things better with each project and to define at least some standards and common procedures. These are all good things to do in most if not all projects, but they are essential practices for firms building mission-critical software or enterprise applications and systems. For less critical projects, it is possible to cut some corners, although a software producer should never want to ship products or release systems with quality levels below the customer requirements or what competitors are offering. This is, of course, easier said than done in competitive markets with time and budget constraints.

81.2 Innovation and Design Strategy

In fast-paced markets, there will be many projects where managers stress creativity and invention and encourage design changes even late in a project and at the risk of producing more defects and delaying the ship date or overrunning the budget. The danger is that loosely managed projects will spin out of control—never ship anything because of “infinite defect loops” (the state where every code change, such as to fix a defect, introduces yet another defect—Cusumano and Selby 1995, pp. 256, 333) or because they are too ambitious, with too little time for experimentation. It follows that managers need a strategy for managing the process of innovation and design, so they do not leave too much to chance.

81.2.1 Level of Control

We have seen distinct and deliberate variations in how much control managers introduce into software projects. For example, at the dawn of the mass adoption of the Internet, a company called Netscape, founded in 1994, built a mass-market browser and the enterprise-class servers and tools. Managers at this firm had a specific philosophy of allowing projects to be “slightly out of control” in order to increase speed to market as well as stimulate innovation and creativity (Cusumano and Yoffie 1998). Microsoft, founded two decades earlier in 1975, pioneered personal computer (PC) software and was more organized than Netscape but less structured than IBM, its initial partner in PCs and the market leader in mainframe computing. Microsoft, like Netscape, wanted to be faster to market and more flexible in experimenting with PC software technology than a highly bureaucratic, waterfall-ish IBM process allowed (Cusumano and Selby 1995).

The downside of less control, taken to the extreme, is that too little structure can lead to bad decisions, failed projects, and missed ship dates. For example, process problems at Netscape helped Microsoft win the browser wars of the 1990s, just as shipping delays for later versions of Windows encouraged users to adopt Apple computers and other alternatives to Microsoft products in the 2000s. Perhaps for this reason, we see a mixture of different approaches at companies such as Google, where mission-critical systems such as for AdWords or back-office operations have been managed much more tightly than smaller projects, and often in more of a waterfall-ish rather than agile style (Striebeck 2006).

81.2.2 Risk Management

One thing we have learned is that iterative or agile development techniques as we know them today—such as building systems in small increments, with frequent or continuous testing, debugging, integration, and synchronization of work under development—are particularly useful for risk management. These types of techniques provide mechanisms to add visibility and assess progress in a software project as well as make frequent adjustments such as in project scope, priorities, schedules, or staffing.

A form of iterative development called “synch-and-stabilize” (a term coined by myself and Richard Selby in our 1995 book *Microsoft Secrets*) relies on techniques such as vision statements, evolving specs, development work broken up into subcycles, daily builds, milestone stabilizations, early integration testing, and various customer feedback mechanisms during development (Cusumano and Selby 1995, pp. 187–326). These practices represent a middle approach to risk management between a highly bureaucratic, waterfall-ish style of software development and a potentially chaotic “hacker” style of development. For example, the vision statement that kicks off a project is essentially a team contract that should scope out, very clearly, what the team hopes to do and what it is *not* going to do. Microsoft vision statements have been as short as one paragraph or one page, and others extend many pages. Then evolving the product spec from an outline and reevaluating it periodically during the project avoids spending time detailing specs for features that the team will never get to or reject. The Microsoft-style iterative process has about a 70% overlap with agile development techniques such as followed in Extreme Programming (XP) projects (Cusumano 2007b).

Also, as part of risk management, project teams should have a “multiversion release” mentality whenever possible. The idea here is that there is no need to try to create a “perfect” product or system that includes every favorite feature from customers, executives, sales, and marketing or that tries to do the equivalent of rocket science in a commercial setting. If a company is making a software product and it is successful, there is probably going to be a second and a third version. Even in custom development, software and services companies usually have a chance to refine their work with maintenance releases or a phased rollout. So there is rarely the need to attempt so much in any one project that the risk of failure becomes higher than the likelihood of success.

81.2.3 Late Changes

Another important observation that comes from experience, and which has been associated with iterative or agile development, is that *late design changes can be good*; they do not necessarily reflect mistakes or a step backward. Some managers and engineers find this hard to understand, no doubt because of their education and experiences with delayed schedules and buggy code. Many software developers and managers once thought the same way, before experiencing the fast-paced markets for PCs and Internet software and services.

My recollection is that software engineering texts and classes in the 1970s and 1980s used to emphasize two particular ideas. One was that most problems occur because projects do not have a good requirements document and a complete specification before engineers start coding. A second was that late changes in the code or the design are too risky because they can destabilize the product, create more bugs, and make the project later, which then creates a destructive dynamic if the project shortchanges additional testing.

Mainframe software producers such as IBM and Japanese software factories got around this problem by giving tremendous authority to their QA departments. For example, at Hitachi, NEC, Toshiba, and Fujitsu, QA managers had to approve any product ship decision, and most used historical data telling them how many bugs they should be finding in design documents or code at different stages of development and how much more testing was necessary before they could consider a product to be of high quality (Cusumano 1991, 1993). But new products for new markets or on new platforms (such as mobile

phones compared to mainframes or even PCs) do not have this kind of historical data. Furthermore, fast-paced markets may require different standards and procedures, within certain limits.

The main point is managers and engineers should recognize that any initial specification will be incomplete. Encouraging evolutionary designs through an iterative, agile, or prototype-driven development process allows a team to respond to unforeseen market changes, user feedback, and competitors' moves. Late changes may produce more defects and delay the schedule. But, as some research has shown, a coherent set of countermeasures—such as frequent builds, design and code reviews, and integration testing with each change—can mitigate the level of bugs and lateness (MacCormack et al. 2003). A process that expects and allows projects to accommodate change with a minimal impact on quality and productivity is a great competitive advantage in the business of software.

81.2.4 Economies of Scope

Another strategic aspect of innovation and design is how to increase not simply creativity or structure but also *economies of scope*—efficiency and effectiveness in building multiple products or conducting multiple customer engagements with the same engineering assets. This kind of efficiency and effectiveness is almost always important to an ongoing software business. Simple economies of scale are not generally present, except in replicating a software product or in funding in-house R&D or tools development used by multiple products or projects. Scope economies in general come from reusing system architectures, design frameworks, pieces of working code, support tools, test cases, and historical product and process data (such as how long particular kinds of projects usually take and how much testing resources they normally require).

Code reuse seems to happen most often when companies package components in ways that are easy for developers in other projects or departments to understand and redeploy, like “black box” parts in the auto industry. If programmers have to change a lot of the design or code to use a part, then reuse can become inefficient. For example, Toshiba, before the days of object-oriented design and class libraries, found that its engineers could change up to 20% of a module and still find the reuse effort cost-effective. If engineers had to change more than that, then they were better off writing new code from scratch. Toshiba also kept track of reused modules and gave out awards to encourage programmers to think about reuse and writing popular modules—an interesting way to channel the energies and creativity of the engineers (Cusumano 1991, pp. 264–265).

Another way to achieve scope economies is to buy or license components or whole products and incorporate them into a new system, including open-source “freeware.” Cheap or free standardized packages or libraries of components often require some trade-offs in functionality. Nonetheless, from a business point of view, surveying what you can buy or get for free rather than build should be part of every organization's innovation and design strategy.

81.3 Architecture Strategy

An iterative or agile style of development (evolving specs, encouraging lots of feature changes during a project, and doing daily builds and continuous testing) requires a particular type of product or system architecture. With the wrong architecture, too many components and teams will be highly interdependent, leading to difficulties in testing and wasted time when trying to work in parallel.

The best strategy is to encourage a team to think ahead and, from the beginning of the release cycle for a new product or system, devote some engineering effort to designing an architecture that will last at least a few years and accommodate functionality likely to be important in the future. For example, in the early years of development products such as Office and Windows, senior Microsoft managers believed they should devote about 20% of their engineering resources to architectural work and reworking code (Cusumano and Selby 1995, pp. 280–281). They might allocate more for new strategic products or best-selling products that desperately need rearchitecting, though not too much more.

81.3.1 Importance of Modular Designs

Modular designs are important to decouple components and allow at least some coding and testing to proceed independently or in parallel. Modularity also facilitates future design changes and enhancements. There are no specific rules on how large or small a software module should be; it depends on the system. Moreover, there is a sliding scale of modularity for almost any complex product. For example, most automobiles have about 15,000 discrete components but automakers design and build their cars using subsystems. For some companies, the number of subsystems is relatively low, such as 25; for others, it is relatively high, such as 300. The difference is the degree of functionality that each company is designing into the modules or subsystems of its products (Cusumano and Nobeoka 1998, pp. 43–47, 97).

However one defines it, a module in software should be some subset of functionality that is smaller than the whole product and hides information from other modules so that programmers can isolate it from other small chunks of functionality (Parnas 1972). Software companies making products, smartphone apps, or Internet services often think in terms of “features,” which contain modules within some larger subsets of functionality understandable to a user.

The opposite of a modular architecture is an *integral* architecture, where components are tightly coupled. It is difficult to change and test pieces of a product with an integral architecture without creating problems in dependent components (Baldwin and Clark 2000; Ulrich and Eppinger 2006). Integral architectures do the equivalent of binding the legs of everybody in a project together—slowing down even fast programmers. Managerial discretion is important here, though, because, in some software systems, an integral architecture is necessary to reduce size or generate superior performance, analogous to a custom-built racing car optimized for speed.

But, as code bases have grown to millions of lines of code for many common products and applications, a modular architecture often becomes essential for development and testing. The architecture needs to lay out what the subsystems of the product are, how the subsystems (collections of modules) relate to each other, perhaps what a module is within a subsystem, and, most important, what the interfaces are so that subsystems and individual modules can exchange data or instructions and work together. Interfaces should be stable for some period of time and not altered without communicating changes carefully to a development team because developers depend on knowing how to get modules to interact with each other.

Modularization also helps a project team prioritize features and build them in order of importance to the product or the business, like a sequential (or “horizontal”) list that the team gets to one by one. With prioritization and modularization, a team usually has the option to cut lower priority features if the project falls behind schedule. If the modules are too interdependent, then a project might need a very large team to build all the desired features in parallel. A smaller team might have to build pieces of the product sequentially. With the sequential process, though, the project will usually have to adopt a waterfall type of schedule and not test the pieces in an integrated fashion until the team is mostly done—and when it may be too late to fix major problems or make important changes for the customer.

Again, I can cite examples from my study of Microsoft (Cusumano 2006a, 2007a). This company experienced firsthand the problems of inadequate modularity with the Windows Vista release, which eventually shipped in 2005 after several years of delays and wasted efforts. Microsoft may have adopted a particular strategy in the late 1990s and early 2000s to tie as many functions together into Windows so as not again to appear to violate antitrust law. The Vista (formerly called “Longhorn”) project began with the Windows NT code base. The desktop version of the product was supposed to contain many new features and quickly grew to more than 50 million lines of “spaghetti” (i.e., nonmodular) code that proved impossible to build daily or test thoroughly and stabilize. The poor state of the code forced Microsoft to abandon years of work on new features, go back to the 2003 Windows server code base, and make some refinements to its engineering and design approach.

Microsoft eventually decided to break up Windows into different branches and rewrite as much code as possible into smaller, tighter modules. This approach resembled how company engineers had designed

Word, Excel, and PowerPoint and treated these products as “branches” or subsystems of Office, building them separately and then integrating the branches periodically, such as weekly. The new modularization and branching strategy made coding and daily builds for Windows and Office much more manageable than designing and building these as single “monolithic” products. Some teams also used new testing tools from Microsoft Research that helped check automatically for a wider variety of errors (code coverage and correctness, application programming interfaces and component architecture breakage, security, problematic component interdependencies, and memory use) and automatically reject code at desktop builds and branch check-in points (Larus et al. 2004).

It is possible to evolve the architecture of a software system incrementally to make it more modular, even if it did not start out that way because of time pressures or simply a lack of foresight and experience. Microsoft, my example again, gradually rearchitected Office over several years to make the applications within Office able to share features. The company formerly sold Office as a collection of packaged “vertical” applications that were really separate products. Each product (mainly Word, Excel, and PowerPoint) had its own separate features for text processing, file management, table creation, cut and paste, printer drivers, etc. A separate team figured out how to redesign the products and share at least some of these features across the applications. Within a few years, Office became the product, with Word, Excel, and PowerPoint becoming subsystems that shared about half of their code, at least in some versions. This sharing evolved to the point where, for Office 2000, fully 38% of the developers working on the product were creating common features shared by one or more of the applications (MacCormack 2000).

81.3.2 Long-Term versus Short-Term Trade-Offs

Working to get the architecture right or improving it incrementally is really an investment in the future—making it easier to maintain and enhance a system. Not all software companies or producer organizations have the money and time to make such investments, and users may not want to pay higher prices for such work when the trade-off may be less new features. Many new software companies also have to ship products quickly because the window of opportunity for their market may disappear.

It is unreasonable to expect new software businesses to devote too much effort to figuring out how to design a product architecture that will last for years. It is not clear what the right number of staff is to allocate to architecture development, especially for a start-up. But to make zero investment in architecture for the future would seem to be a technical and business mistake for any company that hopes to have a future.

81.4 Team Management

Another piece of common wisdom in the software engineering field is that a small team of very talented programmers works much better than a large team of mediocre people, and that talent is more important than experience (Brooks 1975; DeMarco and Lister 1987). Every experienced software manager has encountered programmers who can write much more and often much better code than other members of the same team. The rule of thumb given by Tom DeMarco and Timothy Lister, the authors of *Peopleware*, is that your best programmer will probably be about 10 times better than your worst programmer and about 2.5 times better than your average programmer (DeMarco and Lister 1987, pp. 44–46).

81.4.1 Problem of Large Teams

But one problem with managing by this philosophy is that “super programmers” are hard to find and maybe harder to keep. No rapidly growing company is likely to find enough programmers at the very upper end of the talent level to develop all the software it needs. So the more common problem in

software development is how to get relatively large groups of programmers with varying skills to work together like nimble, efficient small teams.

The synch-and-stabilize techniques, as well as iterative or agile development more broadly, can help managers tackle this problem of how to make large teams work like small teams. Selby and I made this argument in *Microsoft Secrets*, describing how this company tackled the problem with the following approaches: project size and scope limits; modular architectures; project architectures mapped to the product (so that everyone knows why they are building what they are building); projects divided into small relatively autonomous teams (three to eight developers per feature team); rigid rules to force coordination and synchronization, such as through daily builds and periodic milestones; good communications and shared functional responsibilities; and product and process flexibility to handle real-time learning and the appearance of unpredictable problems (Cusumano and Selby 1995, pp. 409–417; Cusumano 1997).

81.4.2 Teamwork Principles

Many researchers have also found it important to have strong project leaders to make sure that even the top programmers follow a few basic rules to improve teamwork. One is the need for overlapping functional responsibilities. In the Microsoft case, for example, product managers take charge of writing vision statements but they are responsible for consulting program managers in order to do this. Program managers write functional specs but they have to consult developers, who generally have de facto veto power because they have to estimate the time and people required to write the code. Developers and testers are paired and jointly responsible for testing code. Good communications and overlapping responsibilities help an organization avoid becoming too functionally oriented, bureaucratic, and compartmentalized, with large separate groups that simply hand off work to each other.

In general, software product companies tend to organize separate groups for each product and then smaller feature teams within these product units. Managers can also scale up this type of structure by creating more product units and more feature teams, as long as the product architectures allow teams to proceed more or less in parallel. Within a product unit that has an effective leader, the right set of development techniques, and a modular product architecture, a company can have a large team of several hundred people or more working together almost like one nimble small team.

Companies such as IBM, Accenture, or Infosys that design or enhance custom systems also rely on small teams to build small chunks of functionality, but their structures are often far more complex. They generally organize at the company level in a matrix, with some managers and personnel assigned to industry or “vertical” specializations, such as manufacturing or banking sectors, and others in a variety of “horizontal” functions and specializations that cut across industry domains, such as experts in SAP, Oracle, Microsoft, or open-source systems. Bespoke projects generally have some team members, such as for the requirements phase or final customer acceptance testing, located at the customer site, while much of the actual software development takes place elsewhere (Carmel and Tjia 2005; Cusumano 2008).

81.5 Project Management

It is worth repeating that the traditional waterfall model, though it may sometimes deliver software on time and meet customer requirements relatively closely and with few bugs, is not a good process for fast-paced markets driven by the need to adapt to continuous innovation, uncertainly in customer requirements, and unpredictable competition. The waterfall model originally came about in fairly stable but complex development projects, like rocket systems, where NASA needed to control requirements and schedules in great detail (Royce 1970). To NASA and contractors such as Lockheed, not making changes that might create bugs has been far more important than being innovative or fast to market. Most commercial software producers, however, whether they make mass-market products or custom-built

systems, need a process that lets them evolve designs and incorporate customer feedback in real time, during a project. For these kinds of environments, projects should do some preliminary planning but then more detailed requirements specification, program design, coding, and testing as concurrently as possible and with as much customer involvement as possible.

81.5.1 Divide and Conquer

Tackling any complex task brings up the age-old principle of “divide and conquer.” In software, this means that managers should break large projects into multiple subprojects (many firms use the term subcycles or milestones) of no more than a few days, weeks, or months duration. It is much easier to manage several small groups that are doing a focused, small amount of work and that have a deadline not too far in the future than manage a large group building a lot of features scheduled for completion in months or years. Too many things can go wrong or change when a project deadline is too far into the future, when a team is too large, or when the amount of code that needs to be integrated is too extensive.

81.5.2 Individual and Project Discipline

It is also important to get commitments from people to work as a team and deliver on individual promises. Programmers and testers should schedule their own work, rather than have managers dictate schedules. It is often not necessary to press programmers in product companies working in highly competitive markets to shorten their estimates because they tend to be overly optimistic about what they can do. Self-scheduling by developers, therefore, produces aggressive schedules, which managers like, as well as fair schedules because they come from the bottom-up. But historical project data are still useful so that managers can evaluate the realism of individual estimates and schedule some buffer time into a project to accommodate misjudgments as well as unforeseen changes or problems that turn out to be more difficult than anticipated.

81.5.3 Infrastructure Investments

Software producers generally invest heavily in various tools and infrastructure such as build teams or process experts. For example, it is important to make checking in easier and faster for programmers and to automate as much testing as possible. If check-in times take too long, then the frequent build process becomes burdensome and programmers will avoid it. But the real benefit of a smoothly working build process is that, again, a few simple rules can be enough to have discipline and still be subtle. Programmers do not like to rewrite their code.

81.6 Quality Assurance

Finally, we come to the topic of testing and quality assurance. This is an entire subject in itself, as well as essential for any software-producing organization to be successful.

81.6.1 Building in Quality

In automobiles and other industries, we learned from Japanese companies decades ago that it is cheaper ultimately to “build in” quality continuously rather than to test and fix product flaws at the end of a development cycle or production process. This has been especially true in waterfall-style software development projects, where it has long been recognized that fixing a bug at a customer site can cost perhaps a hundred times more than finding and fixing the bug early in a project (Boehm 1976, 1981). Software products with modular architectures and built with iterative or agile techniques appear able to make design changes and fix problems late in a project more easily and with much

lower costs than traditional waterfall processes. But fixing problems in the field such as by sending out patches is still expensive and can be harmful to a company's reputation.

Another point here is the importance not only of continuous feature testing—done manually by testers or through automated tests—but continuous *integration* and *system-level* testing. For example, creating a better drawing feature is fine. But if the user cannot print the object then the new feature is not properly integrated and the product has a *bug*. It is better to identify these problems earlier rather than later. Data from process surveys have reinforced this observation—the earlier a project can do integration testing, and the more it does integration testing, the higher the quality and the more likely the project will be closer to the schedule and budget targets (MacCormack et al. 2003).

It is also important for projects to automate as much feature or unit testing as well as component-integration and system-level testing as possible. Automation makes it possible to rerun tests frequently, such as with each code change, and find bugs generated by those changes. However, it is a myth that automation significantly reduces the need for people. The reason is that organizations always need people to update the tests as a project moves forward and incorporate more functionality or changes in user interface designs. Most automated tests run off the user interface and have to change as the user interface changes.

81.6.2 You Can Never Have Too Many Testers

In general, software managers would do well to adopt the philosophy that they *can never do too much testing*. This is especially true for a mass-market software products company. But it is also true for any mission-critical or enterprise-class software system. And, increasingly, consumers are expecting flawless functionality even in inexpensive or free software or functionality accessed over the Internet.

Many people are surprised to learn how many people Microsoft started to allocate to testing in the 1990s—as many as it does to programming, with testers usually assigned as “buddies” to developers in a one-to-one ratio (Cusumano and Selby 1995; Cusumano 2004). Some people are also surprised that, given this enormous investment in testing, Microsoft's quality is not higher. It is important to understand these two observations. First, Microsoft's quality has improved dramatically over time and, in multiple ways, reduced bugs but also produced products that are far more complex yet much easier to install and use compared to the old MS-DOS or early Windows systems and applications. These results directly reflect the enormous investment in testing as well as in process and product improvement more broadly. Second, many of Microsoft's testers, especially in the applications groups, are more like an advance army of beta users. These testers try to use a new product or version under development as a user would and try to detect user types of problems early on. It is a good investment to make because Microsoft sells tens or hundreds of millions of copies of its most popular software products. A few bugs or products that are difficult to install and use can generate millions of customer complaints.

81.6.3 Continuous Process and Product Improvement

Over multiple projects, it is desirable to have a strategy to improve process and product quality on a continuous basis—the now-familiar Japanese notion of *kaizen*. One way is to conduct postmortem analyses and share the results with the team and then act on the conclusions. For example, in the late 1980s and early 1990s, Microsoft adopted a practice of creating postmortem reports. These generally had three parts to them, compiled by the managers for each function on each project—product management, program management, development, testing, customer support, and user education (documentation). Each manager was supposed to interview his or her team members and come up with a summary of (1) what went well on the project, (2) what went poorly, and (3) what should they do differently the next time. Most of the Microsoft teams stayed together for a few years and had an opportunity to apply what they learned in a subsequent project (Cusumano and Selby 1995, pp. 331–339).

Another important source of learning is data from customers through the product support organization. With data-collection tools, it is possible to create detailed lists of bugs and fixes. Good teams will

also develop heuristics about how to avoid and fix common bugs. They will create checklists or handbooks or run training sessions for their testers and developers to help avoid common errors.

A phrase common at Microsoft in the 1990s and at other companies such as Netscape and Google—“eat your own dog food”—captures yet another useful practice. That is to use the product internally as you are building it so that you get a firsthand experience of whether or not it is any good. For example, if you are building the next version of Windows, as soon as the team gets to a point where basic functionality works, a developer will start using it to do basic things, like saving files and running the e-mail program. If the product is lousy and crashes, then the developer has to eat the programming equivalent of dog food.

Microsoft and other software product companies have also introduced a variety of mechanisms to get customer feedback during development. Early beta releases can provide important feedback on the quality as well as the design of a product from actual customers. Betas that come too late in the development cycle do not allow the team enough time to make major design changes. Another technique is the usability lab, where companies bring in people to test features or user interfaces under development. In the Microsoft case, programmers watch from behind one-way mirrors to see what percentage of users struggle to understand their new features. Microsoft also has sent developers and testers to staff customer support lines after a new product ships so that, again, they can get firsthand feedback on customer reactions. Product teams complement usability lab data and customer support data (summaries of which teams received on a weekly basis) with customer satisfaction surveys, product usage surveys, and other feedback mechanisms.

Another good practice to monitor and improve the operations of a software development organization is to have each project track a small number of quantifiable metrics covering product quality, the size and performance of the product, and the development process. It is important to understand the major factors driving performance of teams and customer responses to products. Project managers need to be able to measure these factors quantitatively if they are to manage them effectively. This idea of statistical analysis and feedback has also been central to the SEI philosophy, especially for projects aiming to reach CMM Level 5 (Humphrey 1989).

81.7 Results from Project Surveys and Conclusions

During 2001–2003, several colleagues and I became curious about how widespread iterative development techniques were becoming around the world, in contrast to more waterfall-ish approaches, and what, if any, measurable impact they were having on project output measures like quality, productivity, and scheduling. We conducted a pilot study at Hewlett-Packard (HP) and Agilent and then followed this with a survey of 104 projects from a variety of major software producers around the world (Cusumano et al. 2003).

81.7.1 Global Differences in Practices

In the global survey, we first asked about conventional best practices. For example, how many projects wrote architectural and functional specifications as well as detailed designs before coding? How many used code-generation tools? How many implemented design and code reviews? Then we asked about the newer techniques: How many projects divided up into subcycles or milestones, used beta tests, paired programmers with each other and with testers, followed daily builds, and did regression tests on each build? We also divided the sample into regions: India, Japan, the United States, Europe, and others.

About 85% of the sampled projects wrote functional specs, and nearly 70% wrote architectural and detailed design documents, rather than just writing code with minimal planning and documentation. These conventional good practices were especially popular in India, Japan, and Europe. The major difference was that few US projects wrote detailed designs. (I had observed this practice earlier at Microsoft, where projects in general did not write detailed designs but went straight from a functional

specification to coding in order to save time and not waste effort writing specs for features that teams might later delete.) Code generation (a technique that uses special software programs to generate code from design frameworks or design tools) was most popular in the Indian sample. Design and code reviews require particular process discipline, as promoted in the SEI recommendations. Not surprisingly, all the Indian and Japanese projects did design reviews, and all but one of the Indian projects did code reviews as well. Most projects in the other regions also followed these good practices, though not universally.

As for the iterative techniques, these were by now popular around the world, but with some variations. Most projects used subcycles, for example, though these were most common in our Indian and European and other samples and least popular in Japan. Projects that did not use subcycles, in our definition, followed a conventional waterfall process. More than half the Japanese projects, therefore, seemed to follow a conventional waterfall schedule. Most projects also used beta releases, which had become a useful testing and feedback tool since the widespread use of the Internet in the mid-1990s. Over 40% of the projects surveyed paired testers with developers—a Microsoft-style practice especially popular in India. Thirty-five percent of the projects used the XP-practice of pairing programmers, and, again, this was especially popular in our Indian sample (58%). More than 80% of the sample used daily builds at some time during the project and about 46% used daily builds at the beginning or middle, which is closer to the Microsoft style of development. More than 83% of the projects also ran regression tests on each build. Again, this good practice was most common in the Indian sample (nearly 92%).

81.7.2 Links between Practices and Performance Metrics

Researchers on software engineering over the past two decades will not be surprised with two of our findings from analyzing the HP and Agilent survey (MacCormack et al. 2003). This set of projects was roughly comparable in techniques and metrics, compared to the global sample, which had a wider variety of projects.

First, the HP and Agilent developers tended to be more productive in terms of code output when they had a more complete design before starting to write code. Second, more complete designs before coding correlated with lower levels of bugs. These results make sense and have led many software managers to insist on having complete specs before programmers start writing code—the old waterfall process. It is logical that programmers can be more productive in a technical sense if they make fewer changes during a project and thus have less rework to do. They also have less chance of introducing errors if they make fewer design and code changes.

In a business sense, however, locking a project early into a particular design may not produce the best result for the customer or enable the firm to compete effectively in a rapidly changing market. We did, in fact, find some evidence that HP and Agilent managers thought their customers were more satisfied with designs that evolved during a project. We also found that use of early betas and prototypes—opportunities for customers to provide early feedback on the design—was associated with higher code productivity and fewer defects, probably because the HP and Agilent projects were able to make early adjustments. In addition, running regression tests with each build, breaking projects into multiple subcycles, and conducting design reviews were associated with fewer bugs.

The most important conclusion from the HP and Agilent data is that, at least within a single development culture, iterative techniques such as described by the synch-and-stabilize philosophy appear to form a coherent, effective set of practices. Software projects can be more flexible in the sense of accommodating design changes with minimal impact on quality and productivity when they use several of these techniques together, rather than just selecting one or two. Our results suggest that there are trade-offs associated with using different techniques, especially with regard to allowing specifications to evolve after the start of coding. Use of particular techniques, however, helps projects overcome these potential trade-offs.

In short, when the HP and Agilent projects used beta releases to get early user feedback, conduct design reviews, and run regression tests on each build of the code (i.e., after each change or addition of new code), then the correlation between having an incomplete design when coding starts and high levels of bugs disappeared. It seems, then, that software producers can have the best of both worlds. With the right set of techniques, they can write high-quality code in a productive manner and quickly adapt to customer feedback and changes in the marketplace *during* rather than *after* a project, as in the old waterfall style.

81.7.3 Regional Differences in Performance

Project performance across firms is difficult to measure and even more difficult to compare regionally from such a small sample, but we used some crude measures and found some noteworthy differences in our global sample. Based on the data we collected, the Japanese had the best quality levels (median of 0.005) in terms of defects reported per 1000 lines of code in the 12 months after implementation at customer sites. The Indian projects (0.033) and US projects (0.030) were quite similar and very good by historical standards but still six times more “buggy” than the Japanese projects. Projects from Europe and other areas (0.05) fell in between the Japanese and the US and Indian levels. In terms of lines of code delivered per programmer per month—a measure of programmer output but not really productivity—the Japanese ranked at the top. They had a median output level of about 469 lines of code per programmer per month, unadjusted for programming language or type of project. This was more than twice the level of the Indian projects and about 70% more than the US projects, though only slightly higher than the European and other projects.

Early research on Japanese software practices found few defects along with high levels of nominal code productivity and reuse, so these results are not surprising (Zelkowitz et al. 1984; Cusumano and Kemerer 1990). US programmers often have different objectives and development styles. They tend to emphasize shorter or more innovative programs and spend much more time thinking about what they are writing and in optimizing code—which reduces lines of code productivity in a gross sense. The Indian companies have mainly US clients and seem to have adopted a US-type programming style, which tends to view shorter programs as better than longer programs. Nonetheless, we expected bug levels in India to be similar to the Japanese, given the emphasis of the Indian companies on achieving high SEI levels.

Overall, the data suggested some technical strengths in India and Japan with regard to software development but ongoing weaknesses from a business perspective. As is common in this type of research, due to the extreme variations in performance from project to project, it is hard to draw any definite conclusions. But it is important to remember as well that no Indian or Japanese company has made any real global mark in software innovation or establishing globally adopted technology platforms, which have long been the province of US and a few European firms. Code productivity is by no means a good measure of business performance and is less valuable than quality numbers in judging a software development organization. Japanese companies still seemed preoccupied with producing close to zero-defect code, and one can only wonder how much this practice constrains their willingness to experiment and innovate in software development. The global survey data also suggest that Indian companies are doing an admirable job of combining conventional best practices with iterative techniques. But they tend to treat software as a custom service business and, like the Japanese, lag behind the United States and some European firms in establishing global platforms for software products (Cusumano 2005, 2006b).

82.1 Introduction

When planning a project, two critical areas that must be addressed are project personnel and organization. In this chapter we walk the reader through the steps of how to put together a team and explain the options and potential obstacles you will face. We first discuss how you go about deciding the types of personnel that you will need on your team. In this discussion we highlight not only the different types of roles and responsibilities that are common with today's varying methodologies but also emphasize why just assigning a role to an individual is insufficient to ensure project success. How team members acquire the needed skills and competencies to fulfill their assigned role is explained. We also explain the different ways you can organize your personnel along with the advantages and disadvantages of each approach. In the latter part of this chapter, we focus on what makes a team and how a team differs from just a random group of people. This section includes a discussion on how a team is formed and moves through multiple stages. What distinguishes a high-performance team is highlighted.

Throughout this chapter we examine the options you will have, the issues you are likely to face in organizing the personnel, and underlying principles and best practices. We conclude the chapter with a

discussion of future research areas with a focus on the social side and the ability of teams to function in whatever circumstances they find themselves in.

82.2 Determining the Types of Personnel Required for Your Project

Before you can decide on the types of personnel, you need to understand the problem you are facing and have some idea about the solution and the technology you will use to solve it. This will lead you to the skills and competencies you will need in the composition of your team. Projects can quickly get into trouble when they prematurely bring people onboard before adequate analysis of the problem. A common best practice many organizations have learned the hard way is “don’t add people faster than your understanding of the problem.”

82.2.1 Looking Closer at Project Personnel from the Team Perspective

It is easy to state you need to understand the problem and something about your solution to identify your skill needs. However, this oversimplifies the real challenge often faced by project managers. There are usually multiple additional factors the project managers face, such as an aggressive schedule, a limited budget, and unrealistic stakeholder expectations. How well these additional factors are handled often comes down to qualitative aspects related to how well the project personnel perform as a team.

The skills and competencies of the personnel must be deployed and combined in some way to achieve the goals of time, cost, and quality. This is where individual team members must combine with other team members to function as a team and not as a collection of individuals. The topics of what makes a team and what makes a high-performance team are addressed in detail later in this chapter.

82.2.2 Ensuring Project Personnel Understand Their Responsibilities

Once you have decided on the types of personnel needed on your project and have those resources assigned, you will need to ensure your project personnel understand their responsibilities. One common best practice is to provide defined roles and responsibilities.

Clear roles and responsibilities help a team avoid the common problem of too many leaders, support accountability, and minimize the potential problem of excessive work overlap among team members.

There does not exist a single standard set of roles and responsibilities for project personnel. A role includes a set of responsibilities that an individual, or a group of individuals, may take on. The same individual may also take on more than one role at the same time or at different times on a project. Roles are important because they clearly establish the “who” is responsible for certain activities. Without clear roles it is easy for important work to be overlooked since no one is responsible for it or for two team members to take on the same work task. How an organization or project defines its roles depends on many factors including the nature of its product or service and its choice of methodology. The following section provides examples of roles and how their definitions can differ using three common methodologies:

- Scrum
- Team software process (TSP)
- Rational unified process (RUP)

Keep in mind that most organizations tailor their roles and responsibilities based on the specific needs of their project and product. Use the following information as a guide to help you determine appropriate roles in your organizations.

82.2.2.1 Scrum

Scrum (Schwaber, 2004) is a management framework for developing complex products. Scrum defines three roles:

- Product Owner
- Developer
- ScrumMaster

The Product Owner is the person responsible for managing the product backlog.

The product backlog is an ordered list of everything that might be needed in the product and is the single source of requirements for any changes to be made to the product. The Product Owner is responsible for the product backlog, including its content, availability, and ordering.

On small projects the Product Owner may be the actual customer. On large projects where there may exist multiple customers, or the customer is not readily accessible by the development team, the Product Owner may be a representative of the customer or customer community.

By explicitly defining this role as part of the team, Scrum helps to address the common problem observed on many software efforts of scope creep and unclear customer priorities.

Developers are members of the development team, which is a self-organizing team* when using Scrum. The development team is cross-functional with all the skills necessary to accomplish their work. Scrum recognizes no titles other than developer for all development team members. There are no exceptions to this rule as it supports the important Scrum principle that the team as a whole is accountable for their work.

The ScrumMaster is responsible for ensuring the rules of Scrum are understood and followed. The ScrumMaster does not direct the team but rather is a servant-leader. The ScrumMaster coaches the development team and assists the Product Owner in finding effective techniques to manage the product backlog.

82.2.2.2 Team Software Process

TSP (Humphrey, 2006) is a framework and a process for building and guiding development teams. TSP defines 10 standard team roles:

1. Team leader
2. Team member
3. Customer interface manager
4. Design manager
5. Implementation manager
6. Test manager
7. Planning manager
8. Process manager
9. Quality manager
10. Support manager

At first it appears that TSP is more complex in its role definitions than Scrum, but on closer examination the difference may not be as large as one might think. TSP teams, like Scrum teams, are self-directed. This means the team as a whole is responsible for its work and the quality of its products. Software development is a complex and creative activity with many factors that require close attention to ensure the right product is built leading to a satisfied customer. These factors include ensuring the team is listening to its customers, ensuring appropriate design effort is conducted, ensuring the designs are being properly implemented, ensuring appropriate testing is being conducted, ensuring appropriate planning

* Self-organizing teams are discussed in greater detail later in this chapter.

is being conducted, ensuring the team is keeping their processes current and following them, ensuring data are being recorded appropriately, and ensuring team members have appropriate tools and training.

The eight manager roles in TSP are roles that are taken on by team members who essentially become the eyes and ears of their self-directed teammates with respect to these factors. It is the developers on a TSP team who take on these manager roles, not “managers” outside the team. All self-directed software development teams must ensure these factors are being addressed. The difference between Scrum and TSP is the degree to which these responsibilities are documented and formally trained or remain tacit knowledge among team members.

82.2.2.3 Rational Unified Process

The RUP (Kroll et al., 2003) is a software engineering process framework developed by the Rational Software Corporation, a Division of IBM. It is not a single prescriptive process but a framework that is intended to be tailored. A role in RUP goes further than roles in Scrum and TSP in that it breaks out responsibilities at a finer level of granularity, and it also defines the competency required and how the individual should do the work. Examples of roles defined in RUP include

- System analyst
- Business analyst
- Business-model reviewer
- Requirements reviewer
- Requirements specifier
- Test analyst
- User-interface designer
- Software architect
- Developer

For more information on RUP and its role definitions, refer to Kroll et al. (2003).

82.2.3 Additional Roles Dependent on Project Circumstances

As stated previously, there does not exist a single standard set of roles and responsibilities for project personnel. Dependent on your project circumstances, other roles may be required. For example, in organizations that develop large complex systems, there is often a software (or system) architect role. One of the purposes in establishing a Software or System Architect role on a large complex project is to aid communication and coordination across the software development teams (Dikel et al., 2001; McMahon, 2006).

82.2.4 Ensuring Project Personnel Have Appropriate Skills and Competencies

Organizations must compete for the talent required to produce their products or perform their services. One of the major challenges faced by many organizations today is how to acquire and sustain a high-quality work force (Curtis et al., 2001). This includes ensuring your personnel have appropriate skills and competencies to accomplish their assigned responsibilities.

In this section we focus on the skills required of personnel including soft skills, such as communication skills, and listening skills, as well as the technical skills. Group skills will be covered later when we deal with teams.

There are multiple best practices commonly used today by organizations to ensure project personnel have appropriate skills and competencies. Two of those best practices discussed in the following section are

- Training
- Coaching

82.2.5 Training and Coaching

Competencies are not the same as roles. Roles define a set of responsibilities, but when an individual accepts an assigned role, it doesn't guarantee one is competent to perform that role. Helping to ensure project personnel are competent to perform their job is the purpose of training and coaching. Many organizations have developed extensive formal training programs for their personnel and have defined minimum training requirements for their people to fill standard roles defined in their organization. However, not all training needs to be formal classroom training. Over the last few years in an attempt to provide training in a more flexible and efficient way, many organizations have moved toward online web-based training that people can take as a quick refresher when needed or at a time that fits their personal schedule.

While formal training is necessary to ensure competency, it is not sufficient. No prescriptive training course can answer all the questions and address all the situations that arise on the job. This is where coaching is needed to supplement a formal training program.

82.2.5.1 Is the Coach the Same as the Team Leader?

A coach is a distinct role from a team leader although in many small organizations the same individual may take on both roles. The team leader on a self-directed team does not direct the team members but focuses on the project requirements, schedule, and success factors. Basic principles that an effective coach follows include

- Build talent
- Set high standards
- Focus on success
- Focus on improvement
- Improve in steps
- Celebrate every step (Humphrey, 2006)

As projects proceed, project conditions change. It is the responsibility of both the team leader and coach to be on the lookout for conditions that might warrant changes in team personnel to ensure the right people with the right competencies are taking on appropriate roles. While coaching can be effective in many of these situations, sometimes the best approach to address a potential trouble spot is to make a change in the personnel assigned to a project or to change an individual's responsibilities on the project.

82.2.5.2 Relationship of Competency to Methodology and Agility

The competencies that project personnel must acquire to carry out their assigned responsibilities can vary depending on the project's chosen methodology. Boehm and Turner (2004) point out that as you increase the agility of your methodology, the required skill levels of your people also increases. This is due to multiple factors. First, as organizations move increasingly in the agile direction, there is usually less documentation to help the personnel perform. Second, increased agility implies more rapid decisions often with less information. Third, increased agility implies self-direction and self-management, which means personnel need to be competent in planning and estimating and communicating with stakeholders, as well as being technically competent. This is where the "soft" skills often become critical to success.

82.2.6 Need for Measurement, Listening, and Negotiating Skills

Watts Humphrey has stressed that software work is knowledge work (Humphrey, 2011). Because knowledge work takes place in the workers head, rather than with their hands (Drucker, 1996), it is necessary for software professionals to measure and manage their own work. This also implies a need to be able to communicate the results of their measurements to stakeholders, listen to feedback, and negotiate appropriate to the situation.

When using more traditional plan-based methods planning, estimating and communicating with stakeholders often fall under the responsibilities of a manager's role. The manager in traditional functional organizations breaks the work down, estimates the work, and assigns it to project personnel. The manager also assesses progress and maintains the schedule. On self-directed teams all of these tasks fall under the responsibilities of the team that implies a need for greater competency of team members.

82.2.7 Consider All Competency Requirements to Break Down Walls between Interfacing Groups

Personnel in quality assurance groups and systems engineering groups also require communication skills. A common weakness often found in functional hierarchical organizations is a culture that breeds walls between software development groups and interfacing groups, such as quality assurance and systems engineering groups. Similar walls are often found between systems engineering and software engineering. This culture results when systems engineering and quality are viewed as separate functions rather than integrated functions. Too often in these organizations, the view becomes one of quality as being the responsibility of the quality group rather than everyone's responsibility and software being viewed as something distinct from the system it is a part of. Both of these cultures lead to increased bureaucracy and reduced product quality for the customer.

To address these common organizational weaknesses, all required competencies, including the soft communication skills, should be assessed when selecting project personnel to fill key project roles. Too often on software intensive efforts, only technical competencies are considered, which increases the risk of project failure.

82.3 Organizing Project Personnel

Organizations are complex people-based systems constructed to achieve a larger purpose (Rechtin, 1999). In the case of a software organization, that larger purpose is to produce or maintain a software product that may operate stand-alone, embedded within another product or interface to another system. The structure of a software organization can vary depending on the software or service produced. How you go about organizing your project personnel depends on multiple factors including constraints that may be levied upon you by policies in your overall organization, as well as your project's chosen methodology.

In this section we first examine varying organizational structures in use today and how these different organizational structures may affect the decisions you make on your project for organizing your personnel. The organizational structures discussed in this section include

- Functional hierarchical organization
- Integrated product team (IPT) organization
- Self-directed team organization
- Product-line organization
- Hybrid software organization

82.3.1 Functional Hierarchical Organization

Traditional large software organizations are functionally partitioned hierarchical structures with personnel at each level reporting to the level earlier. This organizational structure supports the fundamental principle of solving a large complex problem through "divide and conquer." Typical functional groups may include system architecture, systems engineering, software development, system integration and test, quality assurance, and configuration management. Depending on the product or service, the systems and software groups may be further partitioned based on the product architecture (Figure 82.1).

FIGURE 82.1 Functional hierarchical organization.

The primary advantage of a functional organization is that it provides focus on key functional needs and the allocation and management of personnel with the appropriate skills to address each specific function required. There are, however, multiple negative consequences that have been observed when employing a strict functional hierarchical organizational structure.

Common negative consequences observed include too narrow of a focus on the groups specific function causing loss of proper attention to the ultimate end product goal and the customer's needs. Functional organizations often include a system architecture and system integration and test group to help ensure proper attention to dependencies between functional groups and requirements that cross multiple functions. A common side effect often observed especially on large complex projects employing functional hierarchical organizations is long integration schedules due to too poor communication across functional group boundaries. This poor communication is often caused by inefficiencies introduced by a need to communicate up and back down the hierarchical management chain to get things done.

82.3.2 Integrated Product Team Organization

A common approach employed to address the problems observed in strict functional organizations is to use an IPT approach to software development. While this organizational approach still supports the fundamental principle of solving a large complex problem through “divide and conquer,” the criteria for division of work are now based on a partitioning of the product architecture rather than a functional partitioning. With IPTs the organizational architecture more closely reflects the product architecture, rather than the generic functions within the product (Figure 82.2).

With IPTs personnel with the required functional skills are assigned to each product team. The primary advantage to the IPT approach is improved communication as it removes the need for communication up and down the chain and therefore supports more rapid decision making. This organizational structure provides more autonomy to individual teams within the overall project organization. However, a common negative side effect of IPTs is that it can still create communication problems,

FIGURE 82.2 IPT organization.

but in these cases the communication difficulty moves to dependencies between components of the architecture, rather than dependencies between functions. Another commonly observed negative side effect of IPTs is a power struggle between project IPT team leaders and functional managers in the larger organization.

82.3.3 Self-Directed Team Organization

In small organizations self-directed teams are commonly employed. Self-directed teams are similar to IPTs in that they include personnel with all of the skills needed to solve the software problem. A strength of self-directed teams is that the members figure out what needs to be done on their own, and they do whatever is needed to get the job done. Self-directed teams stick together to the end of the job. Key characteristics of self-directed teams include (Humphrey, 2006)

- A sense of membership and belonging
- Commitment to a common team goal
- Ownership of the process and plan
- The skill to make a plan, the conviction to defend it, and the discipline to follow it
- A shared commitment to honest, truthful, and respectful behavior
- Dedication to excellence

Strengths of self-directed teams include improved communication and more rapid decision making with conflicts handled by the team rather than through escalation to higher level management. One of the weaknesses observed with self-directed teams is scalability and difficulty communicating outside the team. Self-directed teams are typically small. While self-directed teams could in theory be large, in practice self-directed teams that perform well are usually no larger than 15 people. Large projects can be broken down into multiple self-directed teams as long as some kind mechanism is established for communication among the teams.

82.3.4 Product-Line Organization

Projects, regardless of how they are organized, have different motivations than software businesses. Software businesses are motivated by the financial bottom line to the business. Projects are motivated by cost, schedule, quality of the specific software product, and the customer needs (Royce, 1998). Projects do not tend to invest in technology or services that their immediate customer is not asking for. Product-line organizations are structures that are set up specifically to address the broader long-term needs of a product beyond just a single immediate customer.

In organizations with IPTs, team members are usually fully responsible for technical decisions affecting the product. With the product-line approach, technical decisions related to core product assets become the responsibility of the product-line organization. In making technical decisions, this organization must consider the goals of the product and other current or potential customers that use the product-line.

Strengths of a software product-line organization include (Clemens and Northrop, 2001)

- Large-scale productivity gains
- Improve time-to-market
- Maintain market presence
- Improved product quality
- Increased customer satisfaction
- Increased reuse

Because product-line organizations are focused on the broader issues associated with the product, and because they have multiple customer needs to consider when making a change, one weakness often

FIGURE 82.3 Product-line organization.

observed is their lack of rapid response to the changing needs of individual customers. Product-line organizations are usually structured around the product architecture with a focus on reuse (Figure 82.3; see Clemens and Northrop, 2001; p. 316, Sections 6–10).

82.3.5 Hybrid Software Organization

Because all software organizational structures have weaknesses, often the best choice is a hybrid approach. An example of a hybrid software organizational structure could be the use of self-directed teams together with an architecture team and an integration and test team to aid coordination and communication.

82.3.6 Where Product, Organization, and People Intersect

It is not uncommon, especially in product-line organizations, to see organizational architecture reflect the product architecture. This can be both good and bad. It can be good because it brings focus to the skills and competencies needed for product development and support. But it can be bad because in today's rapidly changing world, continual product evolution is required to keep pace with changing customer needs. This also implies a need for continual evolution of personnel skills and competencies.

Too often when organizational architecture is structured too close to a product architecture, politics and fear of change get in the way of the product innovation needed to remain competitive. Best in class organizations counter this risk by keeping their personnel challenged continually updating their skills. When organizations provide planned career growth paths for their people, and actively support these plans, organizations and products evolve naturally. When organizations fail to pay proper attention to the growth of their people, fear of change often takes over leading to product stagnation and lost organizational competitiveness.

82.4 What Makes a Team?

To distinguish between a team and a random group of people collected together in the one place for some arbitrary purpose, we must first revisit what a team is. One very useful definition is "A team can be defined as a social system of three or more people, which is embedded in an organization (context), whose members perceive themselves as such and are perceived as members by others (identity), and who collaborate on a common task (teamwork)" (Hoegl and Gemeunden, 2001).

The obvious question is "Why can't the team simply follow the process?" The answer is that processes provide guidance but cannot deal with the uncertainty and variation inherent in software development or, indeed, many of the tasks undertaken by teams. The team needs to understand, frequently to considerable depth, what they are doing, why they are doing it, how to do it, when to know that they have done it among other things. It is more useful to think of the software development as a problem to be solved than as a thing to be produced. A team can be thought of as a distributed cognition system rather than some sort of production system in which each member is a component.

Although there are as many ways to transform a random group of people into a functioning team, they all seem to go through similar stages during their transformation. Bruce Tuckman reviewed published research on groups before hypothesizing that all groups go through stages of “forming,” “storming,” “norming,” and “performing.” The model was reviewed again in 1977 and found to be sound other than to add a final stage of “adjourning.”

82.4.1 Forming

In software development teams are most often formed anew for each project. It is rare that a team remains intact from one project to the next so forming the team becomes a routine but important activity. During formation the team meets, gathers information about the task and each other, and decides how to approach the task. The team also learns about opportunities and challenges before considering team goals. At this stage the team is likely to be acting independently since they have yet to learn about issues and objectives of the team. Although we may believe that all teams are similar enough that that can simply be brought together and immediately become productive, it does not happen like that.

Watts Humphrey (2001) proposed the following when he considered what it is that a team must agree on:

1. What are our goals?
2. What are the team roles and who will fill them?
3. What are the responsibilities of these roles?
4. How will the team make decisions and settle issues?
5. What standards and procedures does the team need and how do we establish them?
6. What are our quality objectives?
7. How will we track quality performance and what should we do if it falls short?
8. What processes should we use to develop the product?
9. What should be our development strategy?
10. How should we produce the design?
11. How should we integrate and test the product?
12. How do we produce our development plan?
13. How can we minimize the development schedule?
14. How do we assess, track, and manage project risks?
15. How do we determine project status?
16. How do we report status to management and the customer?

Individual circumstances may vary, Humphrey’s list will be a good place to start.

A more recent study (Gilley et al., 2010) proposes that teams need to build skills in several areas: conflict resolution, problem solving, communication, organizational understanding, decision making, goal setting and performance management, and planning and task coordination. Certainly a team would need all of those skills to answer Humphrey’s questions.

82.4.2 Storming

Every group will next enter the *storming* stage in which different ideas compete for consideration. This is not necessarily a bad thing nor does it need to be antagonistic or acrimonious despite the connotations of the term “storming.” Brainstorming is an accepted technique of bringing out different possibilities that each can be considered in turn after the brainstorming session has ended.

This is the time when the team may know “what,” but not “how.” Somehow the team must identify and consider all the possibilities they can. Premature agreement or forced agreement will usually result in later need to reconsider the matter, usually at greater cost than if time had been taken earlier.

82.4.3 Norming

Having identified all of the decisions the team needed to make in the “forming” stage and explored all the possible answers in the “storming” stage, the team must now decide which of those answers to accept and act upon. Gradually the team builds up a mental model of the way the team will function (Walz et al., 1993). The “norming” stage does not conclude tidily with answers to everything the team may have considered, but enough of them will have been well enough resolved for the team to start performing.

82.4.4 Performing

This stage is reached by some teams who manage to resolve sufficient of their issues to start working smoothly as a unit without inappropriate conflict or the need for external supervision. Team at this level would normally be considered as self-directed teams. Conflicts are expected but are resolved appropriately; new issues arise and are similarly dealt with appropriately.

Teams can, and will, occasionally revert to earlier stages in response to some external changes. Perhaps the team composition changes, or the task changes enough that they need to learn a new domain or new techniques, or their organization changes their supervision arrangements.

82.4.5 Distributed Teams

What must be done differently when the team is distributed?

Distributing the team challenges their ability to communicate with the same immediacy and richness that face to face communication affords. To some extent the diminished communication richness can be compensated by electronic means such as video conferences, electronic chats, or social media. However, the informal coordination that high-performing teams depend on for their effectiveness usually must be augmented by some formal coordination such as project schedules, specifications, backlogs, defect registers, configuration management, and project meetings, among other things. Distance between team members is like any other stress on software development: greater attention is required to ensure small problems do not become large problems. Where a collocated team can rely on informal, and to some extent accidental communication, a distributed team must go to some effort to create communication. Where a collocated team can get by with informal issue tracking, a distributed team usually needs formal issue tracking. That additional formality adds time and slows responsiveness.

Today using physically distributed teams has become an accepted software development approach for many organizations. When the Agile (Cockburn, 2006) movement began around 2000, many of the experts were claiming that agile software development teams needed to be small and collocated. While collocation can aid optimal conditions for software development, today it is recognized that agile approaches, as well as other development approaches, can work effectively with physically distributed teams (refer to Schwaber, 2004).

Nevertheless, one should not assume that the skills required on a distributed development team are no different from that of a collocated team. Experience has shown that many inexperienced project personnel work best when they are placed in an environment where they can easily listen to conversations of their teammates and easily ask questions at the moment the need arises. Collocation usually works best in these situations.

The fundamental problem of global software development is that many of the mechanisms that function to coordinate the work in a collocated setting are absent or disrupted in a distributed project (Herbsleb, 2007). There is much less communication and it is less effective. In many ways it is the problem of “out of sight, out of mind.” Communication is less frequent because we must consciously think to communicate instead of being reminded by frequent cues such as their appearance in the hallway. When communication is immediate, there is opportunity to clarify, to respond to puzzled looks, to answer questions, and to change vocabulary to suit the listener. Communication over a distance tends

to be less responsive, much more likely to be written and with less opportunity to question and clarify. When people are distant, there is also a lack of awareness of their specific context, which can lead to misunderstandings between sites.

To work effectively as a distributed team requires personnel who are self-starters and have strong self-discipline and self-management skills. Similarly, not all managers are good at managing remote personnel. Some managers are uncomfortable when they can not see and have direct personal interaction with the people they are managing. These factors should always be considered when selecting project personnel for distributed team efforts (McMahon, 2000).

82.4.6 Globally Distributed Teams

Whenever software development is globally distributed, it is usually with a distribution of collocated teams rather than the teams themselves that are distributed. Nevertheless, it is worth reviewing what has been found about distributed software development.

Most attention has been paid to cultural aspects of globally distributed projects possibly because the effects of culture can be subtle and difficult to deal with or can be obvious but requiring attention all the same. Some examples are the attitude to defects where one country could not see the point in classifying or prioritizing defects because they believed that all defects should be rectified before the product was delivered (Borchers, 2003). A more subtle problem is what Hofstede (1991) refers to as power distance. Cultures with small power distances tend to expect subordinates to raise issues with their superiors and openly to discuss matters, whereas cultures with a larger power distance will tend to expect the subordinate to carry out their superior's instructions without question. This can come as a surprise to many western team members who tend to question their superiors but who also can be surprised that a team member has acted on something they believed was offered only as a suggestion to be discussed.

Cultural differences are not the only challenge facing globally distributed teams. Obviously communication can become a challenge when time zones do not overlap by much, even though the IT industry is becoming accustomed to conference calls outside regular working hours.

Technologies are becoming available also to overcome many of the communication challenges facing distributed teams. Video conferencing, cheap voice calls, collaboration websites, and social media sites are all helping not only to reduce the communication costs and barriers but also to help team members become familiar with each other's cultures.

82.4.7 Large Teams

As the problems we try to solve become larger and more complex, the teams we need also become larger. Large problems have been successfully dealt with by decomposition into smaller problems. However, the problem of how to integrate the component solutions into a coherent whole again is less easy to manage. Change is inevitable to the requirements, to the technical solution, to the manner of integration, and to the work that must be done. Solutions to these challenges have emerged in the shape of Microsoft's "synch and stabilize" (Cusumano and Selby, 1997), code check-in gates that provide enough to assure a clean build without becoming burdensome, and interfaces that serve as contracts between components (Brechner, 2005). Coordination is achieved through the common code repository and the rules about how to incorporate code into that repository. It does not do away entirely with the need for some administrative oversight of what gets developed and when it gets integrated, but it reduces dependence on it.

Common too is the idea that there should be just enough process to ensure that people can interact successfully without compromising independence and creativity. So processes will define relationships between people and between components, but not how someone is expected to perform a task. It is assumed that they are competent.

Another approach to increasing team size is "Scrum of Scrums" in which there is a cascade of Scrums. To date this has been reported as reaching a depth of three Scrums but most frequently is only

two Scrums. The general idea is that a delegate from each daily Scrum attends a higher level Scrum in which matters of overlap and integration are discussed.

82.5 Challenges and Research Directions

Larger, more complex and more critical projects and the knowledge of what is required to achieve success coevolve. We attempt such projects because we believe we can succeed and we learn what is required to succeed through our attempts. In this area three main challenges seem to be emerging: self-management, governance, and performance measurement. In this section we will first discuss self-management through different approaches to aligning the goals, understanding, and work processes. We will then discuss emerging trends of governance before concluding with a brief discussion of performance measurement.

82.5.1 What Makes a High-Performing Team?

As briefly discussed earlier, a team needs to do more than simply follow instructions. Moreover, with many of the task to be performed in software development, it is not possible to provide a set of instructions that can prescribe how to develop software. Instead there have been various studies of teams and teamwork designed to identify the elements of teamwork.

Work gets done better when there is a common understanding of both the task and the means to accomplish that task. There is less need for over coordination and less need for administrative and organizational support or interference in the task.

82.5.1.1 Mental Models

Team mental models are team members' shared, organized understanding and mental representation of knowledge about key elements of the team's relevant environment (Mohammed and Dumville, 2001). The content of a team mental model includes shared representation of tasks, equipment, working relationships, and situations (Mohammed and Dumville, 2001).

The notion of a team mental model was developed to help account for the differences in performance levels of teams. The mental models of individual team members will be quite different at the start then converge toward a common representation. Both team work and taskwork mental models relate positively to team process and performance. In other words, teams with greater convergence in their mental models will perform better.

The concept of a mental model is quite rich, to the point where it can be useful to separate different aspects of them. For example, team performance could be enhanced if the team shared a model of the team itself, its collective skills, and who had those skills. This could be separate from a mental model of the task, what sequence of activities were needed for its completion and which team member would be responsible for different activities. Separate again from the mental model of the software product to be developed.

Whereas teamwork and taskwork reflect knowledge structures, varying interpretations and perspectives regarding key team issues reflect belief structures (Mohammed and Dumville, 2001). If the belief structures are too dissimilar, miscommunication and misunderstanding will prevail. However, if there is too much similarity, there is a danger of group think.

Information sharing and transactive memory research has been task oriented, concentrating on domains of expertise. Some knowledge will need to be common to all team members, but other, more specialized information is not needed by all team members so can be left to a few individual members who can apply that knowledge when needed.

In contrast, knowledge of how the group will function together, how they will communicate, and how they will resolve their differences should be held by all members (Mohammed and Dumville, 2001).

82.5.1.2 Collective Mind

In a study of flight deck operations, Weick and Roberts (1993) proposed the concept of “collective mind” distinguishing it from “group mind.” The term collective refers to individuals who act as if they are a group, taking care to interrelate their activities. Weick and Roberts are interested in the actions and how they are interrelated within the group. An individual can contribute to a collective mind, but a collective mind is distinct from an individual mind because the collective mind is made up from the pattern of interrelated actions within the system.

Weick and Roberts used three characteristics when describing the workings of collective mind: construction, representation, and subordination.

Construction occurs when individuals in the group construct their actions as if there are social forces operating within the group. They decide what actions they believe are expected of them and what actions they believe are expected of others. In a formal organization such actions would be described in formal organization charts and the distribution of roles and responsibilities. To some extent that is also true in teams except that in most teams there are more actions required than are formally described. In some way individuals within the group decide, or construct, their actions and the actions they expect of others. Importantly individuals look for signs that the expected actions have occurred in order to carry out their own actions. For example, if a programmer was scheduled to integrate someone else’s code into their own work, they would normally look for cues about the status and stability of the other work before committing their own work to it.

The second characteristic of collective mind is representation in which people envisage a social system of joint actions. Within a team each has some awareness of the totality of actions to be undertaken by the group, who will undertake them and how they interrelate. Again, a certain amount of this is given by the work breakdown structure and allocation of work within a project but this does not capture the detail of all of the actions of software development.

People relate their envisaged actions within the constructed system of actions. They know what they have to do and how it fits into the overall picture. This “subordination” is the third characteristic of collective mind and is clearly necessary in order that the whole collection of interrelated actions functions well.

Software development is not quite as action packed nor as immediately dangerous as flight deck operations of military aircraft carriers, but the lessons of how to form high-performance, high-reliability teams appear to be applicable to a wide range of domains, including software development.

82.5.1.3 Transactive Memory

In tasks of any size, very few people are able to know everything about the task and how to accomplish it. Instead different people know different parts, but the team collectively knows all of it. Transactive memory is defined as the set of knowledge possessed by group members, coupled with an awareness of who knows what (Wegner, 1987).

When teams are a primary mechanism for accomplishing organizational work, effective coordination of teamwork becomes an important organizational issue.

Members of a team come to understand how their individual know-how and skill become linked together within a spatial and technology environment. The team is then able to respond as a complete system to meet situational demands even though the complexity of the task is beyond the cognitive capabilities of individual team members (Faraj and Sproull, 2000).

Need to know where the expertise is. The driving force behind one organization in Sydney, Australia, related how he overcame the problem of developing awareness of team members’ knowledge and skills. From time to time, the team members were required to describe the knowledge and skills of another team member to a potential or actual client:

I think I’m a pretty good technologist but I think my real skill is putting together incredibly high performance teams and people. That’s what I think I hang my hat on. The way I do that is I make sure everyone is familiar with the competencies and skills and the value that each other brings to the table. So they can account for that when they are creating or designing or thinking of an idea

for a customer. How I manifest that within my team is anyone of my team, and I have them do this on a regular basis, can stand up and explain to a group of people what the role, responsibility, history and experience, career path of another member of the team to everyone else. The purpose of that is to ensure that each member of the team understands intrinsically what the skill or the value or the capacity of other members of the team are. The benefit of that, the ability to reflect the knowledge base or the understanding of another team member manifests itself in a very cohesive team and a team that is very open in its communications.

—Stefan Gillard, CEO Studio Engine

Faraj and Sproull demonstrated that expertise coordination contribute to team performance above and beyond traditional factors such as group resources and the use of administrative coordination.

82.5.2 High-Reliability Teams*

The level of reliability expected of software systems coupled with the increasing size and complexity of those systems challenges the ability of teams to meet those expectations. We can draw some lessons from high-reliability organizations where the potential for disaster is overwhelming yet the organization has little choice but to function reliably. For software development the equivalent is to produce high-performance software for life critical systems. It can be done with those same humanly fallible people that make up teams in any organization. High-reliability organizations share five characteristics:

82.5.2.1 Preoccupation with Failure

High-reliability organizations pay attention to small problems, treating all of them as symptoms of failure in the system. Small errors could develop into large problems if left undetected and unchecked. Thinking about the potential consequences of each incident counters the tendency to dwell on success and become complacent.

82.5.2.2 Reluctance to Simplify Interpretations

The usual tendency is to simplify in order to pay attention to the few key issues and key indicators. High-reliability organizations fight such a tendency, acknowledging that the environment in which they operate is nuanced, complex, unstable, unknowable, and unpredictable. They encourage diverse experience, skepticism toward conventional wisdom, and ways of negotiating differences of opinion without destroying the nuances that diverse people detect.

82.5.2.3 Sensitivity to Operations

High-reliability organizations are less strategic and more situational in their outlook. When people have well-developed situational awareness, they can make continuous adjustments that prevent errors from accumulating and enlarging.

82.5.2.4 Commitment to Resilience

Resilience is a combination of keeping errors small and improvising work-arounds to keep the system functioning. Both of those avenues of resilience demand deep knowledge of the technology, system, team members, self, and materials. The signature of a high-reliability organization is not that they are error free but that errors do not disable it.

82.5.2.5 Deference to Expertise

High-reliability organizations push decision making down and around. Decisions are made on the front line, authority migrates to those with the most expertise regardless of rank.

82.5.3 Governance

“Consensus has not yet emerged on a definition of IT governance” (Bannerman, 2009) but can instead be taken as the arrangements to direct, monitor, and control at the level of software development. In the main these arrangements have been the responsibility of project management, quality management, and, to a lesser extent, human resources. What is challenging about software development governance now is that past methods appear to be inadequate for highly complex, highly uncertain volatile project environments that face many teams.

Instead of relying on directives from higher levels of management, teams have to interpret the goals and intent of higher management. Instead of relying on precise specifications from customers and other stakeholders, teams have to understand their goals and intent. This is challenging because there are few reliable methods of knowing if the development team are “on the same page” as their customers, higher management, and other stakeholders. From a corporate perspective, it is insufficient simply to trust that the team will somehow incorporate the goals and intent of others into their own goals.

Software development is not the only organization that operates in highly uncertain, highly volatile and often hazardous environments. Military operations too are faced with many of the same challenges, albeit with higher consequences. The military has the concept of “commander’s intent” to guide individual initiatives, actions, and decisions (Augustine et al., 2005).

The military may have significant experience in commander’s intent as other domains may have experience with other methods but software development has some catching up to do, both to overcome past experience of development teams pursuing their own agendas and of development teams lacking the tools and methods to elicit and understand the goals and intent of their senior management, customers, and other stakeholders.

82.5.4 Performance Measurement

Measures of performance are used to monitor projects, to determine their state and status, and to determine the need for change. Developing a system for a well-understood problem in a stable environment can rely on long-term planning and associated measures such as budget, earned value, and delivered artifacts. In such an environment, it is reasonable to equate time with progress since actual progress does tend to reflect planned progress.

But in volatile environments and when developing a system for something that is largely unknown, being discovered, and solved on the run, such performance measures prove inadequate. In such volatile and uncertain circumstances, measures of risk or, more specifically, risk reduction have been proposed as more appropriate and more useful (Eisenmann et al., 2011; Ries, 2011). The biggest risk is that a system will be developed that solves the wrong problem or no one wants. So instead of measuring against a plan on the assumption that all will happen as it was planned, projects are measured against risk reduction. What are the biggest risks facing the project and how could those risks be resolved at an acceptable cost?

The challenges of such a shift in perspective are that we tend to revert back to old habits and convert the highly uncertain project into a sequence of prototypes that are assumed to prove what we want them to prove or we simply launch the project with some open-ended commitment to resolve all the risks then watch the escalating cost of doing so rather than stop the project.

While the work of Eric Ries is very appealing and does offer a new direction to pursue, there is much to be investigated. While Ries and others are eager to point out the risks of new product development, there is little guidance about measuring the types and potential impacts of risks in new product development, their interaction with the development, or how best to manage them. Possibly of more importance is knowing when to shift measurement systems from those traditional measures of stable, long-term production projects to those of risk recognition and reduction of highly volatile emergent projects and back again.

82.6 Summary and Conclusion

In this chapter we walked the reader through the steps of how to put together a team and explained the options and potential obstacles you will face. We examined options you have and issues you are likely to face. This included selecting personnel with the right skills and the importance of clearly defined roles and responsibilities to ensure important work is not overlooked and team members are not working on the same task. We identified critical skill needs including both personal and team skills.

Underlying principles and best practices were identified including training and coaching. We explained why coaching is needed to supplement formal training programs. We discussed differing organizational structures including functional hierarchical organizations, IPT organizations, self-directed team organizations, product-line organizations, and hybrid software organizations. Strengths and weaknesses of each were identified.

We explained what distinguishes a team from a random group of people and we discussed the stages groups go through in becoming an effective team including forming, norming, storming, and performing. We discussed what is different when a team is distributed and why distributed teams require personnel with self-starter, and strong self-discipline and self-management skills.

We discussed the management and coordination challenges of large teams and what makes a high-performance team different. Finally we identified and discussed future research areas including mental models, collective mind, transactive memory, and high-reliability teams.

Future changes in the nature of software engineering will require matching changes in the nature of software engineering teams. While some of the responses to those challenges are likely to be technical in nature, more of them are likely to be social in nature placing a premium on our ability to form functioning teams suited to whatever circumstance we find ourselves in.

83.1 Introduction

This chapter describes two well-known control methods that can be applied to controlling software development projects and to their underlying software development processes. The first method is closely related to traditional engineering methods for controlling manufacturing and communications systems using feedback. That method is most applicable to the overall management control of entire software development projects. The second method is known as statistical process control (SPC). It can be applied beneficially to portions of the software development processes that can be most easily quantified, such as the inspection process. We will describe both of these methods and their underlying mathematical and engineering foundations, and will then provide some examples of their use in typical software development projects. We will end with a brief discussion of the extensive literature in which other authors have described the application of SPC methods to software projects and the successes and failures that they have reported.

All plan-based software development projects must be planned, organized, monitored, and controlled by their project manager. We will refer to the project manager's control activities in executing the project as project control. We will refer to control of the underlying software development processes as process control. Controlling a project and controlling the underlying processes are very different activities, and consequently, they require very different techniques to make them effective.

83.2 Project Control

A project is usually defined as activities performed by people that produce something unique and that have a limited lifetime. It can be described as a set of tasks that are linked together in a network that shows which of the tasks must be completed before subsequent tasks can begin. Software projects usually require tasks that involve the development of requirements, the development of architectural and

design specifications, coding, testing, delivery to the customer, and continuing maintenance. It will also sometimes involve the development of a proposal or a business case, which presents the economic justification for the undertaking, and an agreement, or a contract, with the customer specifying what will be delivered, when it will be delivered, and how much it will cost. At a high level, virtually all large software projects can be defined by these activities. However, because each project produces something unique, the details of tasks that need to be performed to complete the project are usually different from project to project. For most large software projects, the network and schedule relationships usually look similar to Figure 83.1.

For the software development project shown in Figure 83.1, the team needs to develop five different software modules (Mod 1 through Mod 5) and integrate them into two different releases of the product. The project starts with planning and requirements development. The architecture, which defines each of the modules and how they work together, is developed next. Then the design, coding, and unit testing (D, C, and T) of three of the modules is undertaken. When all three modules have been unit tested, they are integrated to produce Release 1 (R1) of the product. Release 1 is then system tested and that release is deployed.

During or shortly after Release 1 has been integrated, two of the resources that developed the first three modules go to work on design, coding, and unit testing of the two additional modules that provide

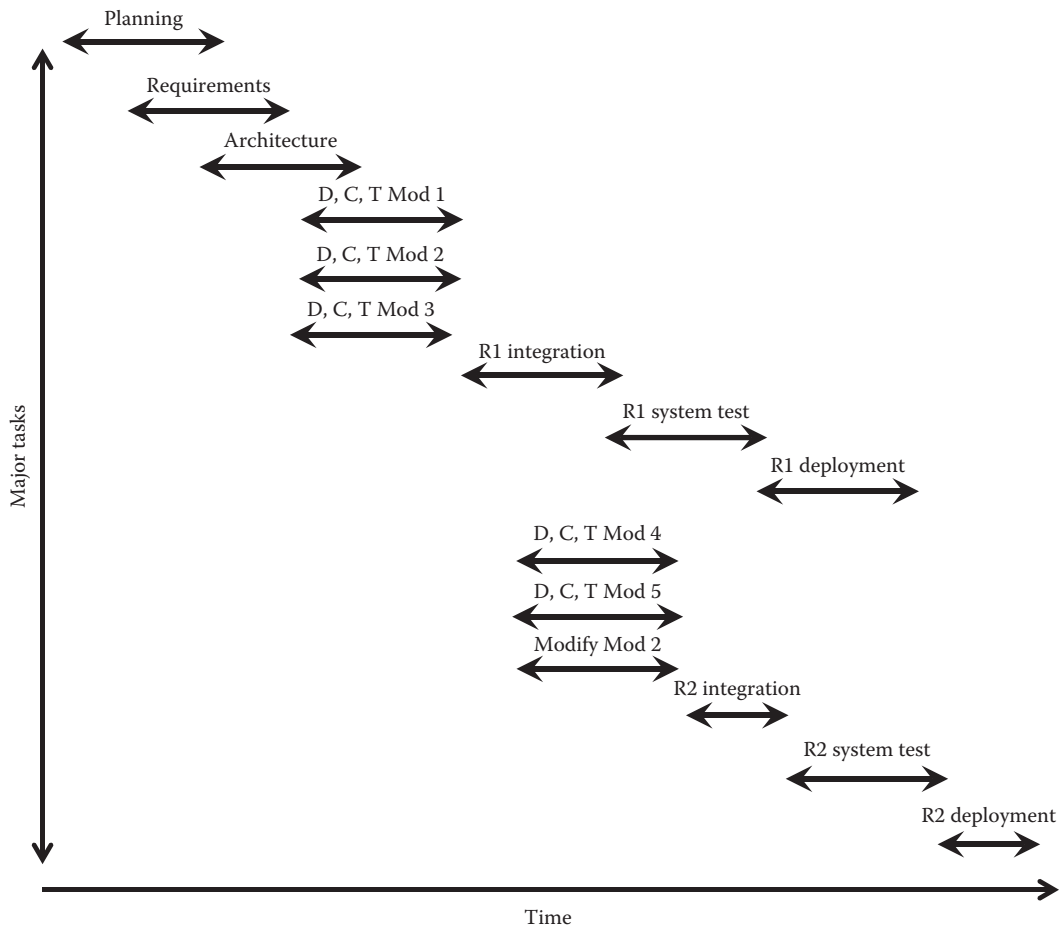

FIGURE 83.1 Typical software development project schedule.

the capabilities included in Release 2. The information in Figure 83.1 also assumes that while Modules 4 and 5 are being designed, coded, and unit tested, someone needs to return to modify Module 2 to accommodate Release 2 (R2) features. When all three modules have been unit tested, they are integrated with the software that was developed for Release 1 to produce Release 2 of the product. Release 2 is then system tested and that release is deployed.

83.2.1 Project Plan

The project plan is a document, prepared by a core team that answers the following questions for the team, for the team's management and for the project's other stakeholders:

- What is the project going to produce?
- How is the team going to produce the product?
- Who is going to do each task?
- When will each task, each release, and the whole project be completed?
- How much will each task and the entire project cost?

The core team that produces the plan should be a set of people whom we expect to work on the project from beginning to end who can represent all of the functions (such as requirements development, architecture and design, coding) that will be required for completion of the project.

The plan needs to specifically define each of the tasks that must be accomplished, who will be responsible for each task, and visible end points for each task so that the project manager and other members of the team will know when each task has been completed. These visible end points might be things like inspections of requirements, customer sign-off on requirements documents, inspections of detailed designs, unit test results, demonstrations of design, coding and unit testing tasks, demonstrations of test results, and sign-off by team members on installation and user documents.

The reason for specifying very visible end points for each task is so that the project manager does not have to be continually asking each person assigned to a task what the status of work on that task is. Tasks should be defined in such a way that they can be completed by one person working full time on the tasks for no more than a few weeks. By defining relatively small tasks and by having visible end points for each task, the manager no longer needs to ask about the status of the task. The task is either completed or not completed. And the manager can confirm when it is completed by viewing the visible end point. This avoids the challenge of having to use subjective estimates of how much of a given task has been completed. Assigning a percent complete to a project task is a guess on the part of the individual who is responsible for that task. This author has observed that individuals frequently provide overly optimistic estimates when asked this question thereby delaying availability of the manager's knowledge that problems may be developing on the project.

83.2.2 Project Operations

The project plan should also contain some general descriptive materials outlining how the project will be staffed; how it will be kicked off; how and with whom the project will communicate, both internally and with its external stakeholders; and, probably most importantly, how the project will be monitored. Most project managers monitor the status of their projects by arranging periodic project meetings on a weekly, biweekly, or monthly basis. Those project meetings provide a forum in which the project's status and the status of individual tasks can be observed and reported. They also serve as a place where current issues are raised, where responsibilities for addressing issues are assigned, where a variety of project data can be shared with members of the team, and where demonstrations of progress can be conducted.

83.2.3 Project Monitoring and Feedback

The project plan should describe the number of people who are expected to be working on the project as a function of time. It should also describe the cost, or budget, indicating how much the management expects to have to pay for salary and expenses in support of the software development team. Finally, it needs to list all of the tasks that need to be accomplished to complete the project and who will be responsible for each task. This information can be displayed in either tabular or graphical form, that is, in a spreadsheet or in a Gantt chart. As an example, Figure 83.2 shows a Gantt chart for the project that was outlined in Figure 83.1. Figure 83.3 shows the same information in a tabular format.

In addition to the status of the project’s tasks, we might also be interested in the resources working on the project and their cost. Figures 83.4 and 83.5 also show, in a graphical format, the number of people we plan to have working on a project and their cost.

83.2.4 Project Control

Now that we have discussed and set up the basics of a project plan, we are ready to start discussing project control. In order to exercise project control, we need to make use of another major project management processes, namely, the monitoring process. Monitoring is the process of tracking the status of the project, comparing the current status with the status contained in the plan for the current point in time, and searching for deviations between the baselined project plan and the actual project status. The deviations are then used as the basis for taking actions to address the deviations, namely, the control process.

Figure 83.6 shows how the monitoring and control processes are used together. Input to the monitoring process includes the project plan, specifically the data shown in Figures 83.2 through 83.5, showing which tasks should be completed at each point in time, the number of resources that should be working on the project at each point in time, and the costs that should have been

incurred at that time. In preparation for each periodic project meeting, the project manager compiles the status of all tasks, the number of people working on the project, and the cost that has been incurred. When the manager discovers that some of the tasks that should have been completed have not been completed, the number of resources is not at the planned levels or the cost incurred is different from the planned cost the manager needs to take control and do something to address the deviation.

FIGURE 83.5 Budget plan.

FIGURE 83.6 Monitoring and control.

“Project monitoring and control” is a key process area in the Capability Maturity Model Integrated Development (CMMI-DEV) [6], developed by the Software Engineering Institute. Inclusion of both monitoring and control in the same key process area, and in most other software development best practice descriptions, indicates that monitoring and control are closely related and highly dependent processes.

Figure 83.6 shows that the outputs from the project control process become modifications of the project plan. The purpose of those modifications is to get the project back on track. While these modifications might not literally result in changes to the written project plan, they will certainly result in

modifications to the way the project is operating. In practice, when an unacceptable deviation from the project management plan is discovered, the project manager needs to take corrective action. As a first step the project manager may ask the individual who is responsible for the deviation to develop and present the steps needed to get back to the baseline plan as quickly as possible.

The project manager may need to provide support to the responsible person. Corrective actions that do not require additional costs or delays in the project completion date should be considered first. These actions could include nonpaid overtime work or the use of resources assigned to tasks with slack to assist with the delayed work.

If no such modifications can be found, the project manager should consider two additional techniques, “fast tracking” and “crashing.” Fast tracking means that tasks that are normally done in sequence are done, instead, partially in parallel. For example, if you would not normally start preparing detailed designs until requirements and an architectural solution were documented, fast tracking might mean starting detailed design or, perhaps, even coding before the requirements and architectural specifications were complete. Fast tracking involves risks that could lead to increased cost and rework later. If the requirements or the architecture changes, this might result in having to redo some of the detailed design or coding work already underway, thereby delaying project completion and/or increasing total project cost.

Crashing the schedule means adding additional resources to tasks on the critical path without necessarily being concerned about the level of efficiency for those tasks. Let’s assume that one person was working on a 4-week design, code, and unit test activity and they are having difficulty getting agreement on how their software module will interface with a module designed and coded by another person. If you really need to assure that the task finishes in 4 weeks, you might add a second person to this task. That person might not have all the right skills for this task, and they might have to work for two weeks just to reduce the overall time on this task by 1 week. That trade-off, on the surface, might not make sense. However, if the project’s delivery date is of utmost importance, we might be willing to make that trade-off even if it results in an incremental increase of the project’s cost. One of the goals of crashing the schedule is to minimize the incremental cost increase. However, in exchange for completing tasks on the critical path on schedule, crashing almost always leads to additional incremental cost. If the project manager is willing and able to spend more to accelerate the schedule, crashing is sometimes the best alternative.

If the schedule will be delayed, the cost increased, or the scope reduced, the project manager will need to consult with the customer and/or other stakeholders to negotiate an increased budget, a project schedule delay, or a reduction in the project’s scope (requirements) to accommodate the necessary modifications. Obviously, prevention of schedule delays, cost overruns, or scope reductions is superior to alternatives that require these negotiations.

All of these actions constitute project control.

83.2.5 Theoretical Basis for Project Control

The methods that have been discussed previously are similar to those used in modern control engineering, also called feedback control. Feedback control uses the difference between signals, determined by comparing the values of system’s output variables to their desired values, as a method for controlling the system. A very common and well-known use of feedback control is the room thermostat used to control the temperature of a room. The setting provided by the user or occupant of the room is the desired temperature. During periods when heat is required to maintain a comfortable temperature, the occupant will position a lever or, with a digital thermostat, set the desired temperature. Based on that input, the thermostat will determine a temperature slightly lower than the desired temperature at which the thermostat will send a signal to the furnace or other heating device to turn “on” and start delivering heat to the environment. When the temperature rises to slightly more than the desired level, it will send a second signal to the heating device to tell it to turn “off.” In the case of

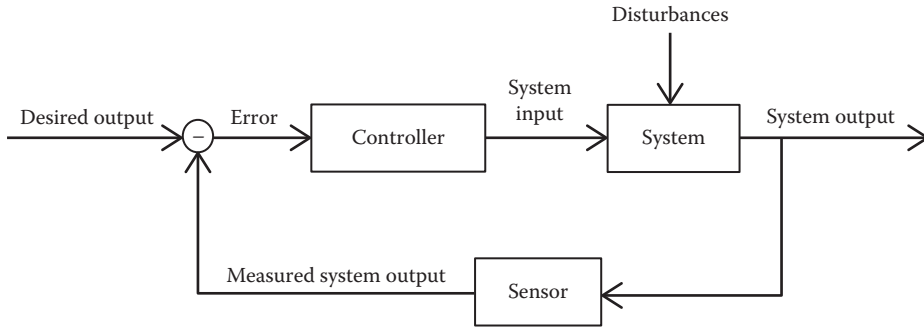

FIGURE 83.7 A formalized control system based on feedback.

room thermostats, turning the switch to “on” or to “off” is usually implemented by a combination of temperature sensitive mechanical devices and electrical circuitry.

This theory of feedback control was first formalized by James Clerk Maxwell who provided the first rigorous analyses of a feedback control system. In 1868, he wrote a famous paper “On Governors,” [4] which is widely considered the seminal paper in feedback control theory. In that paper he anticipated many aspects of modern control engineering. Figure 83.7 is a diagram that shows in a more formal way the use of differences between desired results and actual results to control a system.

Note that the relationships shown in this figure are similar to the relationships between the project monitoring process and the project control process shown in Figure 83.6. The “desired output” is the information contained in the project plan. The System represents the project. The Sensor corresponds to the monitoring process, and the Controller represents the actions taken by the project manager to address deviations from the plan. While the theoretical basis for control of many electromechanical systems can frequently be expressed and analyzed quantitatively, that is not usually possible for project control systems that depend very heavily on the experience and capabilities of the project manager and the project team to implement the control actions discussed previously.

83.2.6 Artifact Control

Another aspect of project operations related to control is those activities that have become known as configuration, or artifact, control. Configuration control is the formalized process of keeping track of artifacts such as requirements, architecture, and design documents as well as code and test cases. After a draft of these documents is formalized by being baselined, any further change in those artifacts requires formal approval. That approval is frequently in the hands of managers who are responsible for the project or, more likely for larger projects, a configuration control board, which is usually a subset of team members who take on primary responsibility for controlling what changes are made to the artifacts and how those changes are integrated into the project’s formal documentation. Those changes may come from customer trouble reports, from customer requests for changes, or from members of the software development team who are making changes to the system. It is imperative that there be a methodology in place to keep careful track of artifacts included in each release of the project so that all team members know which version(s) of the software is in the hands of customers, which are being tested, and which are in development.

While these activities have the word “control” in their names, they are qualitatively a different kind of control from project control and from process control that will be discussed in later sections of the chapter. The most important characteristic of these artifact control activities is the care with which they must be executed and the cost of exercising this kind of control. There are many software-based commercial configuration management systems available that can be investigated by browsing the web. Information on each is readily available there, so we will not go into any further discussion about artifact control in this chapter.

83.3 Process Control

83.3.1 What Is a Process?

A process can be defined as a set of tasks performed by people, machinery, or nature that transform inputs into outputs using resources [1]. So a process must be considered in the context of the agents carrying out the tasks and the resources that are required [2]. The tasks are usually linked together in such a way that some of the tasks need to be completed before subsequent tasks can begin. A process may also be defined as the workflows and sequence of events inherent in processes such as engineering, business, or manufacturing.

83.3.2 Control of Repetitive versus Nonrepetitive Processes

Several methods have been developed for controlling processes. The continuous feedback control methods that were described briefly in the first half of this chapter are particularly suitable for completely automated electromechanical applications such as the room temperature control system described there and many other repetitive operations, particularly in the chemical manufacturing and electrical communications industries. These are all examples of repetitive processes in which the same processes are executed again and again with the objective of performing them exactly the same way every time.

A second method that has been developed for controlling repetitive processes is SPC. SPC was developed by Walter Shewhart in the 1920s and later applied very successfully by W. Edwards Deming during World War II to improve the manufacturing quality of weapons and other products that were important to the war effort. It has become a very effective method for controlling the variability inherent in many repetitive manufacturing processes. SPC makes use of control charts, as shown in Figure 83.8, to record observations of a numerical variable of interest in the manufacturing process. Those limits are used to raise a flag when the variable goes above or below specified limits indicating that the process is out of control. Such excursions stimulate an investigation to determine the root causes of unusual variability and elimination of those causes.

Based on a sequence of observations, the upper and lower control limits (UCL and LCL) shown in Figure 83.8 were calculated. The control limits are calculated using an assumption that, if the process

FIGURE 83.8 Control chart.

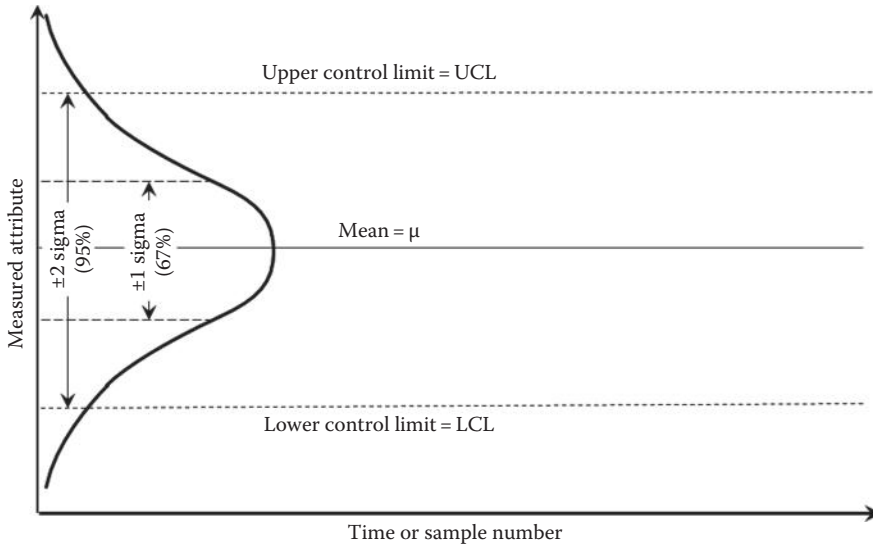

FIGURE 83.9 Assumptions made in calculating UCL and LCL.

is in control, that is, if the mean of the measured attribute and the standard deviation of the attribute are not changing over time, the observed data will fall within plus or minus one standard deviation of the mean approximately 67% of the time and within plus or minus two standard deviations of the mean about 95% of the time (see Figure 83.9). So the observed measurements should appear above the UCL only about once in 40 observations unless there is some systematic cause that results in the observation being out of control more than 5% of the time. Likewise, the same logic could be applied to points appearing below the LCL.

The calculation of control limits is done using the following formulas:

Assume that

X_i is the individual measurements of the variable being studied

μ is the mean (average) of all observations

N is the number of observations

$$UCL = \mu + 2 \sqrt{\sum_1^N (X_i - \mu)^2 / N}$$

$$LCL = \mu - 2 \sqrt{\sum_1^N (X_i - \mu)^2 / N}$$

LCL = 0 if the previous LCL expression is negative

The use of SPC to help control software engineering processes has been encouraged by its inclusion in the CMMI-DEV [6]. However, its use for that purpose has been controversial because of several basic differences between typical manufacturing processes and software development processes [5,8].

Software development processes, while they might look repetitive at a high level, are actually executed differently each time they are performed. We call these nonrepetitive processes. Most projects, whether they are in the construction industry, the software development industry, or in some other industry, must use nonrepetitive processes by their basic nature. This is because part of the definition of a project is that it is an activity, performed by people using resources that produce something unique.

If the objective is to produce something unique each time the project's processes are executed, they must be nonrepetitive and must be uniquely planned, organized, monitored, and controlled. While the application of SPC to software development processes is controversial, in a later section of this chapter we will provide an example of an application of this technique to at least one subprocess of the overall software development process, inspections.

Nonrepetitive processes are frequently controlled using a method called management by walking around (MBWA). Using this method a manager would determine if employees are following the desired process by frequently reviewing the work that they are doing, looking over their shoulders while they work, and talking with them about how they are doing the task in which they are engaged. The manager can then provide informal feedback on how the process is being executed and what should be done to improve its execution.

Alternatively, software development processes can be controlled by defining the process in writing, including in that definition a requirement that calls for written artifacts from the process while it is being executed. Documents produced during execution of the process are then reviewed by the manager and/or audited by professional auditors to determine if the process is being executed in compliance with its requirements. This is the method used to achieve International Organization for Standardization (ISO) 9001 certification of a software development process [3]. For that kind of certification, a team of people in the organization seeking certification writes a description of the process. This description is reviewed by the external auditors to ensure that the description complies with general ISO 9001 process description requirements. It becomes part of the organization's ISO 9001 quality manual. Then the development team does the work, following the description while documenting the work along the way. Finally, a team of external auditors reviews the documentation that has been produced, interviews people on the development team about how they have been doing their work, and compares the process that is actually being used with the process described in the quality manual. Any mismatches between the requirements in the quality manual and the process uncovered by the auditors produce nonconformances, which must be addressed and improved before the next external audit to reduce the probability that the nonconformance will occur again.

The CMMI-DEV is a similar model with corresponding processes. That model specifies specific processes for developing software that are generally considered best practices for software development. The model describes an evolutionary improvement path from ad hoc, immature processes to disciplined, mature processes with improved quality and effectiveness. It provides a method for identifying opportunities for improvement and for comparing the maturity of an organization's processes with the model's components to produce a maturity rating from one to five indicating how completely and correctly each of the model's components have been implemented. The model describes the following 22 key process areas listed approximately in the order of maturity with lower levels of maturity using only processes near the top of the list and higher levels of maturity using processes near the bottom of the list in addition to all of the processes above them toward the top of the list:

- Configuration management
- Measurement and analysis
- Project monitoring and control
- Project planning
- Process and product quality assurance
- Supplier agreement management
- Requirements management
- Decision analysis and resolution
- Integrated project management
- Organizational process definition
- Organizational process focus
- Organizational training

- Product integration
- Requirements development
- Risk management
- Technical solution
- Validation
- Verification
- Organizational process performance
- Quantitative project management
- Organizational performance management
- Causal analysis and resolution

Organizations may conduct an appraisal and earn a maturity level as specified by the model. Appraisal requirements are specified in CMMI ARC [7]. Appraisals focus on identifying improvement opportunities and comparing the organization's processes to CMMI-DEV best practices.

83.3.3 Control of a Specific Software Development Processes

To achieve high maturity levels of CMMI-DEV, organizations must use quantitative project management. This requirement could conceivably be met by tracking the number of tasks actually completed versus the number planned as a function of time, by tracking trends in numbers of customer trouble reports per unit of time or in number of faults found per line of code during testing. However, the most extensive, and theoretically sound, use of quantitative project management techniques has been the use of SPC in analyzing data produced by inspection processes.

Figure 83.10 shows control charts for a set of data that were produced by 15 requirements inspections. In each chart the number of the inspection is shown on the horizontal axes. The vertical axes show defect density in number of defects per 1000 lines of text, preparation rate in lines of text per hour of preparation, inspection rate in lines of text inspected per hour, and document size in lines of text. The UCLs for each chart were calculated using the formula shown earlier in this chapter. LCL calculations indicated that the LCL for each chart was zero.

FIGURE 83.10 Control charts for four attributes (a) defect density, (b) preparation rate, (c) inspection rate and (d) document size of a set of 15 requirements inspections.

It is instructive to look at the data for inspections numbered 3, 8, 12, and 15. For inspection three the defect density, the preparation rate, the inspection rate, and the document size are all within the control limits. We could conclude that inspection number three was a normal inspection meeting and that the document was acceptable with a nominal defect rate. For inspection number eight, the defect density was at or very close to zero. The preparation rate, the inspection rate, and the document size were all within the control limits. We could conclude that this was a normal inspection meeting and that, because the defect rate was at the LCL, this was a very-high-quality document. For inspection number twelve, the number of defects was zero. The preparation rate, the inspection rate, and the document size were all high and were all above their UCLs. Therefore, we could conclude that this was likely to have been a poor inspection and that the document should be inspected again. Finally, for inspection number fifteen, the defect density was high and above the UCL. The preparation rate, the inspection rate, and the document size were all within the control limits. Therefore, we could conclude that the inspection was probably a good one but that the quality of the document was poor. The document should probably be reworked and reinspected.

In each of the four control charts shown in Figure 83.10, only one of the points are actually outside the control limits, which is close to the expected number of times such variation would be expected to occur due to random causes, so there is no strong evidence of any systematic cause for these outliers. However, if these excursions continue to occur in the future or if the frequency of occurrence increases, an investigation of the reason why the process is out of control should be undertaken and actions should be taken to prevent these outliers. Such actions might include not starting an inspection meeting if it is determined before the meeting starts that the document size is outside the control limits or stopping an inspection meeting as soon as it is determined that the preparation rate has exceeded the UCLs. These are the kinds of process improvement actions, based on the use of quantitative SPC methods that could be implemented during the execution of the process.

83.3.4 Practical Implications and Major Challenges

Application of the control techniques discussed in this chapter is relatively straightforward in practice. However, the author has observed that they are frequently not applied by project managers. There could be several reasons for this situation. First, and most obvious, is that if a project is not well planned, then the project manager has no basis for comparing the project's status with a baseline plan. A good plan should specify what is going to be done, how it will be done, who is responsible for each task, when each task will be completed, and how much the project will cost.

If the project plan does not specify the necessary tasks in sufficient detail and if there is nothing specified that the project manager can see to determine when each task is completed, the manager needs to rely only on the word of team members that a task has been completed. Anyone who has managed a project has observed that when reporting on task completions, members of software development teams are sometimes overly optimistic, frequently reporting that tasks are completed when there still remains work to be done. This is particularly bothersome during the creation of the project architecture and the design and coding phases of the project. During those phases it is helpful if the project plan calls for formal inspection of the artifacts that are produced during each task so that the project manager can see a short inspection report indicating that the task has been completed. This also provides a basis for implementing an inspection program and controlling its operation as discussed in the second part of this chapter.

When unit and integration testing has begun, the project plan could call for demonstrations of the results of these tests to the team so that completion of the tasks can be visually confirmed. Finally, when system testing begins, the completion of individual test cases, indicating whether they have passed or failed, can and should be reported and tracked.

Developing a plan that includes resources for all of these activities usually requires more work and overcoming more resistance from team members and stakeholders with financial interests than the

effort associated with monitoring and control of the project. Therefore, the major challenge faced by project managers is usually the development and implementation of a sound project plan that includes all of these activities.

83.4 Summary and Conclusions

We have reviewed the methods commonly used to control software projects. They involve close monitoring of the project as compared with the project plan and taking appropriate actions when it is found that there are significant deviations from the plan. This method was shown to be closely related to feedback control used for controlling many engineered systems. We then moved to the control of software development processes. Methods discussed there ranged from informally observing how the work was being performed through more formal ISO 9001 certification and CMM assessments to the use of SPC for specific subprocesses of the software development process.

Control of both projects and processes is one of the more difficult activities that must be undertaken by software development project managers and their teams. Monitoring projects to find deviations from the plan is quite straightforward once an appropriate plan has been developed. However, deciding what actions to take in response to deviations requires the exercise of considerable care and judgment. Controlling processes is even more difficult, not only because significant effort and cost are required to do it well but also because there is considerable debate about whether the most soundly based method, SPC, can and should be applied to software development processes.

84.1 Introduction

Agile is an umbrella term used to describe a set of paradigms and approaches to the software development process. The term was popularized with the publication of the Agile Manifesto (Beck et al. 2001) by a group of 17 authors and reflects an intention of the signatories to differentiate agile approaches from a trend in software development methodologies that had gained dominance in previous decades.

That trend, in turn, had been a reaction to the *software crisis* that had been widely publicized by the early 1970s (Dijkstra 1972) and had led to the rise of increasingly elaborate and prescriptive approaches to software development. The publication of *Managing the Software Process* (Humphrey 1989) had culminated a long turn away from a focus on individual developers described in Dijkstra (1972) toward a focus on detailed, defined development processes. The Capability Maturity Model introduced by the Software Engineering Institute (SEI) (Paulk and Curtis 1993) moved the defined software process squarely to the center of attention in software development. Large initiatives such as the Ada Programming Support Environment (Fairley 1980) exemplified the attempt to support defined processes with comprehensive tools. The development of the V-Model in Germany in the mid-1980s enshrined a view of the software development lifecycle as a series of activities based upon a particular sequential interpretation of the waterfall lifecycle model published in 1970 (Royce 1970).

The V-model and similar lifecycle reference models also formed the basis of new software development standards such as IEC 61508 (IEC 2010) with numerous associated workproducts in the form of documentation to be produced by developers. Such documentation workproducts (e.g., user requirements) generally became the object of contractual negotiations that were gated prerequisites to progress in projects. These documentation workproducts were often not associated with functioning software (especially in early phases of projects), which often led to antagonistic relationships between customer and developer as each maneuvered for position regarding functionality whose cost could only be predicted with considerable uncertainty.

By the early 1990s, evidence was accumulating and being reported in publications such as the Chaos reports (Standish 1994) that organizations following established software development doctrine were failing at alarming rates. Those who became the signatories to the Agile Manifesto had come to the conclusion through independent experience that the main source of failure was an unforeseen degree of change in systems over all phases of their lifecycle and an inability of the currently popular defined processes to manage that change. They began to introduce the alternative approaches that became known as agile methods.

The primary differentiating characteristic of the agile methods promoted by the signatories of the Agile Manifesto was an *iterative and incremental* approach to the development process. Although it represented a radical departure from the sequential development processes that had become dominant, it was not unprecedented. As Larman and Basili (2003) recount in detail, iterative and incremental development had been practiced and promoted at numerous times throughout the history of software development. In addition to anecdotally documented experience in IBM Federal Systems Division and NASA Project Mercury, publications explicitly recommending this approach were beginning to appear by the late 1960s (Randell and Zurcher 1968). Gilb was a strong early promoter (Gilb 1989) of iterative and incremental development (Extreme Programming [XP] author Beck has explicitly acknowledged a debt to Gilb's work). The 1980s were also characterized by influential publications promoting an explicit iterative and incremental lifecycle representation, such as the spiral model (Boehm 1988).

Likewise, specific practices that came to be associated with agile methods had important precedents. The practice of *test-first development* was being used in the NASA Project Mercury by 1960 (Larman and Basili 2003). The practice of *continuous integration* was noted by Cusumano at the XP2003 conference on agile processes to be strikingly similar to the *daily build* already being practiced in Microsoft (Cusumano and Selby 1995) in the early 1990s. The agile vision of software being its own best documentation has echoes in *literate programming* (Knuth 1992). *Pair programming* had been introduced by Plauger at Whitesmiths several years earlier than its popular reintroduction in XP (Constantine 1992). In an influential article in the mid-1980s, Brooks (1987) advocated the idea of "growing" a system from simple to more complete functionality, in such a way that a running system was always available to stakeholders. This idea was a precursor to the agile vision of "working software."

Likewise, the refocused attention on individuals and interactions in the Agile Manifesto was not unprecedented, as the landmark book *The Psychology of Computing Programming* (Weinberg 1971) had studied both individual and team software development behavior 30 years earlier, coining terms such as *egoless programming* that became precursors to the group ownership practices seen in agile methods. Even during the heyday of institutional process definition activity, books like *Peopleware* (DeMarco and Lister 1987) were seeking to raise awareness of the human factor in software development.

Thus, the rise of agile software development in the late 1990s and early 2000s can be viewed not so much as innovation in specific software practices as a codification and consolidation of long-existing practices into a number of coherent, usable methodologies and frameworks. This

happened within the context of a rebalancing in the nature of large software systems. Whereas the large software systems in the 1970s and 1980s were primarily mission-critical, military, and space systems, a new kind of large software system began to appear in the 1990s with the rise of networks such as the Internet (including the World Wide Web) and financial networks with a global reach. Applications on these new systems were characterized by extremely volatile, rapid feature evolution and high degrees of user interaction and provided the context for the agile methods to take root and thrive.

84.2 Underlying Principles

A set of 12 principles underlying the agile approach to software development was provided by the signatories of the Agile Manifesto (Beck et al. 2001):

1. *Our highest priority is to satisfy the customer through early and continuous delivery of valuable software.*

A direct link to the surrounding business environment is established by several principles in the Agile Manifesto. Although stakeholder satisfaction had always been at least implicit (e.g., through user requirements) in previous approaches, there was a distinctly technical slant in those approaches. Agile software development places an emphasis on delivery of business value, with an implicit (and often explicit) interpretation as economic value (Beck and Andres 2004). While the link to business value had been made in specific subdisciplines such as software reuse (Favaro et al. 1998) and software product lines, it was relatively unusual to find it in general software development methodologies.

2. *Welcome changing requirements, even late in development. Agile processes harness change for the customer's competitive advantage.*

Beyond the link to economic value (which could manifest itself simply as cost savings), a strong, explicit link was made by the promoters of agile software development to competitive strategy, going beyond the simpler time-to-market arguments seen previously. Here, the software development process was interwoven with business strategy—in particular, reacting successfully to changing business conditions. Enabling this new interweaving with competitive strategy necessitated a complete reworking of the lifecycle not only in terms of iterative development but also in terms of introducing interaction points between technical development and strategy development. Whereas technically oriented iterative development had been practiced in the past, there had been much less attention paid to its interaction with iterative business strategy development and execution. The principle of harnessing change and uncertainty for competitive business advantage forms the foundation of the *real options* approach, borrowed from mainstream corporate finance (Brealey et al. 2008) and strategy that underlies and is appealed to explicitly in several of the agile methodologies.

3. *Deliver working software frequently, from a couple of weeks to a couple of months, with a preference to the shorter timescale.*

Aside from enshrining the iterative and incremental development paradigm in agile methods, this principle is also related to promises such as the following (Jeffries et al. 2000):

Customer Development Right #1: [...] You may cancel at any time and be left with a useful working system reflecting investment to date.

Such a promise could not be made with a sequentially defined waterfall lifecycle: a customer wishing to cancel a contract would risk having only a set of requirements and design

documents, with no code written. The promise, however, poses serious challenges for implementation techniques, such as how to implement infrastructure incrementally along with the more user-visible features. It also has led to considerable experimentation with the duration of iteration periods (e.g., determining the shortest possible duration of an iteration that can still result in useful working software), as well as the management of that iteration (e.g., fixed timeboxing versus more elastic boundaries). All agile methods confront these issues in various ways.

4. *Business people and developers must work together daily throughout the project.*

The principle of generating customer satisfaction through frequent delivery of working software implies the need for more frequent interaction between customer and developer than in a sequential process, where customer–developer interaction is primarily at the beginning (requirements definition) and end (acceptance testing) of a project. At a minimum, interaction points must occur between iterations, but agile methods encourage continuous interaction. The most extreme manifestation is the request for a customer representative to be onsite and part of the development team. Not only does this principle redefine the customer–developer relationship in more collaborative terms, but it also places heavy requirements on the customer’s resources (i.e., making personnel available on a daily basis) that can be very challenging.

5. *Build projects around motivated individuals. Give them the environment and support they need, and trust them to get the job done.*

Along with the acceptance of the sequential waterfall process in the 1970s, a view of the cost of changes to systems over lifecycle phases was popularized that embodied the assertion that the cost of changing software grows exponentially over the lifecycle. In particular, it was orders of magnitude more expensive to make a change during programming (the “coding phase”) than during the earlier phases of design and requirements analysis.

The effect of this diagram was that suddenly those earlier phases took over the central importance. The requirements analyst became a “Very Important Person” in the software process, and an entire discipline of requirements analysis grew up around him. The designer (or, more eloquently, the “architect”) became another Very Important Person, and an entire discipline of software architecture grew up around him. Conversely, the programmer was suddenly much less important. With all the real effort concentrated in the earlier requirements and design phases, the programmer became a mere assistant, transforming the results of the requirements analyst and architect in a mechanical fashion into code. No special skill was needed, because at least in theory, the requirements analyst and the design architect had already done the important work.

After the organizational emphasis in the process-oriented approaches of previous decades, with the agile movement individual programmer came back onto center stage, as DeMarco noted:

Part of our 20-year-long obsession with process is that we have tried to invest at the organizational level instead of the individual level ... If agile means anything to me, it means investing heavily in *individual* skill-building rather than organizational rule sets. (DeMarco and Boehm 2002)

6. *The most efficient and effective method of conveying information to and within a development team is face-to-face conversation.*

Agile methods reversed a trend toward physical separation of software developers from each other. One source of that trend was psychological: the argument that programming was an intellectually intense activity that suffered greatly from interruptions, and therefore, programmers should ideally have individual offices (DeMarco and Lister 1987). Another source was technical:

increasingly dislocated teams through improved telecommunications, for example, through the Internet. In contrast, agile methods view programming as a social activity involving intense interpersonal interaction. This involves the heavy use of colocated teams, with open spaces favoring face-to-face communication. It also implies a small size of development teams—a departure from the ever-growing size of development teams in previous years, for example, through the *software factory* initiatives in Japan (Cusumano 1991).

7. *Working software is the primary measure of progress.*

In the agile approach, an expression often heard is, “The code contains all the answers.” Although this is a simplification, it is a reflection of a return to what the agile perspective perceives as the most fundamental fact of software development: the ultimate purpose of software development is the production of a working system. The working system embodies the results of all requirements, design, and coding activities and is seen as the only truly reliable source of information about the software. This is in direct opposition to a sequential waterfall lifecycle, where significant requirements and design phases are traversed before any code is produced.

8. *Agile processes promote sustainable development. The sponsors, developers, and users should be able to maintain a constant pace indefinitely.*

The principle of continuous delivery espoused by agile methods is supported by considerable emphasis on smooth, well-paced production workflow. Much of this emphasis has taken its inspiration from the experience of the authors of agile methodologies with Japanese production workflow management (such as the Toyota Production Management System). For example, the Kanban technique that has been the subject of much recent interest in the agile community is essentially a technique for smoothing the production workflow and rendering it sustainable over long periods. The emphasis on human factors in agile methods also resulted in a set of principles aimed at avoiding overwork, such as the *40 h week* of XP.

9. *Continuous attention to technical excellence and good design enhances agility.*

In spite of the emphasis on organizational issues in the previous decades, a great deal of progress had also been made in technical areas by the end of the 1990s. In particular, the rise of object orientation had stimulated a kind of Renaissance in software construction techniques. Innovative and highly skilled researchers and programmers had introduced new paradigms such as *architectural styles* and *design patterns*. The agile movement featured small teams of programmers who exploited the technical advances of the past decade (many of which they had authored themselves), to create a highly sophisticated technical environment. New techniques were invented by those in the agile movement to support the concept of “continuous attention to technical excellence”: *refactoring* (Fowler et al. 1999) involved continuous improvement of code, a radical departure from the “if it’s not broken, don’t touch it” philosophy of earlier approaches. Small, targeted tools such as JUnit (Massol and Husted 2003)—codeveloped by Beck, one of the agile signatories—together with a test-first approach supported a sophisticated automated testing environment that provided the immediate feedback necessary to support the resulting continuous interventions in the code base.

10. *Simplicity—the art of maximizing the amount of work not done—is essential.*

Although the need to master complexity in software development through simplicity has been recognized for a long time, agile methods made it into a fundamental principle. Variations on established principles such as Occam’s razor were introduced in precepts such as the The Simplest Thing That Could Possibly Work (i.e., the simplest implementation of a feature) in the XP methodology. New principles were, however, also introduced to support an interpretation of simplicity as the avoidance of unnecessary features. The colorfully named *You Aren’t Going to Need It* (YAGNI) principle in XP (Beck 1999) forcefully discourages the gratuitous

implementation of functionality that, while not explicitly required at the present time, is judged not to be difficult to implement at the present time and might be required or considered useful in the future (Favaro 2004). A concept of “design carry” was coined to characterize the added cost of introducing unneeded features in terms of maintenance, understanding, size of the code base, etc., and make explicit the advantages of simplicity in terms of avoided implementation.

11. *The best architectures, requirements, and designs emerge from self-organizing teams.*

The agile approach to development team organization is in stark contrast to previous trends, in which development teams were characterized by an increasing number of roles, often defined according to lifecycle phases—requirements analyst, chief architect, and V&V specialist (including suitable organizational independence from the development team), together with management-oriented roles such as project leader. Agile methods encourage the establishment of few roles, which often have no direct counterparts in a defined process, such as facilitating roles (e.g., Scrum master) that reflect the self-organizing nature of agile teams: the facilitator’s main duty is to ensure smooth running of the self-organized team, not to impose authority. The self-organizing nature of agile teams introduces a set of issues around the distribution of leadership, authority, responsibility, and accountability—all of which are addressed in various ways in the agile methods—as well as issues with roots in group dynamics.

12. *At regular intervals, the team reflects on how to become more effective, then tunes and adjusts its behavior accordingly.*

Although the idea of “process improvement” was already well established in organizational approaches to software development in the past (Paulk and Curtis 1993), agile methods introduce techniques considered to be more lightweight and suitable for the smaller teams. One technique that has gained considerable currency in recent years is *retrospectives* (Derby and Larsen 2006). A retrospective is a meeting held within a project team at certain points in the project. This may be the end of the project, after a certain number of iterations, or even after a single iteration, to reflect upon what happened during the period of time under consideration and how it could be improved upon. The general concept covered by the retrospective may be found in virtually all the major agile methods, including Scrum, XP, and lean development, where it is also known by different names such as Kaizen and continuous improvement.

84.3 Best Practices

Since the publication of the Agile Manifesto, a number of agile methods have entered into regular use in the software industry (Abrahamsson et al. 2002) and have collectively formed a concrete baseline of best practices in agile development. Those that have had the most significant impact on industrial practice are presented in this section, in particular:

1. XP
2. Scrum
3. Lean software development

In addition, the following also have made contributions that are described in a further section:

4. Kanban
5. Rational Unified Process (RUP)
6. Crystal
7. Personal Software Process (PSP) and Team Software Process (TSP)

The following table presents a summary overview of the general relationship between the principles expressed in the Agile Manifesto and the form they take in the three major methods, as well as other characteristics not explicitly appearing in the Agile Manifesto:

Characteristic	XP	Scrum	Lean Software Development
Principles from the agile manifesto			
1. Customer satisfaction first	Economics as a principle, general concern with business value delivery	Product owner determines priorities according to business value.	Optimize the whole, value stream mapping
2. Welcome changing requirements	“Embrace Change”	Continuous renegotiation of product backlog	More implicit than explicit in lean
3. Frequent delivery	Continuous integration	Sprints	Deliver fast
4. Business and developer collaboration	Onsite customer, negotiated scope contracts	Product owner negotiates with implementation team.	Optimize the whole
5. Motivate individuals	Humanity as a principle, accepted responsibility	Scrum master role to facilitate individual excellence	Engage everyone
6. Prefer face-to-face interaction	Collocated teams, communication as a value	Scrum master interacts directly.	
7. Working software as measure of progress	Test-driven development (TDD)	Partial implementation not acceptable in sprints	Implicit in flow-driven paradigm
8. Sustainable pace	40 h week	Extensive planning and velocity estimation to ensure sustainable pace	Attention to flow
9. Technical excellence	Reduced cost of change due to improved technology		Build quality in
10. Simplicity	Direct counterpart in XP		
11. Self-organizing teams	Collective ownership	Direct counterpart in Scrum	
12. Regular reflection for improvement	Daily stand-up meetings	Daily Scrum, sprint retrospective	Learn constantly, Keep getting better
Other principles			
Continuous flow	Flow as a principle	Scrum master facilitates smooth flow.	Comparison with continuous flow system of manufacturing
Eliminate waste	YAGNI principle		Direct origins in lean
Release planning	Planning game	Planning poker	Value stream mapping, Kanban techniques
Options approach	Baby steps, YAGNI, business options, economics principle	Renegotiation of sprint backlog after each sprint	Last responsible moment, learn constantly

84.3.1 Extreme Programming

XP was developed in the mid-1990s and described in an influential book (Beck 1999). It became a catalyst for much of the discourse around agile methods because of its concise formulation, internal coherence, and “...its interesting name” (Larman and Basili 2003). The name is intended to characterize an approach whereby best practices are applied to an extreme degree (e.g., integration is performed far more frequently than in other methods). It received extensive application in the software industry in the decade following its introduction and has stimulated research on various practices that it introduced. The original edition was followed 5 years later by a second edition (Beck and Andres 2004) that provided additional motivation for the approach underlying the method, in addition to reorganizing and extending the set of principles and practices.

To set the context, XP identifies four so-called *variables* that can be manipulated to control (an agile approach to) software development:

- *Money*: The XP method was an early advocate of actively placing constraints on resources available to projects, noting that although underfinanced projects were problematic, overfinanced projects tended to create problems as well, with bloat in both management and technical structures. This point of view may be found also in lean approaches.
- *Time*: Similarly, XP identifies both lower and upper limits in terms of time management. While too little time will clearly cause problems, likewise so will too much time. The preoccupation with time management refers not only to overall project duration but also to the management of iterations.
- *Quality*: The introduction of this variable in XP recognized that delivered quality can be adjusted according to other factors (e.g., time pressure), but the method also explicitly states that quality cannot be lowered beyond a certain point (an aspect of XP that is often misunderstood). The study of *technical debt* that has become popular in recent years is a reflection of this attention to issues in managing the quality of the delivered software over time.
- *Scope*: The most extreme and (initially) least understood variable introduced by XP is scope, which varies along with the set of requirements during execution of the project. In defined sequential lifecycle methods, scope is defined once, at the beginning. Allowing the scope to vary over the course of the project, with requirements being added, modified, and deleted, creates a series of cross-cutting issues ranging from managerial to technical to contractual, each of which has been studied and experimented within the last decade.

84.3.1.1 Values

Although the operational core of XP is formed by its practices, the method was particularly influential in providing a set of four values that summarized an overall approach to software development and set it apart from previous process-oriented methods. Note that these values were published previously (1999) to the Agile Manifesto (2001), and as such, several of them found their way into its principles in a generalized form.

84.3.1.1.1 Communication

This first value reflects the extreme attention to issues of human interaction in the XP method, which is acknowledged in other agile methods but not treated in as much depth. This value is directly associated with several practices that cannot be carried out without high levels of communication. The second edition of the method (Beck and Andres 2004) added a second author with training in psychology, organizational behavior, and decision analysis, further reinforcing the emphasis on human factors. In this second edition, a new and related value was also added: *respect*, both for one's own work (striving for the highest quality) and for the work of others (e.g., by not undertaking activities that may interfere with the work of other team members).

84.3.1.1.2 Simplicity

Another XP value that was absorbed into the Agile Manifesto concerns simplicity, particularly in design. An incremental approach to design is encouraged, allowing the appropriate architecture to emerge over the course of the project. The interpretation of simple design as also the avoidance of implementation that is not explicitly required is justified in the method with a hypothesis on the evolution of technology:

The software development community has spent enormous resources in recent decades trying to reduce the cost of change—better languages, better database technology, better programming practices, better environments and tools, new notations ... It is *the* technical premise of XP. (Beck 1999)

The hypothesis that the cost of change is no longer exponential but rather a flattened curve underlies the recommendation to keep all current implementation as simple as the current requirements justify, because the prospective value of future functionality, the need for which is uncertain, is outweighed by the reduced technological cost of waiting and implementing functionality only when it is explicitly called for by current requirements. This is supported by the practice of refactoring that contributes to minimizing the current complexity of the implementation.

84.3.1.1.3 Feedback

This value enshrines the concept that concrete, continuous feedback about the current state of the system is necessary and invaluable (Williams and Cockburn 2003). Its primary technical support within the XP method is a practice that was developed by the same author and has acquired a significant following on its own: TDD (Beck 2002), in which unit tests are written before feature implementation. Much of the technology for supporting this practice was developed by the same people who developed XP. In addition to JUnit, codeveloped by Beck, the FIT framework (Mugridge and Cunningham 2005) for automated regression testing was developed by Cunningham, often cited by Beck as a primary inspiration for the XP method.

The primary managerial support for this value is the frequent interaction with the customer provided by the short iteration and planning activities, which deliver business level feedback on the state and direction of system implementation.

84.3.1.1.4 Courage

The main interpretation of this value is “a willingness to abandon a failing activity”—in particular, a willingness to discard code that has already been written if it is unsatisfactory in some way (functionality, performance, maintainability, etc.). An additional interpretation in appropriate contexts is a willingness to try something new.

Many consider the *practices* of XP to be its most important contributions to the agile movement, because they give concrete expression to the principles and values. Indeed, they are often combined with other methods (e.g., Scrum), whereby the management of the overall process may be different according to the approach of the other methods, but the practices (with their origins in XP) are maintained. However, wedged between the values and the practices of XP are a set of *principles* that are intended to provide guidelines for putting the practices into place in the local context of the project and implementation team (Fowler 2003). A number of these principles reflect (or conversely, were the basis for) principles expressed in the Agile Manifesto. Certain of these, however, reflect points of view that either originated in XP or at least receive particular emphasis in XP:

- *Accepted responsibility*: From the first edition of the method onward, an emphasis on placing responsibility squarely on the shoulders of the team and not some externally defined role, signaling a major rethinking of the group dynamics of a software development team.
- *Economics*: From the beginning, XP strove to establish a link to established economic theory. The first edition of the method (Beck 1999) included an entire chapter on the economics of software development, and the principles elaborated in that chapter were maintained into the second edition. These rested on the foundation of the time value of money and in particular an approach in terms of real options. As such, XP was one of the earliest agile methods to promote an options-oriented view of agile development, followed subsequently by other methods such as lean software development (Poppendieck and Poppendieck 2003).
- *Baby steps*: Known as “small initial investment” in the first edition, this principle also reflects the economic perspective of *learning options*: staged investments as uncertainty is gradually resolved over the course of the project.
- *Humanity*: A significant emphasis on human factors, leading to several practices that were popularized by XP.

84.3.1.2 Practices

The first edition of XP contained a tightly interwoven set of 12 practices, all of which were characterized as being essential, which were reorganized (Marchesi 2005) in the second edition into a new set of 13 *primary* practices (can be introduced individually) and 11 *corollary* practices (rely on primary practices for their introduction). Among those practices that have been influential on the evolution of agile software development are as follows:

- *TDD*: This practice has spawned an entire subdiscipline of agile development (Jeffries and Melnik 2007).
- *Pair programming*: While it did not originate with XP (Constantine 1992), the practice of *pair programming*—two programmers developing together, at a single keyboard—was popularized through XP and received much subsequent attention in the published literature including extensive tutorials (Williams and Kessler 2002), experience reports (Dybå et al. 2007), and criticism (Stevens and Rosenberg 2003).
- *Planning game*: Iteration planning is a core practice across all agile methods and as practiced in XP has made a significant contribution to the literature on agile planning, including a book coauthored by the author of the method (Beck and Fowler 2000). In the second edition, the planning process was extended and refined with weekly and quarterly planning cycles with characteristics reminiscent of those (e.g., release planning) in the Scrum method.
- *Collocated teams, collective code ownership, whole team*: With practices such as the collocation of personnel in the same open space, cross-functional teams, and the liberty to change any code written by anybody at any time, XP introduced or reinforced the discussion of many of the group dynamic issues that have dominated the discourse in agile methods. For example, the effects of collective code ownership (called Shared Code in the second edition of the method) have been debated vigorously (Levison 2008) since its introduction.
- *Onsite customer*: The practice of having a representative of the customer organization onsite as part of the development team (or at least available to the team for constant consultation) generated much interest and controversy. Detractors point to the increased cost of providing an onsite customer; supporters point to the advantages of being able to resolve questions about requirements quickly. The practice has inspired much experimentation and research (Koskela and Abrahamsson 2004).
- *Negotiated scope contract*: XP entered early into the discussion of legal issues and contractual issues associated with agile software development. As early as the first edition of the method, optional scope contracts were discussed (Beck and Cleal 1999) in which scope was negotiated, in stark contrast to fixed scope contracts associated with sequential lifecycle development processes. Further interest in agile contract mechanisms was stimulated by this practice and continues (Arbogast et al. 2012).

Other practices such as continuous integration were in use in some organizations before the development of XP—indeed, it has been estimated (Cusumano 2007) that there is an overlap of as much as 70% between XP and the iterative development approach previously in use at Microsoft—but without doubt it was the publication of XP that exposed these practices to a broader audience.

84.3.2 Scrum

Where XP has been responsible for much of the success of agile approaches within the IT *development* community, Scrum may be seen as being responsible for much of the success of agile approaches within the IT *management* community. Although XP has disciplined project management practices, they have had less visibility than the development practices and thereby often led to the perception that XP is a “hacker’s approach.” The project management practices of Scrum, on the contrary, are central in the method. Indeed, Scrum is more properly seen as an agile development *framework*, whereby its project management practices constitute that framework.

Several additional factors have contributed to the relatively broad acceptance of Scrum within the mainstream IT management community:

- Its project management practices have been described in great detail in a number of well-received books (Schwaber and Beedle 2001) that continue to be updated over time (Schwaber 2009).
- The method has been practiced in very visible ways in several leading mainstream IT organizations including Microsoft, IBM, and Nokia.
- A number of commercial and open source tools support the method.
- A number of defined roles, together with programs for *certification* (Scrum Alliance 2012) in those roles, lead to a perception of stability and shared understanding of the method.
- Activities for monitoring progress over the lifetime of a project are codified into the method, leading to an impression of *controllability*, a key concern of project managers.

The method evolved over a period of several years from its origins in Japanese product management in the mid-1980s and a consolidation of multiple independently developed methods by the end of the 1990s. The name *Scrum* is a rugby term reflecting the general idea that the whole team cooperates in the development process.

The method defines a quintessential iterative and incremental lifecycle, serving as a model for an archetypal set of agile project management activities. In addition, the method defines a clear set of roles and their relationships to the activities. The Product Backlog is a prioritized list of *user stories* (essentially equivalent to those of XP) to be implemented by the Scrum team. Much attention has been paid in the Scrum community to the development of guidelines for constructing user stories (Navarro 2010). The Product Backlog is the responsibility of the Product Owner, one of the three core roles. The Product Owner is essentially equivalent to the customer in XP and determines the priorities of the user stories in terms of foreseen business value. The implementation team is self-organizing: there is no “team leader” role.

An implementation iteration is known as a sprint and typically lasts approximately 4 weeks (whereas XP iterations tend to be much shorter). The Sprint Backlog is determined before each sprint in terms of user stories to be implemented during the sprint. The Sprint Backlog is negotiated between the Product Owner and the implementation team and results in a set of stories that the team agrees to implement in that sprint. Note that only entire stories may be implemented—no “partial” implementation of stories is permitted. In addition, the stories are broken down into implementation-related tasks by the team. The Product Owner has no influence on this activity, which is considered wholly the responsibility of the implementation team. Within the sprint cycle, there is a tighter, daily cycle in which the implementation team has *daily Scrum* meetings (equivalent to the *daily stand-up* meetings of XP), discussing current problems and potential issues. Progress is tracked against the scheduled implementation commitments within the sprint.

At the completion of a sprint, a working increment of new functionality is available. A Sprint Review meeting is held in which the results of the sprint are examined. A demonstration of completed functionality is presented to the stakeholders (primarily the Product Owner). The Product Owner decides whether a particular delivered Product Backlog item is acceptable according to specified exit criteria (*Definition of Done* in Scrum terminology). Only completed functionality may be demonstrated. A Sprint Retrospective is held to examine the process and make corrections and improvement.

An important role in Scrum is that of the Scrum master, who is not a team leader (as may be implied by the name) but rather a facilitator, whose job is to ensure that impediments to progress are removed and that the Scrum rules are followed. This role, which is characteristic to Scrum, echoes the ideas of ensuring smooth development flow in other agile methods (such as the “flow” principle in XP second edition and in particular the ideas of Kanban).

In summary, Scrum has had a major role in the penetration of agile approaches into mainstream software development and remains a significant source of agile best practices today. Because of the straightforward, concise definition of the core Scrum framework and a small number of clearly defined core roles, over the span of many years, practitioners have been able to gather concrete implementation experience and then refine and document each of the activities and responsibilities. This has resulted in significant contributions of Scrum to the corpus of established best practices for agile software development, including the following:

- *Sprint planning and estimation*: An essential practice in any iterative and incremental method is iteration planning. As in XP, Scrum practitioners have dedicated many resources to the study and documentation of best practices for sprint planning. Similar to the Planning Game of XP, another “game” (Grenning 2002) known as Planning Poker® (a registered trademark of Mountain Goat Software) provides a technique for estimate consensus building and has been widely documented (Cohn 2005) and discussed in the Scrum community.
- *Sprint management*: There are numerous considerations in managing the actual execution of iterations. The Scrum community has debated the management of sprints at great length including issues such as sprint duration, management of tasks, and dealing with interrupted and unfinished work. Several books (Kniberg 2007) have documented practical experience dealing with such issues and recommended approaches.
- *Tracking*: Much of the popularity of Scrum in the general management community is due to its attention to tracking the results of work in iterations. In addition to recording velocity (the amount of work actually done in a sprint, generally measured in story points or in hours) as an aid to improving estimation, *Burndown Charts*—implemented in many ways ranging from hand-drawn charts to spreadsheets to advanced features of sophisticated Scrum project management tools—track remaining work in a sprint. The practice has been extended to variations deemed useful in overall project management, such as Release Burndown Charts, which track progress against an entire release plan over multiple sprints.
- *Modeling and tool support*: The clear and concise definition of the Scrum process and its associated roles and artifacts (Sutherland and Schwaber 2011) has encouraged the development of more formal models as well as support tools incorporating those models. The overall Scrum framework process and its associated artifacts have been modeled with the Eclipse Process Framework (Eclipse 2012). The clear definition of the process is also an enabler for tool support. Tools supporting Scrum include IBM Rational Concert, Jiri, Microsoft Visual Studio, and Polarion. The Scrum culture has been somewhat more receptive to tool support than the XP culture, leading to broader management acceptance.

Although it emerged out of the object-oriented community, Scrum does not place much emphasis on specific technical practices (indeed, none are listed here). Therefore, it is common to combine the Scrum framework with specific technical practices from XP in industrial projects (Kniberg 2007). It has also been combined with Kanban practices (Ladas 2009).

84.3.3 Lean Software Development

The majority of agile methods in current use were developed by the late 1990s, and most of the authors of those methods were also signatories of the Agile Manifesto in 2001. A later arrival is lean software development, as described in a book (Poppendieck and Poppendieck 2003) whose authors had not been signatories of the Agile Manifesto. In 2003, the concept of “lean” had been in use for nearly 20 years in production management and had resulted primarily from exposure to the Japanese automotive industry and in particular the Toyota Production System, as recounted in Poppendieck and Cusumano, 2012, but its application to software development had not yet been popularized.

Lean software development, as in other methods such as XP, provided a set of *principles* intended to guide the developer in implementing an appropriate lean process in his software development context.

- *Optimize the whole*: This is an appeal to a holistic approach. Consider the whole system, of which software is only a part, when pursuing value creation. Not only the development phase must be emphasized but all of the phases (including design and deployment) that have an impact on value creation.
- *Eliminate waste*: This principle is at the core of a “lean” approach: discover and eliminate anything that does not directly contribute to value creation. In the case of software development, it could be anything from time spent in unproductive meetings to implementation of unused features (as in the YAGNI practice of XP) to time spent debugging. This principle also involves the restriction of work in progress (WIP)—that is, partial, unfinished work.
- *Build quality in*: This principle is essentially an appeal to continuous integration of small development increments and fixing problems as soon as they occur, much like the principle of Single Code Base in the second edition of XP.
- *Learn constantly*: This is an appeal to the *real options* approach seen in agile methods such as XP (Erdogmus and Favaro 2002). Two techniques are recommended: elaboration of multiple alternatives and creating an *option to defer investment* (Sullivan et al. 1999) and creation of a *learning option* through small staged investments (Erdogmus 2002).
- *Deliver fast*: This is an appeal to the metaphor of *flow*, similar to the flow principle in XP second edition. Through seeking an ideal of continuous delivery, software development is no longer seen through a metaphor of a project but rather as a flow system as in manufacturing.
- *Engage everyone*: This principle involves the inclusion of team members reflecting all aspects of value creation, rather than only software development. This may include customer-facing personnel, operations personnel, and appropriate types of support personnel.
- *Keep getting better*: This is an appeal to a general principle of continuous improvement found in many agile methods and the Agile Manifesto itself.

Over the last decade considerable implementation experience has been acquired with lean software development (Kniberg 2011). Lean software development seeks to position itself differently from “mainstream” agile methods such as XP and Scrum (Poppendieck and Cusumano 2012). For example, whereas agile methods define a separate customer role to which responsibility for the overall business success of the product is assigned, lean software development defines no such role but rather considers software development to be integrated in a larger product development under the responsibility of a product manager.

However, Erdogmus argues that the *principles* of lean software development, while often employing different terminology, can be mapped to those of the Agile Manifesto and that the true contribution of lean software development lies rather in its *practices* (Erdogmus 2012).

In this regard, he singles out two main practices. The first is value stream mapping (Locher 2008), which provides a technique for analyzing the information flow across the full product lifecycle and identifying potential sources of problems and waste. The second is Kanban.

84.3.4 Other Methods

The set of methods presented in the previous subsections provide representative coverage of the core characteristics of current agile approaches, but the presented set is by no means complete. In many cases, other methods exhibit different emphases. For example, Adaptive Software Development (Highsmith 2000) and agile project management (Highsmith 2009) focus on management and business-oriented aspects of agile development more than on programming-related issues. The following methods each have special characteristics that merit discussion.

84.3.5 Kanban

Kanban is a system of production control associated with the Toyota Production System (Shingō 1989) and therefore in the software context most closely associated with lean software development. Strictly speaking, it is a practice rather than a method. It represents the “on-demand, pull-oriented” approach of just-in-time manufacturing, in which the signals controlling production propagate backward from customer demand, rather than forward as in more traditional “push-oriented” production control approaches. Kanban (literally “signboard”) cards are used to control and limit the amount of WIP in the overall production system. Kanban seeks to achieve an ideal of continuous flow of production, thereby offering an alternative to the time-boxed, iteration-based workflow management found in most mainstream agile methods (Erdogmus 2012). A number of variations exist, such as “Constant Work in Progress” (CONWIP), a simpler single-stage variant (Spearman et al. 1990). An economic analogy between WIP and the financial tracking measure of *economic profit* is described in Favaro, 2003. In Humble and Farley (2010), technical practices for continuous release of software in production environments are described in detail.

By its nature as a production control practice, Kanban may be used within different agile methods. It forms an integral part of the lean software development approach, of course, but has also been used together with Scrum (much like the practices of XP are used within the Scrum framework) as described in Kniberg, 2007 and Ladas, 2009. A full method has been developed around Kanban (Anderson 2010) for implementing and managing flow-based software development. It includes a set of core *practices* that are based upon those observed in successful Kanban systems (visualize, limit WIP, manage flow, make policies explicit, implement feedback loops, improve collaboratively, and evolve experimentally).

84.3.6 Crystal

The author of the Crystal software development method was a signatory of the Agile Manifesto. While having much in common with other agile methods, Crystal distinguishes itself in being a “family” of methods (known as Crystal Light) in the sense that it is explicitly tailored in two dimensions: project scale and criticality. In the scale dimension, the Crystal Clear variant is intended for projects of 2–6 persons, Crystal Yellow for 6–20 persons, and Crystal Orange for 20–40 persons (Cockburn 2001). Thus, it was an early method to take into explicit account the problem of scaling agile methods. Even more notable is the second dimension of criticality, which is segmented according to the consequences of system malfunction: loss of comfort, loss of discretionary money, loss of essential money, and loss of life. This scale constitutes an informal version of an *integrity level* scale seen in most modern standards for mission-critical systems, such as the Safety Integrity Levels (SILs) of the IEC 61508 standard (IEC 2010) for electrical and electronic systems. In the Crystal Light family, this informal scale is described as corresponding to “hardening” of the method according to increasing degrees of criticality. This approach corresponds roughly to the way in which standards such as IEC 61508 prescribe increasingly rigorous practices in the development process according to the SIL of the item under development. As such, the Crystal family can be seen as one of the earlier methods to attempt to explicitly address the problem of adapting the agile approach to the development of mission-critical systems.

The best-documented member of the Crystal Light family is Crystal Clear (Cockburn 2004).

84.3.7 Rational Unified Process

The RUP was developed in the 1990s at Rational Software Corporation (Kruchten 1998). Although it was not developed specifically as an “agile method” (none of its authors was a signatory of the Agile Manifesto), it presents an iterative and incremental approach to software development and may be used in a way that is fully compatible with the principles expressed in the Agile Manifesto. Analogous to Scrum, the RUP is more properly a process *framework* (rather than a single, specific process) that is intended to be tailored and instantiated for a specific implementation context, while selecting from a large number of provided practices. In this respect, it has been criticized for being so flexible that anything from an iterative, agile

process to a pure sequential, waterfall process can be accommodated. Nonetheless, the intent behind the framework was clearly to support iterative development, as may be seen in the four defined lifecycle phases:

- *Inception*: This is primarily a phase in which the business case and feasibility studies for the project are developed.
- *Elaboration*: In this phase, an architecture is established for the system under development. In some respects this is the most characteristic, distinguishing phase of the method. The *architecture-centric* nature of the RUP has been a stimulus for much discussion about the relationship between agile development and architecture and has also been the source of some criticism that the RUP encourages excessive up-front design.
- *Construction*: In this phase, the system is constructed (following the architecture) in a series of iterations.
- *Transition*: This phase consists essentially of transitioning the system from development to production and deployment.

Within these phases, a number of activities are carried out inside a set of nine predefined disciplines: business modeling, requirements, analysis and design, implementation, test, deployment, project management, configuration and change management, and environment.

Like many agile methods such as XP and lean, the RUP also provides a set of guiding principles, or best practices, to guide the application of the method:

- *Develop software iteratively*: An explicit appeal to iterative and incremental development.
- *Manage requirements*: The authors of the RUP pioneered the use case approach to development that is the heritage of the user story-driven approach of agile methods. This principle has sometimes been misinterpreted to favor pure up-front requirements definition.
- *Visually model software*: The coauthors of the Unified Modeling Language were strongly associated with the RUP and bring a strong bias toward visual modeling into the method.
- *Verify software quality*: The same strong emphasis on continuous assurance of high quality seen elsewhere in agile methods.
- *Control changes to software*: This principle is in the same spirit of “embracing change” as expressed in the Agile Manifesto, whereby constant change is expected and mechanisms are provided to protect the system integrity under change.

Despite criticisms from the agile community regarding its “purity,” the RUP has been an important instrument for introducing best practices of iterative and incremental development into the broader software engineering community. It has consolidated tool support such as the Rational Method Composer (IBM 2013) and has been introduced in many large organizations (Sägesser et al. 2013). Its clear definition has made it possible to define variants with a more specifically agile flavor, such as Disciplined Agile Delivery (Ambler and Lines 2012).

84.3.8 Personal Software Process and Team Software Process

The PSP was developed at the SEI in 1993 (Humphrey 2005) and followed by the TSP in 1998 (Humphrey et al. 2010). As such they are precedent to the Agile Manifesto and most current agile methods. Nevertheless, the PSP represents an early attempt to provide a process oriented toward the individual—a fundamental characteristic associated also with agile approaches. Its emphasis on use of concrete data to drive schedule prediction is also reminiscent of the emphasis on feedback in agile methods. Finally, it emphasizes individual accountability as in agile methods. TSP includes PSP-trained individuals in a team process in which product development may be iterative, another fundamental characteristic of agile approaches. It also includes an emphasis on *self-directed teams*, exhibiting respect and responsibility within its membership, reminiscent of the self-organizing teams of the principal agile methods. PSP and TSP thus represent an interesting variant coming from (and trademarked by) a source normally associated with so-called heavyweight processes.

84.3.9 Discussion

Agile methods as exemplified by those presented in this section (in particular the first three methods) have established themselves within the mainstream of software development. Over the last decade, one of the principal issues addressed by practitioners has been their relationship to the methods that preceded them. Shortly after the publication of the Agile Manifesto, analyses began to appear that sought to compare and contrast them to these other methods. In Boehm and Turner, 2004 a distinction between *agile* and *plan-driven* methods was made, and a “home ground” was identified for each in which its application was more suitable, according to four project characteristics:

- *Application*: Rapid value delivery, small teams, and turbulent environment (agile home ground) versus predictability, stability, high assurance, larger teams, and stable environment (plan-driven home ground)
- *Management*: Dedicated onsite customers, internalized plans, and tacit knowledge through interpersonal communication (agile home ground) versus as-needed customer interaction, documented plans, and explicit documented knowledge (plan-driven home ground)
- *Technical*: Prioritized informal stories changing in unforeseeable ways and simple design in short increments with refactoring (agile home ground) versus requirements with foreseeable evolution and extensive design in long cycles (plan-driven home ground)
- *Personnel*: Collocated, high percentage of highly qualified personnel throughout project, and thriving on chaos (agile home ground) versus concentration of highly qualified personnel in early stages with lower-level personnel later, not always collocated, and thriving on order (plan-driven home ground)

A risk-based strategy for balancing agile and plan-driven approaches according to the characteristics of projects is presented in Boehm and Turner, 2003.

For many, the iconic plan-driven approach is represented by the Capability Maturity Model Integration (CMMI) of the SEI (2012), and it has been often remarked that agile methods arose as a reaction against the CMMI. Seven years after the signing of the Agile Manifesto, the SEI published a report (Glazer et al. 2008) that argued forcefully that the perceived incompatibility of CMMI and agile methods is unwarranted and largely due to misunderstandings of the nature of each approach. The report stresses that CMMI is fundamentally a model rather than a process standard, as viewed by many agile proponents, and its rich set of mechanisms for facilitating process improvements has great potential to contribute to a fully compatible agile process. It cites a number of cases (Sutherland et al. 2007) in which CMMI and agile methods have been integrated successfully. The discussion of the relationship between plan-driven approaches and agile approaches is likely to continue in the foreseeable future. In any case, in 2010 the US Department of Defense issued a report (USDOD 2010) recommending that the department’s IT procurement policy be modified to promote development practices that are fully compatible with the Agile Manifesto—a strong indication that agile methods are here to stay.

84.4 Research Areas

Since the publication of the Agile Manifesto, there has been vigorous research activity in agile software development. A literature survey in Dingsøyr et al., 2010 reports that from 1997 onward, several hundred papers were published in countries all over the world. Although the single country with the largest number of publications was the United States, Europe constituted the largest overall source when the countries comprising Europe were taken collectively. A systematic review (Dybå and Dingsøyr 2008) of empirical studies of agile software development reported on four broad thematic groups:

- *Introduction and adoption*: Most empirical studies tend to report that agile methods are easy to adopt, although XP was found to be difficult to introduce in organizations of higher complexity.

- *Human and social factors*: Not surprisingly, given the human-centered character of agile approaches, many studies focus on various specific human factors. Interestingly, XP was found to work well in many very different kinds of development environments.
- *Perceptions of agile methods*: Many studies focus on perceptions of agile from the point of view of different stakeholder groups (e.g., architects). Customers in general were found to be satisfied with feedback opportunities but less satisfied with demands for onsite customer involvement. Satisfaction among developers using XP was generally found to be high.
- *Comparative studies*: Studies of agile methods against other approaches (e.g., waterfall) have tended to find that methods such as XP increase productivity.

Despite positive results such as the last one cited earlier, the authors concluded that more empirical studies of agile software development are needed, within a broader and more complete research agenda. Research in specific areas is discussed in the following sections.

84.4.1 Role of Architecture in Agile Software Development

The 1990s were a period of great advances in the discipline of software architecture (Shaw and Garlan 1996), and methods developed during that period such as the RUP were characterized as explicitly *architecture-centric*. Ever since the characterization of architecture as *emergent* within agile software development was coined, however, controversy has surrounded its role within agile methods. The de-emphasis of Big Design Up Front in agile methods seemed to exclude the possibility of architecture-centric approaches in agile methods. In Abrahamsson et al. (2010), it is suggested that much of the controversy may be due to underlying misunderstandings, since authors of several major agile methods have incorporated concepts that reflect a positive attitude toward architecture, for example, “divisible system architecture” of Poppendieck and Poppendieck (lean software development), the “walking skeleton” of Cockburn (Crystal), and the “system metaphor” of Beck (XP).

Some recent research has been oriented toward making the effects of architecture on agile development more explicit (Madison 2010). In Nord et al. (2012), the use of a Kanban board within a lean development process is described as a technique for rendering more visible how architecture either supports or inhibits throughput.

In Falessi et al. (2010), researchers from the University of Rome and the Italian Ministry of Defense collaborated with practitioners from IBM to conduct an exploratory study of attitudes of professional developers who use agile methods toward software architecture. They found that overall, agile developers consider software architecture to be relevant and important to their work; in particular they displayed a favorable attitude toward such practices as the use of architectural design patterns. Conversely, however, they found that those not practicing agile development were more likely to find architecture approaches to be in contrast with agile approaches. Thus, the controversy over their compatibility is likely to continue in the future, both in research and in practice.

84.4.2 Human Factor Research

Given that the very first principle of the Agile Manifesto emphasizes “individuals and interactions over processes and tools,” it is not surprising that much research in agile software development has concentrated on human factors. An early ethnographic study (Sharp and Robinson 2004) of XP teams noted that “we seek here to explore the values, beliefs, and assumptions that inform and shape agile practice and ... to explore the manner in which a community of agile developers sustains itself.” In Robinson and Sharp (2004), several human characteristics of XP teams are identified and discussed: respect, responsibility, quality of working life, faith in abilities, and trust.

Within university environments, courses on human aspects of software engineering began early to present case studies in agile development methods (Hazzan and Tomayko 2004). Interdisciplinary

approaches to the study of agile human factors were also introduced. In Falcone and Favaro, 2003 an environment called the Agile Theater is described in which classical techniques of theatrical improvisation were used to teach and explore interactions and roles in agile development teams. Agile Theater sessions with experienced developers revealed that, without exception, the continuous exchange of roles, interaction of participants, and conflict development and resolution always brought out a discussion of the problem of leadership in agile teams. The issue of roles in agile teams was also studied in Dubinsky and Hazzan 2004, which concluded that adding a specific role for each member of an agile team beyond normal technical responsibilities augments the sense of personal accountability and responsibility in the individuals.

Extending earlier interdisciplinary work concerning creativity in requirements engineering (Maiden and Robertson 2005)—in which experts were brought into an air traffic control environment from fields as diverse as railway signaling, oriental textiles, and cooking—Maiden and Hollis (Hollis 2011) performed research on creativity in agile development. Calling into question a common assumption that agile development automatically produces innovative solutions (Oza and Abrahamsson 2011), they embedded creativity techniques into a full agile software development process—specifically, within Scrum, during the envisioning process and at the beginning of selected sprints containing those epics with the most potential for creative outcomes. A case study was performed in a BBC Worldwide project, with results indicating that more novel requirements were generated through the extended epic process.

In XP, collective code ownership is associated with many benefits. A study at Microsoft (Bird et al. 2011) examined the relationship between different measures of ownership and software failures in Windows Vista and Windows 7 development. The study distinguished different levels of ownership (major versus minor contributor to components) and found that strong ownership is indicative of higher quality—which may contradict the usual claims for the benefits of collective ownership.

The colocation of development teams is a cornerstone of agile approaches, but strong business motivations (e.g., offshoring) exist for distributed development; consequently, the effects of distributed development on agile teams have become a subject of research. An overview of the challenges encountered in distributed agile development is provided in (Kajko-Mattsson et al. 2010) in which six classes are identified: culture, time zone, communication, customer collaboration, trust, and training and technical issues. The specific problem of trust in distributed agile projects is also discussed in Dorairaj et al. 2010, while the problem of communication is discussed in Dorairaj et al. 2011. Techniques for supporting multisite and offshore Scrum development are presented in Larman and Vodde 2010.

84.4.3 Agile Development of Mission-Critical and Embedded Systems

Agile software development methods had their first successes within environments exhibiting high interactivity (e.g., web-based systems) and changing often malleable requirements. They were largely ignored in mission-critical and embedded systems environments, due to a perceived lack of compatibility. However, as the benefits of agile development were publicized, practitioners and researchers began to search for suitable adaptations of agile approaches for these environments. An early example is (Fredriksen 2002), in which a mapping of the RUP to the IEC 61508 standard (IEC 2010) for development of safety critical software for electronic systems was made as part of a research initiative and found to be feasible.

In Smith et al. 2009 an adaptation of XP to a lifecycle for the development of embedded medical instrument software is described. It was noted that significant adaptation of XP was required, which may even lead to challenges to its claim to be still an agile approach. A prototype TDD embedded system test framework called Embedded Unit was developed by the researchers. Another example of applying TDD to embedded systems software development is Grenning 2011. A full methodology is developed in Douglass 2009.

A survey of the state of the art in the use of agile methods for embedded systems development (Srinivasan et al. 2009) classified the major challenges into two categories with six areas:

- *Technical*: Requirements management, testing
- *Organizational*: Process tailoring, knowledge sharing and transfer, culture change, support infrastructure

Future research is likely to be concentrated in these areas.

84.4.4 Economics of Agile Development

Given the explicit commitment of agile methods to the delivery of business value, it is natural that there would be a great interest of researchers in the economics of agile software development.

The exhortation in the Agile Manifesto to “welcome change” positions agile methods in the area of economic research known as *decision theory*. In Drury et al. (2012), research is described that analyzes the decision-making process over the iteration cycles of several real-world projects and identifies six obstacles to decision-making (an example is “unwillingness to commit to decisions”) in agile development and then maps those obstacles to descriptive decision-making principles to analyze their impact.

Even more narrowly, agile methods are positioned at the heart of decision theory in the area known as *decision-making under uncertainty*. Because of this, the relevance of *real options* was recognized early (Favaro 1999), and a treatment of the YAGNI principle as an option to defer investment appeared in the first book on XP (Beck 1999). Several other real options associated with agile development were subsequently analyzed (Erdogmus and Favaro 2002), and lean software development (Poppendieck and Poppendieck 2003) promoted a real options approach to decision-making, singling out the *option to defer* and introducing an informal characterization of this real option as decision-making at the “last responsible moment.” Another discussion of agile decision timing and delay is provided in Favaro (2003) using the “tomato garden” metaphor of Luehrmann. The integration of the concept of the last responsible moment and a general real options approach to architectural decision-making in agile development is described in Blair et al. (2010) as responsibility-driven architecture.

Given the intersection of human factors and economics in agile methods, interest has recently been growing in the relationship of some branches of behavioral economics to agile software development. An early investigation is represented by Erdogmus (2009) in which the application of *diversity* (Page 2007) to the formation of cross-functional teams (as seen in agile methods like Scrum) is discussed. The author draws on diversity theory to conclude that a diverse group of average yet sufficiently competent people will often outperform a homogeneous group of star performers who have overlapping skills. Nonetheless, the caveat is provided that a single top expert will still perform better on average than a not-so-wise group—and thus, competence management in cross-functional agile teams remains relevant and important.

Within behavioral economics, prospect theory (Kahneman 2011) has been perceived as particularly relevant due to its emphasis on the psychological foundations of decision-making under uncertainty. In Makabee (2012), the planning fallacy of prospect theory is studied as a source of insight into why planning estimates in Scrum are often significantly inaccurate. The fourfold pattern of prospect theory is discussed in Favaro and Erdogmus (2012), in the context of the tendency to undertake desperate measures to salvage projects that are failing, rather than adopting the agile values of “courage” and “celebrating failure.” The concept of *high-validity environments* is also discussed as a prerequisite for reliable expert intuition, and it is hypothesized that a primary effect of agile development practices such as continuous feedback and integration is to move software development toward a high-validity environment in which expert intuition can develop reliably.

84.4.5 Technical Debt

Technical debt refers to the quick implementation and delivery (e.g., to meet time pressure) of a feature while sacrificing quality, with a promise to remediate at some later point. Although technical debt has become a concern in general software management, it is closely associated with the agile movement both in origin and practice. The expression was coined by agile pioneer Ward Cunningham (Cunningham 1992), and indeed it has been remarked (Bavani 2012) that technical debt is central to the definition of agile itself. Other authors from the agile community (Fowler 2009) have written extensively about technical debt (Gat 2010).

It is studied most frequently in the context of agile project management because of its natural affinity to iteration-oriented development (Sterling 2010). An appeal was recently made (Kruchten et al. 2012) to the research community to establish a theoretical basis for the concept of technical debt that goes beyond the current *ad hoc* definition as a metaphor.

84.4.6 Measuring and Quantifying Agile Development Practices

Agile software development has been presented by proponents as a more effective alternative approach to previous software development methods, but the evidence has often been anecdotal. Likewise, the evidence for comparative effectiveness *among* agile methods themselves has often been mostly anecdotal.

One early exception was a series of empirical investigations of the effectiveness of *pair programming*. An empirical study was undertaken by Williams et al. 2000 in which it was determined that pairs spent on average 15% more total effort than solo programmers to complete the same programming tasks, but that code written by pairs on average passed an additional 15% of the specified acceptance tests. This study was followed by another (Erdogmus and Williams 2003) that concluded that pair programming long-term productivity could achieve a 30% advantage over productivity of solo programmers. Overall, all such studies found that pair programming is costly in the short term but appears to exhibit a quality advantage for complex tasks (Dybå et al. 2007). Notwithstanding, with regard to the effectiveness of pair programming, Wray (2010) points to the need for further experimentation, noting that “we are no longer in the first flush and the pros and cons seem farther apart than ever.”

Another subject of numerous empirical studies is TDD. As noted in Turhan et al. (2010), TDD “... is one of the most referenced, yet least used agile practices in industry.” An early study was conducted by Erdogmus et al. (2005). A subsequent (Turhan et al. 2010) systematic literature review focused on studies that evaluated TDD with respect to productivity, quality, and test support. Their findings, summarized in Shull et al. (2010), concluded that there is moderate evidence in favor of TDD. More recent studies (Rafique and Misić 2012) report similar conclusions—for example, that TDD appears to support quality improvement with more complex tasks.

With the emergence of *evidence-based software engineering* (Dybå et al. 2005), anecdotal claims regarding effectiveness of agile methods began to come under the closer scrutiny of researchers. For example, one of the key premises underlying claims of the superiority of lean software development approaches is the literature on Japanese automobile manufacturing successes (Womack et al. 1990). But Dybå and Sharp (2012) point out that the evidence for the claims made in that literature is open to valid alternative interpretations that potentially diminish their strength considerably.

As a consequence of the trend toward evidence-based software engineering research, in recent years the research community has undertaken numerous initiatives to measure and quantify the effects of agile practices in particular and agile development in general, along several dimensions. In Sjøberg et al. (2012), an initiative is described in which the comparative effectiveness of the use of the Scrum and the Kanban approaches is investigated using data gathered from more than 12,000 work items produced over a period of 3 years. In the study described, an organization almost halved its lead time after replacing Scrum with Kanban, improved its productivity, and reduced the number of weighted bugs by 10%. The authors provide several caveats regarding interpretation of the results, including the fact that

introducing Kanban after Scrum may have introduced a bias toward Kanban because the development professionals were more familiar with agile software development by that time.

One of the largest ongoing initiatives to measure the comparative effectiveness of agile software development methods based upon industrial project data is that of QSM, an early pioneer in software estimation and benchmarking. QSM has collected industrial project data continuously since 1978, compiling a database with validated data from over 10,000 projects suitable for comparative benchmarking. Its Software Lifecycle Model (SLIM) (Putnam 1978) provides input project data parameters of *time*, *size*, and *effort*, which were reinterpreted in an agile context in order to enable data collection for agile projects. For example, size is estimated through stories, story points, and lines of code; development effort is modeled as one estimate with milestones for the iterations, or alternatively each iteration may be an estimate. An initiative of the Central Ohio Agile Association and QSM over the 2012–2013 time frame (QSM 2012) within a specific industrial community (Columbus, Ohio) yielded benchmark data indicating that the agile projects included in the study exhibited defect data that are significantly better than industry averages, with a 30% improvement in completion rate over industry norms.

84.4.7 Conclusions on Agile Research

In Dingsøy et al. (2012), the observation is made that the research community has been very active ever since the publication of the Agile Manifesto, with over 60 countries contributing to the corpus of research, in numerous special issues of reputable journals, dedicated conferences, and many books, including best sellers in the software engineering market. But the observation is likewise made that researchers are still not paying enough attention to establishing the theoretical underpinnings of agile development and its associated practices. The establishment of these theoretical underpinnings as a basis for solid, effective future research remains of the most urgent themes in agile software development.

84.5 Summary

The so-called agile movement in software development began with the publication of the Agile Manifesto in 2001. Although agile methods were already in use by that time, the Agile Manifesto coined the term and codified its characteristics through twelve principles. The agile movement was widely seen as a reaction to rigid, sequential, defined processes of the previous two decades. The iterative and incremental approach embodied in the agile movement, however, had deep roots in practices that had been proposed at various times throughout the history of software engineering.

Two agile methods in particular are emblematic of industrial best practices in the decade following the publication of the Agile Manifesto. XP offered a concrete set of core practices that exemplified the quintessence of agile software development practice and was well received by programmers. Scrum provided a framework for the overall management of an iterative and iterative development project that was well received by managers. In parallel, methods such as lean software development brought a flow-based character into the movement, later strengthened by the introduction of Kanban. Several analyses appeared over the decade comparing the appropriateness of agile approaches versus more traditional plan-driven approaches in different environments.

Academic research in agile methods began in earnest even before the publication of the Agile Manifesto. Human factors and economic aspects were consistent research topics from the beginning. Agile methods in demanding environments such as critical embedded systems became another research topic, as well as the problem of understanding the role of architecture in agile software development. There has been a steady increase in publication of empirical studies of pre- and post-adoption impact of agile methods.

In February 2011, on the tenth anniversary of the publication of the Agile Manifesto, ten of the original signatories provided commentary (Hunt et al. 2011) on its impact on software development during the intervening decade. Although there was general agreement that the Agile Manifesto and the principles and practices it embraced had significantly affected the software engineering community, there was likewise general disappointment that the agile approaches had not been adopted to the expected degree. In particular, the observation was made that the processes and practices of agile approaches had been implemented by too many practitioners in a slavish and formulaic manner, reflecting a fundamental misunderstanding of the word “agile.” Thus, the adoption of agile methodologies as envisioned by the signatories of the Agile Manifesto remains a challenge even today for the software development community.

Key Terms

The agile vocabulary is vast and as varied as the number of agile methods. The following glossary contains terms that are important to understanding agile approaches and/or common to several methods.

Backlog: In Scrum, those tasks or stories that will be worked on in the future.

BDUF: Big Design Up Front. Refers to the practice of designing a system before any implementation has begun, in contrast to the emergent design approach of agile methods.

Burndown chart: A technique in Scrum to track and display work remaining to finish.

Continuous integration: An approach to software development that involves frequent integration of individual work into the whole system. Generally this occurs at least daily.

Daily stand-up: Agile methods often encourage short daily meetings to report on progress and plan future actions. They are often held while standing up in order to discourage a long duration.

Epic: In Scrum, a large user story that eventually is partitioned into smaller stories.

Iteration: A period (ranging from days to 2 months) in which an agile team implements an increment of functionality.

Kanban: Japanese, roughly translates to “signboard.” A technique generally associated with lean software development, for visualizing work in progress.

Pair programming: An agile practice in which two programmers share a single workstation, with one acting as coder and the other as reviewer or “navigator.”

Refactoring: Rewriting of code to improve its design and maintainability. Generally the refactoring actions are small and local.

Retrospective: A meeting at the end of an iteration (or entire project) in which the team considers what could be improved. A way to implement process improvement in agile methods.

Scrum: Rugby term regarding a method for restarting play after an infringement. Refers to teams huddling together in a group. Used as the name for the agile method.

Spike: An investigation of feasibility outside the normal flow of work.

Sprint: An iteration in the Scrum agile method.

Story: A description (usual textual) of a feature to be implemented. May be seen as a compact version of a use case.

TDD: Test-driven development. An approach to coding that involves first writing a failing test and then writing the code that makes the test succeed.

Timebox: A fixed duration, with reference to the length of an iteration in agile development.

Velocity: A measure of the speed at which an agile team completes its work, usually the number of stories in an iteration.

WIP: Work in progress—a concept in particular from lean software development. Work that has been incurred but not yet delivered to the customer.

YAGNI: You Aren’t Going to Need It. Refers to an XP practice of not implementing a feature for which a firm requirement does not yet exist.

85.1 Introduction

In software engineering, service-oriented development, or service-oriented development of applications (SODA), is a process and activity of developing applications and systems based on service-oriented architectures (SOA). The concept of SOA has received significant attention in the software architecture and development field since the early twenty-first century. SOA is a type of software architecture based on using services available on a network. The fundamental building blocks of the system are services. Services are commonly viewed as self-contained software application modules exposed through interfaces over a distributed environment. The consumers of these services are not end users but rather software applications.

SOA has been emerging as a major integration and architecture framework in today's complex and heterogeneous computing environment (Mahmoud 2005). It represents "a paradigm for organizing and utilizing distributed capabilities that may be under the control of different ownership domains" (MacKenzie and Laskey 2006). Compared with other architecture styles, SOA has the following features and benefits:

- Services have well-defined interfaces that are independent of its implementation. Thus, the clients are primarily concerned with what the services will provide rather than how these services will execute their requests.
- Services are loosely coupled for greater level of flexibility and reuse.
- Services can be dynamically discovered.
- Composite services can be built based on service aggregation.

Service-oriented development has evolved along with a number of computing and software development fields, which have directly or indirectly contributed to the development of SOA and in turn been impacted by SOA.

85.1.1 Component-Based Software Engineering or Component-Based Development

Component-based software engineering (CBSE), or component-based development (CBD), is a branch of software engineering that emphasizes the building of applications based on software components (Wang and Qian 2005). A software component is a reusable piece of code that encapsulates a set of related functions and data and communicates with other parts of the system via interfaces. The concept first became prominent with Douglas McIlroy's NATO conference address on software engineering in 1968 (Mcilroy 1969). The approach is characterized by reusability, development focusing on defining, implementing, and composing loosely coupled independent components into systems. Popular implementations of components include Enterprise Java Beans and web services. Software components are considered to be part of the emerging platform for service orientation. Services can be built from service components and inherit further characteristics that were not part of an ordinary component.

85.1.2 Distributed Computing and Components

Distributed computing is a field that studies distributed systems that consist of multiple autonomous computers that communicate through a computer network. A computer program that runs in a distributed system is called a distributed program or application. Components then can be accessed and used by multiple programs across multiple computers. The significance of the change is the way of communicating with components over the network. The major change of the environment leads to major changes on interfaces and communication protocols and other issues like persistency, state, and synchronization. Microsoft's DCOM and OMG's Common Object Request Broker Architecture (CORBA) are two major architectures supporting the distributed components.

SOA can be viewed as an evolvement of distributed components to a more generic and loosely coupled level. In some cases, they are similar. For example, both services and components could support abstraction (component via an interface, service via a contract) and thus with loose coupling. But component-based architecture (CBA) and SOA are different:

- CBA is based on component models and technologies. There is no universally accepted component standard up to the present (Szyperki 2002).
- SOA is at a higher level and CBA is more dependent of detailed implementation and bind to a framework/environment (Sessions 2004). Both SOA and CBA are similar in principle, but they are different in implementation.
- It is difficult for component-based systems to work over Internet firewalls as they usually use nonstandard ports.

85.1.3 Web Services

A web service is a software program designed to support interoperable machine-to-machine interaction over a network (Haas and Brown 2004). It is also built based on the software components exposed through standard web interface called services. Web services play a pivotal role in a majority of SOA initiatives and are supported by the major development tool and enterprise package vendors (Haines and Rothenberger 2010). However, web services itself are not equal to SOA. It is one implementation that can realize an SOA.

An SOA may be realized with technologies other than existing web services standards. However, web service has been the most promising technology for SOA and for the foreseeable future (Vogels 2003).

85.2 Underlying Principles

Software development involves several stages such as analysis, design, implementation, testing, integration, and maintenance. There are many different paradigms to develop software, each with its strength and limitations. These paradigms could also be called software development styles, approaches, methods, or principles, because each paradigm defines uniquely its own approach to conducting and producing system requirements analysis, system architecture, implementing language and environment, testing methodology, and maintenance activities. For instance, object-oriented software development uses “object” as a fundamental concept during development process. The key of object-oriented development is to identify objects and specify objects during the analysis phase, design a hierarchy of objects with well-defined relationships, and implement those objects with high-performance code. Another example is component-oriented development, which is similar to object-oriented development but more general and more powerful in terms of software reusability and granularity. A component is a self-contained and self-deployable unit, while an object is self-contained but not self-deployable.

Service-oriented development is a new software development paradigm, which has its own system specification language, its own system design approach, and its own implementation and testing methodology. In a service-oriented development process, all development activities evolve around the central concept called “services.” A service is a software component, a piece of self-contained, self-deployable computer program with well-defined functionality and can be integrated with other services through its interface. Therefore, service-oriented development can be viewed as a special case of component-oriented development, if we recognize services as reusable components.

With the advances of technologies in computing and networking, software development has evolved from machine-code programming, structured programming, object-oriented programming, to component-oriented programming. Software components are interchangeable units encapsulating functionality and providing services through well-defined interfaces. A service is a software component. Thus, the underlying principles of service-oriented development follow the principles of component-oriented development. This section introduces some general principles of service-oriented development, followed by a detailed discussion of “service infrastructure,” including principles and models for service-oriented development.

85.2.1 General Principles for Service-Oriented Development

85.2.1.1 Principle 1: Services Represent Decomposition and Abstraction

The basic and effective strategy for tackling any large and complex problem in software development is “divide and conquer.” One major idea in service-oriented development is to create software modules that are themselves self-contained and independently deployable. Thus, different developers will be able to work on different services independently, without needing much communication among developers, and yet the services will work together seamlessly. In addition, during software maintenance phase, it will be possible to modify some of the services without affecting all of the other services. When we decompose a system, we factor it into separable services in such a way that each service is at the same level of details; each service can be solved independently; and the implementations of these services can be integrated to satisfy the original system requirements.

Abstraction is a way to do decomposition productively by changing the level of detail to be considered. Service components hide certain details in an effort to provide only necessary information to the clients through their interface. The strategy of abstracting and then decomposing is typical in software development process.

85.2.1.2 Principle 2: Reusability Should Be Achieved at Various Levels

Software exists in different forms throughout the software development process. At the modeling and analysis phase, the requirements specification is seen as a form of software. In the design phase, architectural design and detailed design documents are part of the software. Source code and executable code deployed to the customer site are certainly software. Therefore, software reusability includes the reuse of any software artifacts in various forms. In service-oriented development, there are five forms of software components, namely, service specification, service interface, service implementation, installed services, and service objects. Each form of the service components could be reused in different stages of software life cycle.

85.2.1.3 Principle 3: Service-Oriented Development Increases the Software Dependability

The dependability of a computing system relies heavily on the trustworthiness of its software part, as opposed to its hardware part. Service-oriented development provides a systematical way to achieve dependable systems. Owing to the abstraction of services and systematic integration of services, it is much easier to validate critical requirements and verify safety for the service-based systems. On the other hand, reusable services have usually been tested through the validation process and real usage for a long time and, therefore, their quality can be assured.

85.2.1.4 Principle 4: Service-Oriented Development Could Increase the Software Productivity

Service-oriented software is constructed by assembling existing reusable components rather than developing from scratch every time—reuse instead of reinventing the wheel. This process is much faster than developing an application from scratch in most cases.

85.2.1.5 Principle 5: Service-Oriented Development Promotes Software Standardization

Service standards must be in place before a mature service market in software industry. Standards can be used for creating an agreement on concrete interface specifications, enabling effective composition, and ensuring service-oriented development to be a new programming paradigm in which “plug and play” becomes a reality in software development just like the hardware counterpart.

85.2.2 Service Infrastructure

A service infrastructure is the basic, underlying framework and facilities for service construction and service management. It consists of three models:

1. A service model
2. A connection model
3. A deployment model

A service model defines what a valid service is and how to create a new service under the service infrastructure. Service developers build reusable services according to the service model. Each service infrastructure has a reusable service library containing building blocks conforming to the service model. The connection model defines a collection of connectors and supporting facilities for service assembling. Thus, the connection model determines how to build an application or a larger component out of existing services. The deployment model describes how to put service components into a working environment. The deployment model deals with all issues related to service distribution and maintenance.

85.3 Best Practices

The concept of SOA has been around for more than 10 years. The field is matured with abundant best practices, design patterns, software products, development methodologies, and standards. In this section, we select and discuss some important practices: using reference architectures, adopting enterprise service bus (ESB), choosing service interface style, and adjusting development activities.

85.3.1 Reference Models and Architectures

SOA is just a general architecture style or paradigm that can lead to various different implementations. In the earlier years, even the understanding of basic SOA concepts and terminologies was inconsistent. Eventually many people realized that it is important to agree on a common understanding of basic concepts and semantics that can be used across different implementations. Reference models and ontologies (MacKenzie and Laskey 2006; The Open Group 2010) have been developed for this purpose. On top of that, reference architectures have been developed to provide high-level architectural that can be used as the basis of many implementations. The reference architectures incorporate the best practices and design patterns of developing SOA systems. Utilizing these reference architectures has a number of benefits:

- They can be used to set the context for a system, to provide a common foundation of understanding for developers and users to map products to and design services for, and to articulate a set of building blocks for solutions (Kreger et al. 2012).
- Reference architectures help produce well-designed system (in both technical and business perspectives).
- Reference architectures can shorten development cycles and increase software productivity.
- Reference architectures can reduce development cost and improve implementation quality.
- Reference architectures serve as the learning guide for junior developers.

There can be more than one reference architecture, and the actual implementation may not necessarily follow exactly one reference architecture. Reference models and architectures have been produced by standards bodies such as the Organization for the Advancement of Structured Information Standards (OASIS) and the Open Group, as well as big IT companies like IBM (Arsanjani et al. 2007), Microsoft,* and Accenture.† In the following sections, two notable efforts by two IT standards organizations are introduced.

85.3.1.1 OASIS SOA Reference Model and Reference Architecture

The OASIS, an IT industry standards body, has been working on the SOA Reference Model and Reference Architecture since 2005. The reference model (SOA-RM) was voted into standards in 2006 while the reference architecture (SOA-RA) is still under development. According to the OASIS, the reference model and reference architecture are different. A reference model aims to provide a higher and more abstract level of common understanding, while a reference architecture provides more detailed and concrete guidelines. A reference model consists of a minimal set of unifying concepts and relationships in a particular problem domain and is not directly tied to any standards, technologies, or other concrete implementation details, such as web services (MacKenzie and Laskey 2006). The OASIS SOA-RM is a conceptual and abstract framework that is used primarily for a common and consistent understanding of key entities and relationships between them. The OASIS SOA-RAF, on the other hand, provides more descriptive solutions to the problem of building an

actual SOA-based system. OASIS-RAF describes a complete SOA ecosystem including the context within which the system functions and the participants involved in making it function (OASIS 2012). It covers both IT and business perspectives in constructing, using, owning, and managing an SOA system.

Following IEEE's recommendation for architecture description (IEEE 2000), the OASIS-RAF describes the SOA development from three views and corresponding viewpoints (OASIS 2012):

1. *Participation in an SOA Ecosystem*: this defines an SOA ecosystem's context, structures, and actions. It identifies roles, responsibilities, and relationships of participants.
2. *Realization of an SOA Ecosystem*: this focuses on the infrastructure elements that are needed to support the construction of SOA-based systems. The viewpoint defines four models: service description, service visibility, service interaction, and policy.
3. *Ownership in an SOA Ecosystem*: this addresses the concerns involved in owning and managing SOA-based systems. Many of these concerns are not easily addressed by automation; instead, they often involve people-oriented processes. Four models are defined: governance, security, management, and testing.

It should be noted that the OASIS SOA-RAF is not a concrete guideline for building a specific SOA system. It is more of a view-based abstract reference architecture foundation that is used to guide other reference architectures and eventual concrete architectures. SOA-RAF models SOA from an ecosystem/paradigm perspective and is the first standard that extends SOA from a pure technical realm into the business world (Poulin 2006).

85.3.1.2 Open Group SOA Standards

The Open Group published a serial of SOA standards and guides including the Open Group SOA Ontology, the Open Group Service Integration Maturity Model (OSIMM), the Open Group SOA Reference Architecture, and others.*

The Open Group SOA Ontology defines SOA-related concepts, explaining what they are and how they relate to each other (The Open Group 2010). Compared to OASIS SOA-RM, it provides a more refined and formal specification of some of the core concepts (Kreger and Estefan 2009). The ontology is formally represented in web ontology language (OWL) to enable processing automation by directly using applications.

The Open Group SOA Integration Maturity Model (OSIMM) provides a way to assess an organization's SOA maturity level. The model consists of seven levels of maturity (silo, integrated, componentized, service, composite services, virtualized services, and dynamically reconfigurable services) based on the evaluation of seven dimensions of consideration that represent significant views of business and IT capabilities (business, organization and governance, method, application, architecture, information, and infrastructure and management). OSIMM defines a process of a staged and incremental adoption and implementation that maximizes business benefits at each stage. It acts as a quantitative model to aid in assessment of current state and desired future state of SOA maturity (The Open Group 2011a).

A little different from OASIS SOA-RA, the Open Group SOA Reference Architecture can represent both abstract enterprise designs as well as concrete SOA implementations (The Open Group 2011b). Originally based on IBM's SOA Solution Stack and Service-Oriented Modeling and Architecture (SOMA) (Kreger et al. 2012), the Open Group SOA-RA includes nine layers or nine key clusters of considerations and responsibilities that typically emerge in the process of designing an SOA solution or defining an enterprise architecture (Figure 85.1).

One key building block is the services layer. It is important to understand different types of services in the development of a service portfolio of an SOA. Categorizing services affects how both business

and IT views and understands the architecture and the service portfolio that supports it. A common high-level classification based on logic type puts services into three categories (Erl 2007): entity services (which represents business logic related to business entities), task services (which represent narrower scoped business logic, or steps in a process, that are within a business entity), and utility services (which provide functionality that is common to many functionalities, such as event logging, notification, and exception handling).

The reference architecture provides a finer level categorization scheme for services, based on their functions and purposes (Figure 85.2). One of the significant services is the ESB, which will be described in more detail in the Section 85.3.2.

85.3.2 Enterprise Service Bus

Because of its loose coupling style and flexibility, SOA is particularly suitable for enterprise systems where various applications need to be integrated. The enterprise is rather a closed environment with management and infrastructure planning consistency, but technological heterogeneity still poses a big challenge. One of the key practices in designing application integration is the implementation of ESB, which is also included in the Open Group Reference Architecture as a communication channel. An ESB is considered as an SOA implementation pattern used for designing and implementing the interaction and communication between services (Flurry and Reinitz 2007). It is one of the key components for messaging in the field of enterprise system integration. In a typical enterprise environment, different applications need to communicate to one another through messages. Instead of having applications to communicate directly end to end, ESB provides a communication bridge for all services. However, ESB should not just be perceived as the SOA itself, nor should ESB be implemented without other proper plan and design of other services that provides business utility (Woolf 2007).

The key concept in ESB is the bus. In ESB-based architecture, the bus acts as the single message path between applications. Every client directs all its requests through the ESB instead of passing it directly to a central broker. Because the communication is usually accomplished using messaging techniques, it is also called a message bus (Hohpe and Woolf 2003). In the traditional enterprise application integration, a centralized message broker is also implemented as a communication bridge. But ESB is different in that the message translation is not centralized to the broker. Each application uses adapters to conform to a canonical message format.

ESB is not a standard and can provide different functions and capabilities in different implantations. The following are usually considered to be the basic set of capabilities of ESB:

- Message queue and routing
- Data transformation and mapping
- Monitor and control routing of messages
- Provide commonly needed commodity services like security, event handling, exception handling, protocol conversion, and service quality monitoring

ESB is usually implemented as a message communication service. It is provided as an enterprise architecture integration tool by vendors like IBM (WebSphere ESB), Microsoft (BizTalk), and Oracle (BEA Logic). There are also open source projects such as Apache ServiceMix and Synapse, JBoss, Open ESB, and NServiceBus.

85.3.3 Web Services: SOAP versus REST

Services are exposed and accessed through interfaces. The interface is a contract of how to use the service. Currently, the most common and reliable implementation is web services. Traditional web services utilize the simple object access protocol (SOAP) message, but more recently another style representational state transfer (REST) is gaining popularity.

The original web services standards include three parts: SOAP, web services description language (WSDL), and universal description discovery and integration (UDDI). SOAP is a protocol specification that defines a message architecture and format for exchanging structured information. It uses an extensible markup language (XML) for its message format and usually relies on other application layer protocols, most notably hypertext transfer protocol (HTTP), for message transmission. SOAP-based web services mirror the traditional IT integration style of distributed objects with messaging technologies layered on top of web technologies (Vogels 2003). WSDL is an XML-based language for defining an interfaces syntactically (including the syntax and structure of request and response messages). UDDI is an XML-based mechanism to register and locate web services on

the Internet. All three standards utilize the XML language and can be processed directly by software programs, thus effectively hiding the perceived complexity from the application programmer and integrator (Pautasso et al. 2008).

More recently, another more lightweight style REST has been gaining popularity among many web mash-up applications. REST is an architectural style for distributed resources, introduced by Roy Fielding (Fielding 2000). REST requests and responses between servers and clients are built around the representation (addressing and transferring) of resources (Rodriguez 2008). The World Wide Web is the most well-known example of the REST architecture. A web service implemented based on REST principles is often called a RESTful web service. A concrete RESTful web service follows four basic principles (Rodriguez 2008):

- Explicitly use HTTP methods (GET, POST, PUT, DELETE) for operations.
- Resources are exposed through directory structure-like URIs.
- Resources are usually represented by standard format like XML, JavaScript Object Notation (JSON), or both.
- Be stateless. Stateful interactions are based on the concept of explicit state transfer (Pautasso et al. 2008). A number of techniques exist to make HTTP stateful, including URL rewriting, session cookies, and hidden form fields, all of which embed the state information in response messages for future reference.

Web services are very ambitious, providing extensibility and processing models, with extension of dealing asynchrony, reliability, integrity, confidentiality, etc. It is protocol independent although almost majority is implemented with HTTP. Service interfaces are more complex but more functional. Compared to the heavyweight full stack of web service, REST is a lightweight implementation of services over the web. It is simple in implementation, resource oriented, with simple interfaces. The necessary infrastructure for REST has become pervasive. The effort required to build a client to a RESTful service is also very small. Developers can begin testing such services from a common web browser, without having to develop custom client-side software, and deploying a RESTful web service is very similar to building a dynamic web site (Pautasso et al. 2008). Furthermore, it is possible to discover RESTful web resources without a centralized repository approach that requires registration like UDDI.

However, REST is not a substitute for web services. Rather, it is an alternative style that could be considered as an alternative approach for designing SOA. It has been perceived as a way to provide web services with less dependence on proprietary middleware (e.g., an application server) than the “big” web services. Exposing a system’s resources through a RESTful interface is more flexible to meet integration requirements where data need to be combined easily among different kinds of applications (e.g., the mash-ups). Generally, REST is more widely chosen for simple web applications over the Internet where consumer clients are mostly unknown, while SOAP web services are used more within an organization’s enterprise system. A quantified method of choosing REST- or SOAP-based service can be found in a tutorial at the 19th International Conference on World Wide Web (Pautasso and Wilde 2010).

85.3.4 SOA Development Activities Adjustment

SOA not only brings technical changes but also business and organizational changes; therefore, the development of SOA needs to make adjustments in development phases and activities. Generally in SOA development, there are three basic tasks: building a service infrastructure, building services, and consuming services in applications. These activities are different in terms of a development methodology. On one hand, the infrastructure is the overall basis upon which the whole system is built. Its changes are more likely to have a greater impact on other applications that use the infrastructure. Services, or at least their interface, are used by multiple applications. They need to be well designed

and planned for relatively small changes. Because of this stability requirement, building the service infrastructure and services may require a more rigorous approach with careful planning and design (Haines and Rothenberger 2010). On the other hand, the internal implementation of services is more independent of how their interfaces, and composite applications built on services need to quickly respond to changing requirements. They require a more flexible and shorter development cycles. This may in many circumstances benefit from using a more agile software development approach (Haines and Rothenberger 2010).

Some traditional development activities need to be adjusted because of this duality of SOA development. Certain activities may need to be added, emphasized (or de-emphasized), or rearranged. Figure 85.3 (Haines and Rothenberger 2010) summarizes some key adjustments in the typical development activities in the system development life cycle.

The most radical changes are probably in the design phase due to the paradigm shift. In earlier systems, when the technology and infrastructures were not matured, incorporating too many remotely located services in a composite orchestration would be considered a bad design. Now especially in an internal architecture, service management is more matured and reliable; more loosely coupled system is encouraged to advocate flexibility and agility. One of the important considerations of service design is to determine the granularity of services. Services that are too fine-grained and require many roundtrips to complete a business transaction may cause performance problems, while services that are too coarse-grained limit reusability and may result in the wrong applications being built (Haines and Rothenberger 2010).

Phase Adjustments	Important Characteristics and Changes
Planning <i>substantial</i>	<ul style="list-style-type: none"> • More holistic, enterprise-level • Broader more effective communication channels needed • Higher uncertainty, project estimation more difficult • Assessment of relevant standards and vendor support
Analysis <i>lowest</i>	<ul style="list-style-type: none"> • Requires rigorous, disciplined traditional analytics • Development of common data models and schemas is a key task
Design <i>most radical</i>	<ul style="list-style-type: none"> • Development of reusable enterprise-level components • Interface design must be explicit part early in the lifecycle that requires learning about standards and tool availability • Determining granularity of services • Limiting remote services (based on current remote management capabilities) • Developing effective interfaces descriptions
Implementation <i>some</i>	<ul style="list-style-type: none"> • Need for increased automation with deployment tools • Increased need for coordination with more independent stakeholders • More complex service management • Implementing multiple channels for business partners with different maturity levels of Web services • Awareness of standards maturity and interoperability issues
Testing <i>substantial</i>	<ul style="list-style-type: none"> • Emphasis on integration testing and different environments • Need for increased automation with testing tools, including generation of test clients as well as test services • Compliance testing (e.g., WS-I) • Increased performance and security testing

FIGURE 85.3 Changes needed in the SOA development. (From Haines, M.N. and Rothenberger, M.A., *Commun. ACM*, 53(8), 135, 2010.)

Another phase with substantial changes is the testing phase. Some best practices are (Ahuja 2009) as follows:

- Maintain automated service integration test suites.
- Adopt a service testing framework.
- Use mock services to test consumers ahead of integration with providers.
- Use test suites to adequately test services ahead of consumer integration.
- Always plan for performance testing.

85.4 Research Issues

As we discussed earlier, a service infrastructure consists of three parts: a service model, a connection model, and a deployment model. Each of these three models has research issues and open questions. Research issues related to a service model include the following:

- How do we formally define a service? A service is a reusable component with properties, references, functional and nonfunctional requirements, and implementation details. These are the basic elements of business function units, which are assembled into complete business solutions by the connection model of deployment model. Therefore, it is essential to define these basic services in a precise and concise manner. Many service infrastructures provide both text and graphical representations of a service component. For instance, the picture that follows was used by OASIS (OASIS 2011). A concise text representation of a service component helps to define service infrastructure as a formal system; thus, formal methods could be applied to service oriented architecture (Figure 85.4).

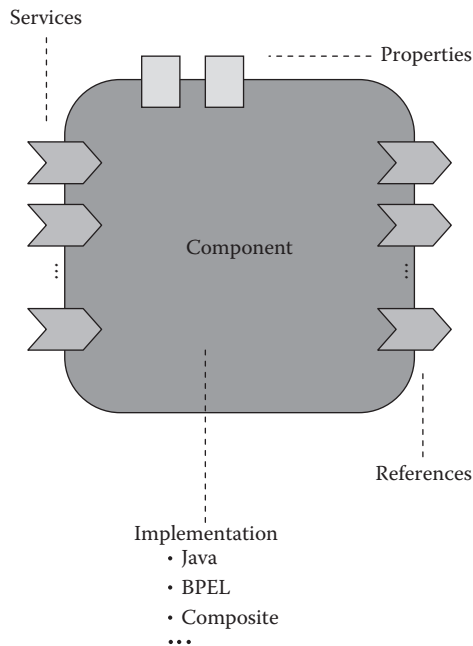

FIGURE 85.4 The Open Group SOA-RA service functional categorization scheme view. (From OASIS, Service component architecture, assembly model specification version 1.1, <http://docs.oasis-open.org/opensca/sca-assembly/sca-assembly-spec-v1.1.html>, 2011.)

- Connections as operations. The connection model of a service infrastructure is the most interesting part for further research. The connection model defines ways to combine new and preexisting service components together into a unified system. These rules of assembly could be described as operations of a component algebra (Wang and Qian 2005), and they are the abstractions to represent different composable aspects of the system.
- Deployment as service binding. The deployment model defines the manner in which a service can be made available and how it can be utilized in different applications. It may also define possible methods of access, for instance, through web services, JMS, RMI- IIOP, or EJB. Nonfunctional requirements could be captured by the deployment model as specific bindings such as security, time constraints, transaction, and reliability.

Currently web services represent an active research area. A web service is an online component that can be described by its interface expressed with WSDL, deployed by a deployment tool such as WSDD, published in a registry such as UDDI, located by a SOAP lookup based on UDDI API, and invoked by a SOAP request. Web services are loosely coupled, contracted components that communicate via XML-based WSDL web service interface.

The development and management of SOA (e.g., methodologies) is also a good research area. The software development process is changed due to the adoption of SOA. What is the impact of such changes? How do we assess them? Future research may investigate the productivity and cost reduction by conducting a comparative analysis of traditional development processes and SOA-driven processes. However, beyond the question of whether SOA is good or bad, it is more worthwhile to study how it can be done right in a given context (Haines and Rothenberger 2010).

Papazoglou et al. (2007) envisions an service oriented computing (SOC) roadmap (Figure 85.5) and put the development and management aspects on top of the research pyramid. Several issues were raised in this chapter and we think the following will be the focal point of future research. First, more research could focus on a specific phase or a specific methodology in a given organizational context using detailed case studies or field surveys. Software development changes can be related to underlying technical

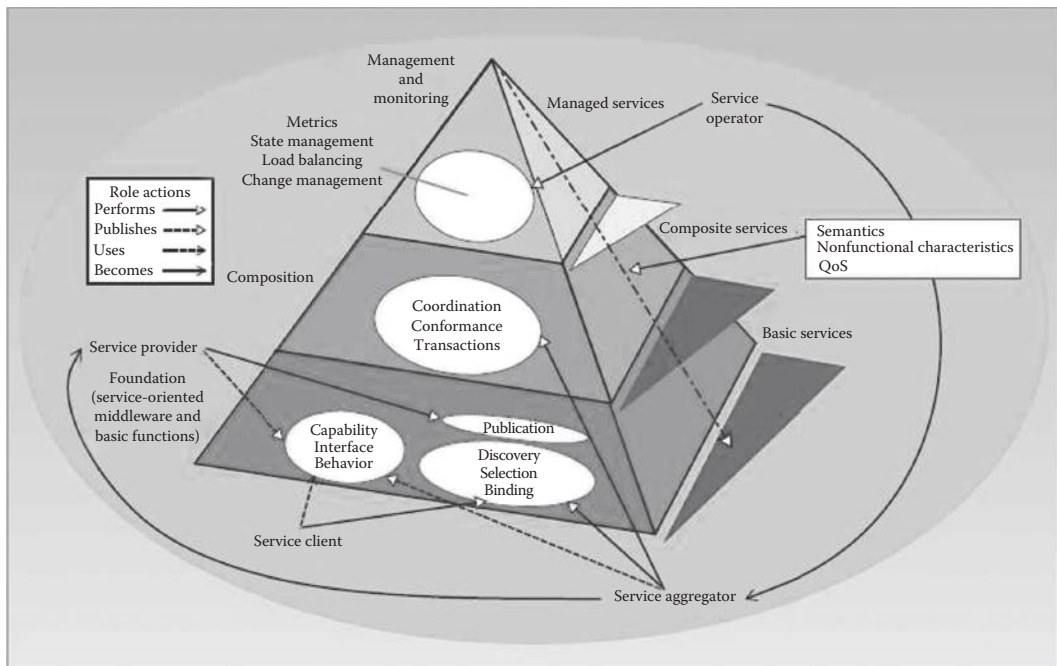

FIGURE 85.5 SOC research roadmap. (From Papazoglou, M.P. et al., *Computer*, 40(11), 38, 2007.)

characteristics to examine if recommendations made for SOA also apply to other development paradigms. Second, the management becomes a critical issue as the number of services grows. Third, it is important to have a highly coordinated process and to consider testing throughout the life cycle. Tools that help automating the process play an important role in effective testing by addressing not only the functional issues but also security and performance.

85.5 Summary

SOA has been around for more than a decade now. It has become a fundamental enabler for many enterprise technologies and systems, such as software as a service (SaaS) and cloud computing. It is also evolving beyond the traditional remote-procedure-call style to encompass more interaction forms as found in REST, web-oriented architecture, and event-driven architecture (Thompson 2009). Reference models, architectures, and patterns have proliferated to guide the service-oriented development. The development also goes beyond simple technical mandate to a high-level conceptual thinking that influences the architectural design. The question nowadays is not just focused on whether or not SOA is a better paradigm but more on how it can be implemented in the right way in a given context.

Key Terms

Enterprise service bus: ESB is an SOA implementation pattern used for designing and implementing the interaction and communication between services.

RESTful web services: Web services implemented based on REST principles.

Service: A service is a software component, a piece of self-contained, self-deployable computer program with well-defined functionality and can be integrated with other services through its interface.

Service-oriented architecture: SOA is a software architecture style utilizing distributed capabilities that may be under the control of different ownership domains. It provides a uniform means to offer, discover, interact with, and use capabilities to produce desired effects consistent with measurable preconditions and expectations. The fundamental building blocks of the system are services.

Service-oriented development: Service-oriented development is a new software development paradigm that develops software systems based on SOAs.

Web services: A web service is a software program designed to support interoperable machine-to-machine interaction over a network.

86.1 Introduction

Due to ever-shorter life cycles, maintaining leadership in software-intensive product development organizations depends increasingly on the ability to improve their design and development processes faster than their competitors. There is clearly a need to considerably reduce development effort by increasing productivity and consistently generating higher-quality software.

It is a well-known fact that in more established engineering disciplines, the use of standard parts and known solutions to recurrent design problems is routine and contributes toward the reproducibility and reliability of the solutions produced. By contrast, in the software development universe, there is a strong tendency to start from scratch each time a new project is embarked on, with software continually being reinvented to perform essentially the same function.

A promising approach is to move the focus from building single systems, where one repeatedly custom-writes routine functionality, to orchestrating families of systems in a range of similar products. Focusing on a “range of similar” products can potentially take advantage of *economies of scope*, a benefit that comes from developing one asset used in multiple contexts by identifying “reusable” solutions that support future development of multiple systems, thus, making it possible to derive individual systems in a prescribed manner instead of creating them anew. Moves toward systematic, institutionalized reuse have shown that similar results can be obtained in the software industry as proposed by software product line (SPL) engineering.

A group of related software-intensive systems sharing a *managed* common set of software assets explicitly recognizing *variability* among *similar* user requirements, or *features*, for the same product is considered a SPL. SPL development is attractive because it enables *strategic and systematic software reuse*, that is, software reuse that is planned and aligned with a business strategy [1]. Strategic software reuse increases software development productivity and improves the quality of the products derived while allowing an organization to expand its products portfolio rapidly. The set of common features is used for developing a platform—a set of core reusable assets—that provides mechanisms for introducing individual system variations among the group of related systems by combining mass production with individual customization.

Over the past several years, issues associated with SPL have attracted the attention of a relatively high number of software engineering researchers and practitioners. However, we do know from experience that the SPL paradigm has not been widely adopted in industry. Why is this the case? What are the impediments to adopting SPL in industry? Correspondingly, what software processes are “required” for effective and efficient SPL development?

In this chapter, we answer these and other related questions to the SPL paradigm. In the rest of this chapter we present an overview of SPL development and best practices and a discussion and arguing that to effectively implement SPL, organizations need to achieve a high level of maturity in the process improvement scale. To buttress this argument, we describe the Software Engineering Institute (SEI)-sponsored Framework for Software Product Line Practice and compare its key practices with those found in the Capability Maturity Model Integration for Development (CMMI-DEV). Finally, we close with some of the most relevant contributions in the SPL research over time and highlight unresolved research issues. We conclude with an analysis of SPL adoption and research challenges, outlining the main issues and unsolved problems that impede the widespread adoption of the SPL approach as a way to deliver software products more effectively.

86.2 About Software Product Lines

The overall goal of SPL development is to produce *quality products consistently and predictably* and at the same time greatly *increase productivity*. A key realization is that most software systems developed conventionally, that is, “in isolation, routinely written from scratch” are not completely new or unique [2,3]. That is to say, software-intensive systems satisfying specific needs of a particular market segment or mission share a common set of “features” [4]. Several focused conferences, books, and more general publications have covered SPL [5]. An annual workshop on product family engineering (PFE) started in Europe in 1996 [6], and the international conference on SPLs (SPLC) started in the United States in 2000 [36]. Both events were held separately until 2004 when they merged to form the leading conference in the subject [7].

An underlying assumption is that the benefits from the reuse of components will offset the potential extra cost for any increased organizational and design complexity. The benefits of SPL are clear, provided that assets can be systematically reused several times, including the following:

- Organizations reduce cycle time and cost of new applications by eliminating redundancy.
- Building systems from a common component base reduces risk and improves quality by using trusted, proven components repeatedly.
- An asset-based approach allows the management of legacy systems more efficiently, increasing the likelihood of longer time-IN-market; the organization evolves a common marketing strategy and strengthens its core competency around strategic business interests and goals [8].
- Despite an initial investment on creating a common platform, the approach reduces time to market and costs significantly when compared to developing the corresponding set of systems each independently and in isolation [9].

86.2.1 Software Reuse: An Elusive Goal

Since the dawn of computer programming, different approaches have been developed for exploiting the benefits of software reuse. Programmers have practiced *ad hoc* code reuse since the earliest days of computer programming: they have always reused sections of code, functions, and procedures. As a recognized area of study in software engineering, software reuse dates from 1968 when McIlroy, from Bell Labs, proposed at the now famous NATO conference on software engineering, basing the software industry on reusable components [10].

Earlier definitions of software reuse and reusability include the following:

Re-use is considered as a means to support the construction of new programs using in a systematic way existing designs, design fragments, program texts, documentation, or other forms of program representation [11].

Reusability is the extent to which a software component can be used (with or without adaptation) in multiple problem solutions [12,13].

Over the decades, more organized forms of software reused, although still not in a systematic way, focused on larger and larger assets: subroutine libraries in the 1960s, modules in the 1970s, objects in the 1980s, components in the 1990s, and web services after that. These approaches represent significant advances in achieving the elusive goal of software reuse; they have indeed increased reusability but only incrementally and in an *ad hoc*, small-scale way—for example, reuse on the basis of a single system. Code from one project can be saved in a “reuse” library in the hope that it will be useful in the future; but unplanned, miscellaneous collections of code components simply fail to achieve high-leverage reuse. They are difficult to locate, understand, and modify, since typically design information is unavailable and adaptability is not designed in. This need for design for commonality and for control of variability results in the introduction of product lines [6,9].

SPL proposes an intentional, systematic, and predictable large-scale software reuse paradigm. Of course, the approach stands on the benefits of the early contributions previously mentioned, which were primarily programming techniques, plus other important ones as discussed later in this chapter.

It is not until systematic reuse is conquered that we will see software reuse widely accepted, and a key differentiator is domain engineering (DE) [14], a process of collecting, organizing, and modeling the knowledge in a domain in the form of reusable assets, “to model software system families and build software modules such that, given particular requirements specs, highly customized and optimized intermediate or end products can be constructed on demand [15].”

Systematic software reuse is the organized creation of common parts or assets with controlled variability that forms the basis for systematically building systems in a domain of expertise by assembling them from these reusable assets, a dual process of DE for building assets and applications engineering for building systems of these assets. When product lines are designed to support an organization’s objective or mission, we are institutionalizing reuse [16]. The achievement of design for commonality and control of variability requires the establishment of a reuse infrastructure as discussed next.

86.2.2 Domain Engineering (DE)

In his PhD thesis [17], Neighbors introduces the term domain analysis (DA) and Draco, which is considered the first approach to DE. With Draco he also introduces the idea of domain-specific languages, currently receiving renewed attention [18].

Systematic reuse requires “original engineering design” work at front, done once, followed by “routine practice” [19]. The former known as Domain Engineering (DE) refers to a *development-for-reuse* process effort necessary to build a reusable asset base as *model solutions*. The latter complementary process, known as application engineering (AE), refers to a *development-with-reuse* process to create specific systems from these model solutions and prefabricated assets. Within this duality products are created by instantiating models and by integrating prefabricated artifacts, mapping needs to solutions rather than building from scratch, that is, not building products from first principles. This duality provides a sound basis for industrial-strength software engineering, a necessary condition that naturally leads to systematic reuse [20]. Fundamentally, reuse has the effect of reducing variance and increasing homogeneity, two essential aspects observed from disciplines that have moved into industrialization.

Modeling is an important practice in increasing homogeneity. As Shaw has put it, supporting the modeling first develop second duality (the underlining added):

Engineering relies on codifying knowledge about a technological problem domain in a form that is directly useful to the practitioner, thereby providing answers for questions that commonly occur in practice.... Engineers of ordinary talent can then apply this knowledge to solve problems far faster that they otherwise could [21].

In this way, development requires original design effort only once while the applications engineering process uses the known solutions repeatedly to create different systems in two ways:

- *Adaptive design*: use known, established solution principles adapting the embodiment to the requirements. It may be necessary to perform original design on some individual parts.
- *Variation design*: arrangements of parts and other product properties (size) vary within the limits set by a previously designed product structure during original engineering (DE).

DE requires careful technical and economic analyses; it involves the discovery of solutions to solve reoccurring problems and goes through all of the development phases of (domain) analysis, (domain) design, (domain) implementation, and testing.

During domain analysis commonality and variability among the systems in the domain are identified and made explicit. Commonality and variability are often traced back to Parnas' work on program families [22], although Parnas himself acknowledges Dijkstra's work on structured programming [23] as the root of his ideas. See [24] for a survey of DA methods.

Commonalities and variabilities of an SPL are typically specified in terms of characteristics visible to the end user called *features*. Kang's work on feature-oriented DA [25] introduces feature models for specifying and modeling relationships among features. Feature models have been further extended and have become the de facto standard for modeling SPL high-level functional requirements. Other important contributions in DA are commonality analysis [26] and SCV (scope, commonality, and variability) [27].

The design activities are supported by system and software architecture technology, most notably architecture description languages (ADLs) [28]. Component design is supported by interface definition languages (IDLs). Jacobson [29] introduced the notion of variation point for identifying locations within software artifacts where variability can occur, including a comprehensive list of variability mechanisms for realizing variation points in the implementation [6,30].

Design-commonality forms the basis for standardizing assets to build products in a domain of expertise by encapsulating common features of related products into a domain model and by defining a common architecture for related products into a domain (or reference) architecture [31]. A specific design is created by instantiating a common design and the product implemented by the identified reusable components.

Control-variability is the basis for providing flexibility in the assets to meet requirements for a variety of products without compromising commonality; it requires careful design to include appropriate levels of parameterization, generalization and specialization, and extension. Like commonality, adaptability must be engineered a priori, and thus analysis must explicitly identify variations that anticipate adaptations specifying optional components, alternate structures, parameterized context dependencies, and the like.

Reuse occurs both within a product line and across product lines, a notion discovered earlier and associated with the concepts of *horizontal* and *vertical* reuse. Assets that cross several systems take advantage of "economies of scope," a benefit that comes from developing one asset used in multiple contexts [32]. Horizontal reuse refers to the use of an asset across several distinct product lines; typically, assets reused in this way tend to be general (i.e., they are application domain independent) and with a very specific set of functionality.

86.2.3 Process Framework for SPL

A framework for practicing SPL has been developed by the SEI [33], and a hall of fame for recognizing representative experiences applying SPL has also been established [34]. The SPL framework provides details of how to perform SPL engineering. It divides the development process into two major categories: core asset development and product development with a management infrastructure.

The SEI SPL framework has 29 practice areas that are divided into three categories: software engineering, technical management, and organizational management as shown in Table 86.1.

Contrast this with CMMI's framework that consists of 25 key process areas (KPs) and four categories of project management, process management, engineering, and support as shown in Table 86.2. The CMMI-DEV is a software development improvement model that provides an organization with a roadmap for improving their development process. The model is a collection of best practices that help organizations to dramatically improve the effectiveness, efficiency, and quality of their software development practices. CMMI-DEV describes five levels of maturity and provides an assessment instrument to measure an organization's software development capabilities against the five-point scale.

A KPA is a body of work or a collection of activities that an organization must master to successfully achieve their goals for the process area. Each KPA has a set of specific goals and specific practices as well as a set of generic goals and generic practices. Specific goals and practices relate “what” must be done to meet the process purpose. The generic goals and practices relate to “how well” the process is carried out. The generic practices guide an organization to move to higher levels of capability.

There are six levels of process capabilities defined in CMMI as follows:

- Level 0: Process performance is incomplete.
- Level 1: Process is performed that means specific practices are performed.
- Level 2: Process is managed, that is, there is a policy that indicates you will perform it. There is a plan for performing it; there are resources provided, responsibilities assigned, training on how to perform it, and selected work products from performing the process area are controlled.
- Level 3: Process is defined, that is, the process is established and maintained organizationally.
- Level 4: Process is quantitatively managed; that is, the defined process is controlled using statistical and other quantitative techniques. A critical distinction between a defined process and a quantitatively managed process is the predictability of the process performance.
- Level 5: Process is optimized with defect prevention, proactive improvement, innovative technology insertion, and deployment.

It is important to distinguish between *process capability* and *organizational maturity*. A single process has capabilities that can be measured on a 1–5 scale (listed earlier). An organization consists of groupings of processes; how well these processes perform their function is a measure of that organization’s maturity. If an organization is rated level 4, for example, that implies that all its processes have reached at least capability 4. Maturity levels feed into each other on an upward trajectory. CMMI provides a path to mastering a practice area with the goal of achieving level 4 capability that is quantitatively controlled and continuously improving. We suggest that a CMMI equivalent of level 4 capability is needed to achieve mastery of SPL practices.

Of particular importance to us is level 4 maturity since we believe that is the necessary level of maturity needed to effectively implement product lines. Level 4 maturity (capability) involves use of statistical and other quantitative methods to understand past and predict future quality and process performance. Through a mature measurement system, organizations establish objectives for quality and process performance based on their business objectives. Projects establish their objectives based on those of the organization and the needs of customers and end users. Projects and individuals use statistical and quantitative methods in their activities to plan, monitor, and control progress against their objectives. Organizations use the resulting information to understand process performance, understand variation, target areas for continuing improvement, and evaluate the impact of proposed improvements.

CMMI-DEV and its predecessor CMM have been in use in a variety of organizations globally since 1987. As a result, a wealth of experiential data is available to support the notion that higher maturity results in higher productivity, higher quality, and shorter cycle time. Boeing Australia, as an example, has reported a 33% decrease in the average cost to fix a defect, reductions by half in the amount of time required to turn around releases, and a 60% reduction in work and fewer outstanding actions following pretest and posttest audits [35].

Therefore, CMMI-DEV has a proven migration path guiding organizations toward increasing process capability and organizational maturity. CMMI-DEV, however, contains only “what” to do and is void of “how” to do it. Since the majority of SPL practice areas map into one or more CMMI-KPA, it is prudent to leverage CMMI experience and create a level 4 management infrastructure wrapped around core asset development and product development processes. There are equivalences among the majority of CMMI-KPA’s and SPL’s practice areas (Table 86.3).

86.3 Research Issues

SPL, although an active research area in software engineering with some recent contributions from the research community, still presents key technical problems that slow down its widespread adoption in industrial settings [36]. Additional work in this direction includes obviously conducting a systematic literature review of the top problems reported and identifying the most influential solutions. What are the main issues and unsolved problems that impede the widespread adoption of the SPL approach as a way to deliver software products more effectively?

Assessing the status of research in this area helps the research community to focus the agenda on the critical problems limiting the advancement of the field. In early studies, including a mapping analysis of the literature, some findings that called our attention were the following:

- *Feature modeling* was ranked high among participants' current research areas (see below). But, according to our study, feature modeling is not one of the top problems.
- *Product derivation* was not considered one of the top problems, but it is the second most active research area.
- *SPL evolution*, the second most important problem we found, has not been featured explicitly in any of the important conferences.

In this section, we report on our findings from a survey directed to understand some of these questions [37]. The main goal was (1) to collect opinions among longtime SPL researchers and practitioners regarding critical problems in SPL adoption, (2) to verify how actively the research community has been working on these problems, and (3) to quantify the SPL research field and find answers to additional questions like the following:

- Which of the previously reported problems remain unsolved?
- How actively has the research community been working on solving these problems?
- What new problems have emerged?

FIGURE 86.1 Top SPL research problems.

To answer these two questions, a mixed empirical study was conducted by combining an expert-focused survey with a systematic mapping study. Expert sampling [38] is useful because knowledgeable researchers and practitioners in SPL are easy to identify but also because data can be collected and coded quantitatively promptly. Researchers are typically ranked based on publications [39–41]. The complementary content analysis and literature review provided more insight on how actively the research community have been working on solving the identified problems.

The findings corroborate previous assessments, citing variability management and evolution among the most important research problems in SPL. Figure 86.1 shows the topmost SPL research problems uncovered by the survey.

Although opinions varied widely, 40 out of 86 reported problems fell into three big groups. These were variability management, evolution, and economic and organizational aspects. Their breakout was as follows:

- *Variability management*, with a frequency of nearly 20% (17 responses), is clearly the top research problem.
- The second most important problem is *evolution* with 15% (13 responses).
- *Economic and organizational* issues were third with 12% (10 responses).
- Others included a plethora of smaller individual problems and counted for 16% of the responses.

86.3.1 Variability Management

In software, variability can be defined as the quality, state, or degree of a software system or artifact to be extendable, changeable, customizable, or configurable for being used in a particular context [42]. In SPL, variability is higher than in conventional software systems, because multiple software systems are derived from a common set of reusable assets. That is to say, reusable assets must anticipate variations for handling differences across the systems in a product line. Furthermore, the driving force behind SPL is that the effort required for introducing these variations is minimal. To achieve this goal, variability needs to be managed following a process for identifying, introducing, constraining, using, implementing, and evolving variations and managing the variants [43,44].

Bosch et al. [45] describe several variability issues that materialize in different phases of the SPL engineering life cycle. The root causes of most of these SPL variability issues are complexity management, visibility of variability, and dependency management.

Complexity management. The value behind an SPL stems from the degree of variability required. The number of possible configurations for an unconstrained feature model is $O(2n)$, where n is the number

of variable features; this number of configurations grows polynomially in the number of versions available. Although variability provides flexibility and enriches an SPL, when thousands of options exist, it is difficult to effectively identify the possible configurations that make sense both technically and commercially. Therefore, complexity management is critical for managing an SPL with a large number of features with complex interdependencies, asset variants, and variation points associated with product configurations. As in conventional software, complexity is an essential problem that cannot be completely solved [46]. Typical approaches for taming complexity in SPL include reducing unnecessary variability [47] and clustering variation points into packaged variants.

Visibility of variability. Documenting variability is one of the key properties that characterize SPL engineering. Variability is made explicit from the outset through variation points that are realized in further stages of production. A product line of industrial size can easily incorporate several thousand variation points, which imposes serious issues in modeling, assessing the impact of changes, and in ensuring consistency in such large amount of variability [48]. Although modeling techniques developed in recent years provide first-class representation of variation point, there is no evidence of its scalability in industrial-size SPL. Furthermore, an expected benefit of modeling and managing variability is to be able to derive products at mass production costs—that is, to automate the derivation of products as much as possible. Achieving this goal requires more visibility of the variation mechanisms selected for realizing the variation points.

Dependency management. A critical problem is the lack of efficient mechanisms for maintaining a mapping between the problem space and the solution space. The problem space constitutes a configuration space typically defined using feature models. However, the solution space is comprised of conventional implementation artifacts with no precise traceability to features. This impedance mismatch between features and implementation artifacts occurs because a single feature can be scattered over multiple artifacts (feature scattering) or several features can be tangled into a single component (feature tangling). Without an explicit mapping between features and implementation artifacts, it is problematic to assure feature-wise systems derivation and evolution.

86.3.2 SPL Evolution

Arguably, products and core assets in SPL evolve more often than in other kind of non-software-intensive product lines (e.g., manufacturing). Product lines require an efficient control of evolutionary changes in both the core assets and the derived products. This is due to the higher degree of interdependency between core assets and products. Components in existing instances of the SPL architecture and derived products in use are frequently replaced by new versions. A lack of an effective control of changes deteriorates the SPL and drains its reuse benefits.

Since an SPL is usually aligned with a business strategy, its evolution is driven by changes in the marketed products, for example, features are added, changed, or removed, or new products are added to the product line. It is thus critical to be able to identify accurately the affected implementation artifacts when feature-based changes occur and, conversely, to identify the features affected by changes introduced in implementation artifacts. Having proper dependency management between features and implementation artifacts is key for maintaining an SPL feature-wise consistent. Existing variation management approaches (see above) support SPL evolution on a solution artifact basis but to the best of our knowledge do not provide feature-based evolution.

A textual analysis of the papers published in the SPLCs from 2006 to 2008 identified the most frequently used keywords as shown in Figure 86.2.

This frequency analysis included all the words containing more than five characters that appeared more than 10 times in a paper. Predictably, the keyword “feature” is the topmost frequent word, but it is considered an outlier. Feature modeling is the de facto standard modeling technique used in SPL and it is very likely that any paper about SPL uses this word very often.

FIGURE 86.2 Top 10 keywords used in SPLC papers.

“Variability” is the most frequent keyword in the last three SPLCs. This result is consistent with its importance in solving SPL adoption problems. “Variation,” usually associated with “variability management,” is within the top 10 most frequently used keywords we found.

“Derivation” and “evolution” were not explicitly among the most frequently used keywords. However, the word “configuration,” the fourth most used keyword found, can be associated with derivation and evolution—that is, product derivation is usually expressed in terms of building configurations, and configuration management usually supports software evolution.

Some other frequent keywords were “component,” “service,” and “aspect.” This reflects the interest of integrating SPL with new technology and paradigms like component-based development, service-oriented architecture, and aspect-oriented approaches.

86.4 Summary and Conclusions

Software gets bigger all the time, becoming very costly to create and modify, and the software industry is very large and growing at unprecedented rates. This enormous demand for software is fundamentally based on two opposing aspects, namely, the critical nature of software for today’s well-functioning world and the poor state of the practice in software development.

Plummeting hardware costs are leading to rapid growth in many new application areas requiring more software being built in shorter time frames. In today’s post-PC era, new artifacts and systems are increasingly more software-driven. Many artifacts, from consumer electronics (e.g., smart phones, personal digital assistants, set-top boxes), transportation systems (including automotive, avionics, trains, etc.), to industrial plants and corporations, all depend on well-engineered software for their continuing functioning.

The other critical reality is the poor record of accomplishment in software construction: software seldom performs as expected, and cost/schedule overruns are very common even in the most sophisticated organizations. This further increases demand. What is worse, it is quite typical that for many such systems each time a new application is built, routine functionality is custom-written repeatedly from scratch. This also contributes to higher demands for more software. Concomitant with these problems, there is a shortage of qualified software professionals [49].

Software is critical to business' strategic advances, and it has become the bottom line for many organizations, even those who never envisioned themselves to be in the software business. Yet, major software projects failure rates are very high, and, although difficult to quantify the financial cost arising from these low success rates, estimates are in the billion of dollars. There is also a serious impact on all aspects of our lives, national economies, and society in general. Software development organizations must improve both the quality of the software they produce and the productivity of their development groups.

For these software-intensive systems, a reuse-driven approach will potentially reduce time to market while improving product quality and reducing uncertainty on cost and schedule estimates. The approach would allow software professionals to come up with the "right" solution quickly and effectively by assembling applications out of "proven" components. The quality of products is maintained through rigorous analysis and prediction, continuous improvement and refinement, and designed experimentation and feedback from observations of actual systems in a clearly coordinated role in meeting a common need. This represents a main motivation for SPL: a desire to modularize a system in such a way that there is a high probability that significant portions of the system can be built from standard parts.

Quality and budgetary issues with software have their root cause in human error. One proven approach [50] to improving the way software is developed is by knowing what you do and how you do it, as described in the CMMI-DEV published by Carnegie Mellon's SEI. In this chapter we placed the CMMI-DEV in juxtaposition with the also SEI-sponsored Framework for Software Product Line Practice. The former is a proven approach to enhance the quality of software products in general, whereas the latter provides a discipline framework for implementing SPLs, a promising approach that increases productivity multifold yet to be widely adopted by industry.

Our conclusion in this area is that this is a winning combination for the production of quality software predictably and within budget and time constraints.

In the SPL conference held in 2006, SPL research status has been assessed based on the insights of recognized experts in a panel with some of the world's leading SPL researchers. Panelists presented their perspectives regarding lessons learned and outcomes from the prior 10 years as well as directions and potential outcomes for the following 10 years. The presented topics have much in common with the results we obtained in a study presented in this chapter corroborating our findings. In particular, the following were in common:

- Variability management topics included "managing variability in requirements engineering," "introducing variability into software architectures," and the need of novel technologies for setting up "variation mechanisms automatically."
- Evolution included the challenges of "controlling versions of components and architectures" with multiproduct nature and "how to keep products unified overtime."
- Organizational and business issues for adopting SPLs.
- Other topics, including tooling and integration with new technologies such as ubiquitous computing, service-oriented architecture, and model-driven approaches. Participants in the survey also ranked "integration with other technology" as the fourth most cited technical research problem.

Some additional findings that called our attention were as follows:

1. *Feature modeling*, a topic ranked third among participants' current research areas, but feature modeling is not considered one of the top problems.
2. *Product derivation* was not considered one of the top problems, but it is the second most active research area.
3. *SPL evolution*, the second most important problem we found, has not been featured explicitly in any of the SPLCs.

87.1 Introduction

The *requirements engineering* (RE) task [11,26–28,39,44,49,51] focuses on gathering information from members of a client's organization in order to produce a coherent specification of the requirements for a *computer-based system* (CBS) that the client desires to be built.

Requirements elicitation (RElic) is the subprocess of RE concerned with gathering information about the CBS to be built

- From whatever source it is available, including requests for proposals, organizational policy documents, documentation about the existing system, and videotapes, etc.,
- From whomever might provide information, including the client and the users, etc.,
- By whatever technique or means available, including interviews, questionnaires, focus groups, and observations of the organization at work, etc., even by invention.

Requirements analysis is the process of refining all the elicited information about a CBS into a *requirements specification* (RS) for the CBS by deriving what is possible from the information, validating what is derived with the client and the users, eliciting more information when questions prevent validation, and repeating all as necessary, until the RS can be written.

The more thorough RE and RElic are, the cheaper the subsequent development, because it is well known that fixing a CBS defect during implementation costs an order of magnitude more than fixing it during RE, and fixing the defect after deployment costs two orders of magnitude more than fixing it during RE [9].

This chapter focuses on RElic. Other chapters deal with specifications, including formal, of CBSs (Chapter 88), with formal methods (Chapter 71), and with model checking of formal specifications (Chapter 89).

87.2 Context of RElic and Vocabulary for the Rest of This Chapter

This chapter assumes that a client, *C*, has come to a *requirements analyst (RA)*, *A*, for the purpose of having *A* produce a RS, for a CBS, *S*, that *C* wants built. *S* is intended to solve a problem *P* that *C* and other people, mostly within *C*'s organization, *O*, are having. Almost always, *S*, the new CBS, replaces an existing system, *E*. *E* could be (1) a CBS built earlier or (2) a paper-and-word-of-mouth-driven *manual system*. The problem, *P*, may be that *E* does not do a needed something at all, or that *E* does it poorly. *P* may be that *E* does something that it should not do. Finally, *P* might even be only that *E* should be automated to take advantage of computers, the Internet, the Web, etc.

S is a *bespoke system*, generally developed for one client, *C*, or is a *mass-market system*, developed for many customers. (The distinction between client and customer is coming up.)

The set of people affected by *P*, that want *P* solved, that are using *E*, and that will use the new CBS, *S*, are *S*'s *stakeholders*. Among *S*'s stakeholders are

- *C*, the client, the person or organization paying for *S* to be developed,
- The customer, the person or organization who buys *S* after it is developed,
- Users of both *E* and *S*,
- Domain experts, who understand *P* and *E*,
- Developers, who will implement *S* from its RS,
- Quality assurers, the people who will do inspections and testing of all of *S*'s artifacts, including its RS and artifacts leading to the RS,
- Compliance inspectors, experts on government and safety regulations,
- Market researchers,
- Lawyers, and
- Experts on systems adjacent to *S*.

Note that sometimes the client and customer are the same; sometimes the client, customer, and user are the same; and sometimes the market researchers represent the customers, for example, for a mass-market CBS, in which case the client might be the head of the developing organization's marketing department, who decides that there is a market for *S*. In the rest of this chapter, the term "stakeholder" is used to mean all or much of the set of stakeholders that have been determined as relevant for the development of *S*. When only a specific stakeholder, for example, *C* or the users, is needed in the discussion, only that stakeholder is mentioned.

With the RS produced by *A*, *C* will go to a developer to arrange that *S* will be implemented according to the RS, to *C*'s satisfaction. It is intended that the RS will say enough about *S* that the developer will not have to ask *C* questions about *C*'s requirements for *S*; all the information about *S* that the developer needs to implement *S* is expressed in the RS.

In this context, *A*'s main jobs are

1. To understand *P*, which *C* wants solved by *S*,
2. To extract the essence of the stakeholders' requirements for *S*,
3. To invent a way to solve *P* that is better for the users than the way it is being solved currently by *E*, particularly if *E* is manual,
4. To negotiate with the stakeholders a consistent set of requirements for *S*, and
5. To record the resulting requirements in a RS for *S*.

RElic is used to carry out Jobs 1, 2, 3, and 4. That is, RElic is used to gather information from various sources to inform *A*'s jobs.

In the rest of this chapter, each of “*A*”, “*C*”, “*E*”, “*O*”, “*P*”, and “*S*” is a proper noun naming a specific RA, CBS, existing system, organization, and problem, namely that in the specific RE task instance at hand. On the other hand, each of “*CBS*”, “*MS*”, “*RA*”, and “*RS*” is a nonproper noun and is always used with an indefinite or definite article. When one of these nouns is preceded by a definite article and has neither a qualifying adjective nor a specific referent in a previous sentence, then the noun refers to the specific instance of the noun in the specific RE task instance at hand. Each of “*RE*” and “*RElic*” is a general noun, used without any article.

87.3 RE and RElic as Part of RE

RE is generally the first step in the development lifecycle of a CBS, especially if the so-called Waterfall Lifecycle Model [45] is followed. Even if an iterative lifecycle model, such as the Spiral Model [10], is followed, then RE is generally the first step in each 360° sweep of the spiral. Even if an agile [1] lifecycle model is followed, then an abbreviated RE process is the first step of each spike.

Two of the problems with the Waterfall Lifecycle Model, shown in Figure 87.1 with the normal flow of information and all possible feedback loops, are the implications that

1. Requirements appear in the starting milestone out of nowhere all ready to use, and
2. One produces a specification, that is, a RS, from requirements just as easily as one produces a design from a RS or a realization from a design.

However, as suggested in Figure 87.2,

1. The starting milestone are the client's ideas,
2. Client ideas are far more nebulous and informal than even the most informally stated natural language RS, which at least *attempts* to be complete and consistent, and
3. The transition from client ideas to the RS is far more torturous, difficult, and haphazard than the relatively systematic transition from the RS to the design milestone.

The wavy line between client ideas and the RS in Figure 87.2 is RE.

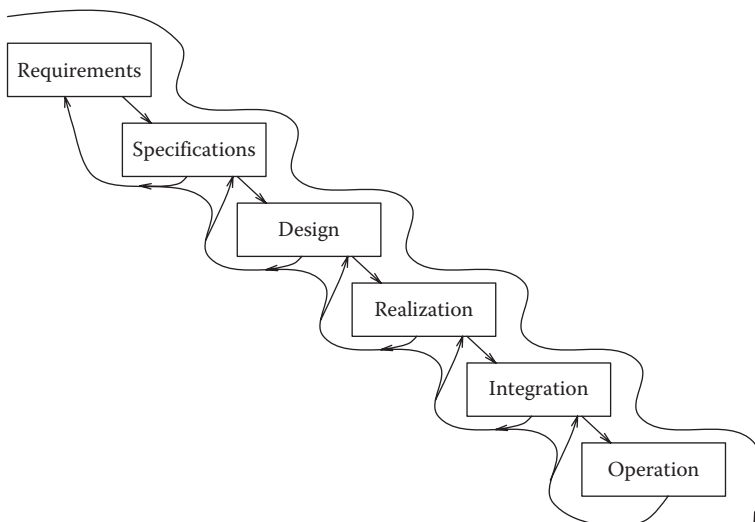

FIGURE 87.1 Waterfall lifecycle model.

FIGURE 87.2 True lifecycle model.

FIGURE 87.3 Requirements engineering lifecycle model.

RE has its own lifecycle that is illustrated in Figure 87.3. Each block represents a phase of RE, conception (of S), elicitation, analysis, specification, and validation. Just as with the general Waterfall Lifecycle Model, this RE Lifecycle Model is an idealization. The reality is that there is a spiral, with each sweep going through this entire waterfall, and all the steps in the sweep happening concurrently. That is, every phase informs every other phase, and every phase is happening throughout RE.

The most important aspect of RE is not the production of the RS, A 's fifth job. It is the process of negotiating requirements that are agreed to by all stakeholders, A 's fourth job. Certainly if the RS is inadequate, the developers will have a hard time building the intended CBS, S . However, even with a totally well-formed RS, if the CBS that the RS specifies is not what C requires, then C will not be happy with the developed CBS. Therefore, the success or failure of the project to develop S depends critically on whether S satisfies its requirements, that is, whether it solves P , C 's problem.

87.4 Elicitation and RElic as Human Activities

An amalgamation of several dictionary definitions of “to elicit” is that it means “to bring out, to evoke, to call forth,” in the case of RElic, “..., information pertaining to requirements.” The main purpose of RElic is to get information about (1) the domain and goals from which the requirements are specified and (2) the requirements from which *S* is developed.

A must get information out of stakeholders’ minds without damaging the stakeholders or their minds! Many times, this information does not come out easily. As is discussed later, the stakeholders do not know it themselves, the stakeholders subconsciously do not want to let it out, or both. Additionally, sometimes needed or relevant information is not in *any* stakeholder’s mind.

RElic is a human activity involving interaction between human beings [17], the stakeholders (including the nonhuman adjacent systems, represented by human beings). If *A* cannot do the human interaction right, *A* is not going to be able to elicit, no matter what technology and methods he or she uses. Technology and methods might help, but they can also get in the way. Often, success in RElic depends on just being able to talk with the stakeholders about what they really want from *S*, the system being developed.

The skills needed for RElic are (1) identifying contexts, (2) spotting linguistic ambiguities, (3) interviewing, (4) brainstorming, (5) facilitating, (6) getting people to open up, (7) spotting equivocation in people, and (8) inculcating guilt (that the stakeholders have not told the RA everything they know [5]). Only the first two are not human interaction.

Gause and Weinberg’s *Exploring Requirements: Quality Before Design* [17] covers a number of techniques, some of which are described later. They are no replacement for the skills, but they do help focus those skills and give ideas on what to do next at an impasse.

A lot of the RE literature talks about eliciting requirements for *S* as if it were simply a matter of asking the right questions of *C* and the users. The reality is not so simple. In practice, requirements for *S* are poorly understood by everyone. It is only by having all stakeholders review and discuss all documents, both provided by *C* and other stakeholders and generated during analysis, that the stakeholders can conduct the negotiations that lead to an agreement about what the requirements *S* really are. If the stakeholders cannot come to an agreement, then the project to develop *S* will probably fail.

87.5 RElic for Each Job of the RA

Recall that *A*’s main jobs are

1. To understand *P*, which *C* wants solved by *S*
2. To extract the essence of the stakeholders’ requirements for *S*
3. To invent a way to solve *P* that is better for the users than the way it is being solved currently by *E*, particularly if *E* is manual
4. To negotiate with the stakeholders a consistent set of requirements for *S*
5. To record the resulting requirements in a RS for *S*

Each but the last involves RElic in some way, and each, including the last, is affected by what is learned in RElic.

87.5.1 Understanding the Customer’s Problem

RElic is necessary in order for *A* to get the information with which to understand *P*, which *C* wants solved by *S*. Obtaining this understanding may require analyzing *E*, the existing system that *S* is to replace, if for no other reason that *E* probably does most of what *O* expects of it. It will be necessary to ensure that *S*, the new CBS, performs at least the functionality of *E* that is still needed as well as solve the problem *P* that prompted the initiation of the project to develop *S*. If *S* is radically different from *E*, the users of *E*, that is, the future users of *S*, may be reluctant to use *S*.

If the intent is to build into S a new-and-improved version of E , then it is necessary for A , with the help of the stakeholders, to determine

- What of E is used and what is not used
- What of E works well and what does not
- How E is actually used
- How E was intended to be used when it was deployed
- What is missing from E that is needed now to solve P
- What the stakeholders wish E could do

If A does not understand E well enough to determine these issues, then there is a good chance that S will be deficient in at least some of the following ways:

- S is so different from E and imposes so new a way of working that the users are reluctant to use S or even rebel against using S .
- S fails to have the obvious improvements to E .
- S fails to implement features of E that were not mentioned or are not obvious. In this case, O may end up running both E and S .

The elicitation of the information about E is done in one or more of several methods [3,11,26–28,39,44,49,51]:

1. A reviews all available documentation about E , including from its development, deployment, and maintenance.
2. A observes O and its users as they use E . This observation should initially be as unobtrusive as possible to guard against the users showing off an unrealistic candy-coated view of the operation of E . Later, after the users are used to being observed without showing off, the observers can and should start to ask questions such as “What are you doing?” and “Why are you doing that?” Such questions asked during the actual doing get better answers than if they are asked in questionnaires or interviews. Almost everybody is better at explaining what he or she is doing at the moment than at explaining what he or she has done or will do. Moreover, during the doing of a task, he or she is more likely than other times to be able to explain
 - The steps of the task precisely,
 - Why the task is done the way it is being done, and
 - Most importantly, the exceptions that can occur, even if they do not occur specifically during the present doing of the task.
3. A prepares questionnaires that ask stakeholders, particularly users, about features of E that they use and do not use.
4. A interviews stakeholders, particularly users, about features of E that they use and do not use.
5. A conducts focus groups with stakeholders, particularly users, about features of E that they use and do not use.

Any or more than one of Methods 3, 4, and 5 can be used (1) to elicit information about issues that did not manifest themselves during the observations and (2) to confirm conclusions drawn during any others of Methods 1, 2, 3, 4, and 5.

87.5.2 Extract the Essence of the Stakeholder’s Requirements

RElic is necessary for A to get all the information to see beyond each stakeholder’s goals and requirements to the essence of all stakeholders’s common requirements. Generally this job involves building a model of O ’s business and of the way that E supports it. Building the model is itself not part of RElic and is covered partially in Chapter 88. Many textbooks [11,26–28,39,44,49] go in depth into the topic of requirements modeling. Nevertheless, as the model is being built, questions will arise that are not

answered by the information that *A* has already elicited. *A* will have to go back to the stakeholders to do more RElic. In this case, *A* will show the stakeholders the current version of the model and ask both:

- Whether the model reflects reality as the stakeholders see it.
- The specific question that *A* had while modeling that prevented him or her from proceeding with the modeling.

87.5.3 Invent New Ways to Do the Users' Work

RElic is important for *A* to be able to invent better ways to do the users' work. Once *A* has an understanding of the work the users of *E* are trying to accomplish, *A* may be able to suggest *new* requirements that would help them because *A* is aware of technology that could help them or *A* can identify patterns in their work of which they are not aware.

Inventing a better way is often overlooked during RElic. Yes, it is important to determine what *C* and users want and to document it. However, if *A* stops with only that determination, then the built system will conform to only the limited notion of what *C* and users think is possible. For real success, *A* must give to *C*, not what he or she wants, but what he or she never even dreamt of having; and when *C* gets it, he or she recognizes it immediately as exactly what he or she wanted all the time—"I'll know it when I see it" (IKIWISI).

One way to invent a better way involves *A*

1. Asking stakeholders *why* the requirements that have been documented thus far are desired, that is, engaging in more RElic, and then thinking about ways to address the goals implied by the offered reasons.
2. Considering ways to give each user more control over his or her activities in *E*.
3. Brainstorming (see Section 87.6.6), with the stakeholders, to invent new requirements.

Thus, *A* needs to go *beyond* RElic to find requirements, to possibly *invent* some.

87.5.4 Help the Stakeholders Negotiate to a Consistent Set of Requirements

RElic is occasionally needed during negotiating with all stakeholders a consistent set of requirements. In general, this negotiation requires that the RA find the inconsistencies among the stakeholders' requirements. Attempting to model all the requirements exposes these inconsistencies as the inconsistencies prevent the formation of the model. The remedy for these inconsistencies is to convene the stakeholders and to show them the inconsistencies. Then ideas on how to resolve the inconsistencies in the form of alternative proposals for requirements are elicited. There are techniques for conducting the negotiations, for example, Win-Win [8] that are outside the scope of this chapter.

87.6 Specific Techniques for RElic

There are a number of specific CBS issues or RElic techniques whose consideration or use help focus RElic or idea invention to be more effective than it might otherwise be [11,26–28,39,44,49,51].

87.6.1 Social and Organizational Factors

In RElic, *A* must keep in mind that any CBS is used within its own *context* that consists of technical *and* social factors. Social factors include organizational factors and these can dominate the technical factors in determining requirements [40,48]. For example, if employees have a particular way of working, *S* should be built to support it. The user interface of *S* must accommodate all of its users, including the most computer illiterate of them. If a future user feels that his or her job is threatened by *S*, he or she may engage in obstructing activities ranging from passive resistance through to active sabotage [16,34,40,48].

87.6.2 Ethnographic Analysis

In ethnographic analysis [22], someone that is trained as a social scientist spends a lot of time observing the members of *O* to observe how they conduct *O*'s work using *E*. The social scientist should try to blend into the background so that the members of the client organization forget that the social scientist is observing them. Normally the social scientist learns strictly by observation. However, variations of ethnographic analysis permit the social scientist to ask questions. Of course, then the members of the client organization are once again aware that they are being observed.

A variation of ethnographic analysis is for *A* to take the role of an apprentice in the client organization, as suggested by Contextual Inquiry [7]. Then, the members of the client organization are aware that they are being observed. However, a person acting as an apprentice is probably perceived more as an insider than a social scientist quietly observing or asking questions because a new employee needs to learn the truth in order to function well within *O*. Thus, the apprentice is less likely than an observing social scientist to be shown abnormal, candy-coated behavior.

87.6.3 PIECES

PIECES [50] can be viewed as a check list for helping to focus RElic. *A* examines *S* from six specific viewpoints and initiates RElic in each viewpoint. The name of the technique is an acronym formed from the first letters of the names of the six viewpoints:

1. Performance, for example, throughput and response time
2. Information and data, for example, relevance, form, timeliness, and accessibility of information and data
3. Economy, for example, trade-offs of costs vs. minimal acceptable performance
4. Control, for example, degrees of automation, of auditing, of robustness, and of security
5. Efficiency, for example, measurement of unintentional waste (differs from economy, which is concerned about acceptable waste)
6. Services, for example, how *S* is to be used by its primary and secondary users

Admittedly, there is some overlap in the viewpoints, but an overlap is better than a gap in trying to ensure that everything that can be relevant is considered. PIECES is oriented toward business information CBSs, but it can be used with other kinds of CBSs. A RA experienced with another kind of CBS can surely think of relevant viewpoints to add to the "PIECES" list for that kind of CBS.

87.6.4 Interviews

In an interview, *A* talks one-on-one with a stakeholder about *P* and *S* and anything else that *A* needs to know. In conducting interviews, it is important to interview *all kinds of* stakeholders if not all stakeholders. It is important for *A* to avoid detailed solution-specific questions and to ask problem-related questions that help understand the problem *P* that *S* is to solve and to extract the essence of the stakeholders' requirements.

A useful technique is for several stakeholders to be interviewed at once to get synergy, as one interviewee amplifies or disputes what another interviewee says.

It is essential that *A* ask calibrating, meta, and unaskable questions. A calibrating question, such as "Is this answer official?", attempts to determine how much the interviewee's answer can be relied upon. A meta question, such as "Am I asking the right questions?" and "Should I be asking some other questions?" attempts to discover all questions that should be asked. Finally, an unaskable question, such as "Are you opposed to *S*?", "Are you trying to make yourself indispensable?", and "Are you trying to protect your job?" attempts to expose hidden agendas and other hidden information.

An interview should probably start with a list of prepared questions, to at least ensure that *A* does not forget to ask any question. However, *A* should be prepared to deviate from the prepared questions to dig deeper into important issues and to explore emergent issues.

87.6.5 Focus Groups

Basically, a focus group [47] is an interview of a group of group of people conducted by a trained facilitator. In a focus group for RElic, a group of stakeholders are gathered for a short period, for example, about 2 h to ask them specific questions about *E*, *P*, *S*, or some combinations of them.

The technique originated in marketing, in which the focus group is used to ask a group of potential customers their opinions about a planned product, service, advertising, *vel cetera** so that the plans can be changed for maximum marketability. The technique has been used to assess the usability of proposed or prototyped user interfaces; this use of focus groups is most like that in RElic. Indeed, to the extent that determining user interfaces is part of RE, this use of focus groups is a RE technique.

The main advantage of a focus group over the interview of an individual is the potential synergistic effect of one group member's response to a question on the other group members' responses, sort of as in a group brainstorm in which participants build on each other's ideas. Also, a focus group can promote a discussion between stakeholders with differing viewpoints on a question, leading to a resolution of the differences. Thus, a focus group can be used to conduct the negotiations among stakeholders that are one of *A*'s jobs.

The main drawback of a focus group that group mentality may lead it, like a herd of sheep, down one particular idea that is not as good as what would have been exposed if each individual could reply alone. It is important for the facilitator to recognize when this phenomenon has happened, to cut off the wayward discussion, and to refocus the group with other questions.

The advice for conducting interviews concerning the contents of questions, the open-endedness of the planned sequence of questions, and the selection of interviewees for interviews applies also to focus groups. Of course, in a given time period, a focus group will be able to consider many fewer questions than is possible in the interview of one person, if for no other reason than to give everyone a chance to speak, but also to allow any discussion that happens. Also, the advice given in Section 87.6.6, concerning managing the interaction during group brainstorming applies also to focus groups, in order that the participants contribute freely and fully.

The more people in a focus group, the fewer the questions that can be asked in the session. On the other hand, one needs to get a representative set of stakeholders participating. Probably, there should not be more than a dozen people in any focus group.

87.6.6 Brainstorming

Brainstorming [37] is hands' down the most popular method of quickly generating new ideas for any purpose including RElic [12]. A brainstorming session consists of two activities: (1) idea generation and (2) idea pruning.

To begin idea generation for a brainstorming session, the leader of the session throws out a question or problem. People try to think of answers or solutions, never mind how outrageous or outlandish. The goal is to generate as many ideas as possible. An outrageous, outlandish idea could trigger yet other good idea.

The rules are the following:

- Shoot for quantity.
- Mutate and combine ideas.
- Do not criticize anyone's ideas, even your own.
- If you don't like someone's idea, including your own, leave it be, but improve on it.

* "*vel cetera*" means "inclusively or others" as "*et cetera*" means "and others".

- Nothing anyone says is to be held against him or her after the session—what happens in brainstorming stays in brainstorming.
- Let your imagination soar; wild is good.
- Feel free to be gloriously *wrong*.

The participants in a brainstorming session for RElic are

1. The stakeholders, with an emphasis on those who know most about or are affected most by *E*, *P*, or *S*
2. Some people from outside the project to develop *S*, in order to get out-of-the-project-box ideas

However, the effect of any participant's power in *O* should be minimized. That is, if a person and his or her boss are participants in the same session, the boss's power should be left outside the session, so that the person can contribute freely.

The number of participants should be kept manageable, so that everyone gets a chance to contribute. With too many people, the shy shut up and only the loud are heard. Among the participants, there are two special roles, the scribe and the moderator.

1. The scribe's role is to write down all ideas. He or she also may contribute ideas and may ask clarifying questions, to improve the accuracy of the list of ideas, but not critical questions.
2. The moderator's role can be described as something between two extremes, the traffic cop and the provocative agent.
 - a. The traffic cop enforces rules but does not lead.
 - b. The provocative agent actively leads, coming prepared with wild ideas to be thrown out at the beginning and whenever idea generation begins to wane. He or she may look for variations and combinations of other ideas, and he or she acts as a traffic cop.

Idea generation should continue until the first of the following happens:

1. The ideas stop coming.
2. Two hours have passed.

Beyond the two-hours limit, efficiency of idea generation and the quality of the ideas seem to drop off significantly.

After the idea generation has been terminated, idea pruning begins. Idea pruning is the removal of *useless* raw ideas and the refining what is left. As *quantity* is the focus of idea generation, *quality* is the focus of idea pruning. The purpose of idea pruning is to make the best ideas possible.

Care should be taken in idea pruning to avoid throwing out an idea just because it *looks* useless, hazardous, or uneconomical. In this sense, creativity is needed also in idea pruning. In addition, it may be useful to bring into idea pruning, stakeholders and outsiders who did not participate in idea generation. For example, it might be particularly useful to get the input of marketing and development people for idea pruning.

There are several choices of how to do idea pruning, including the following:

- Voting with threshold: Each person is allowed to vote up to n times. Keep those ideas with more than m votes. Have multiple rounds thereof with ever smaller n and m .
- Voting with campaign speeches: Each person is allowed to vote up to n times. Keep those ideas with at least one vote. Have someone who did not vote for an idea defend it for the next round. Have multiple rounds thereof with smaller n .
- Ranking ideas by priority or quality: Rank ideas by priority, quality, innovativeness, cost-effectiveness, pervasiveness of requirements coverage, speed of implementation, cheapness of implementation, etc., or any combination thereof. The group works to rank ideas by some method, for example, writing each on a card and placing cards into an ordering or a lattice. Find a cut-off point in the ranking, above which ideas are kept and below which ideas are discarded.
- Blending ideas: Consider pairs, triples, etc., of ideas for combining in some way. Then, go into one of the ranking or voting procedures.

Brainstorming is not the only technique for enhancing creativity in idea generation for RElic. There are other techniques that have more systematic or more focused idea generation [6,13,23,32,38,46]. For example, one problem with brainstorming is that it allows a random walk through the space of ideas. EPMcreate makes the walk through the space of ideas more systematic by having *A* lead a group of RAs to consider all 16 combinations of for and against the viewpoints of two stakeholders of *S* and for each combination to think of ideas that meet the requirements for the combination. One such combination would be “for stakeholder 1 and against stakeholder 2” [32].

87.6.7 Gause and Weinberg Techniques

Don Gause and Jerry Weinberg, the authors of two classic books on RElic [17,18], suggest a number of useful RElic techniques that help *A* to find those hard-to-find new requirements ideas:

- Questioning norms is considering things that are done in *E* and asking why they are done the way they are.
- Questioning assumptions is actively searching for assumptions in what is known about *E*, *P*, and *S* and asking if each is *really* true.
- Questioning existence assumptions is a refinement of questioning assumptions in which the assumptions that are sought and questioned are the very existence of things that are needed for *S* as currently conceived to work, for example, the underlying operating system provides an assumed capability.
- Use of the right brain is promoted by getting stakeholders to draw diagrams showing how they see *E* working, where *P* arises, and how they see *S* working and solving *P*.
- Naming is simply brainstorming for cooler or more precise names for things to encourage seeing them in different lights.

87.6.8 Prototyping

Many people, especially the nontechnically oriented, learn only while doing. They have got to see some kind of working version, a prototype, in order to *discover* what they want. There are several kinds of prototypes that can be built to help *C* and users see what is possible and then to comment on it, in order that they begin to discover what they *really* want:

- A functioning, throw-away, quick-and-dirty implementation of at least some of the functionality of *S*
- A mock up, a program that accepts only preplanned input of *S* to produce only preplanned output of *S* and is devoid of all other functionality of *S*
- A wizard of Oz, a user interface operated by a human being that pretends to be *S* to produce the intended results for any input
- A story board that describes, with, say, screen-diagram pictures, anticipated scenarios of the use of *S*
- A draft user’s manual for *S* that shows with screen-diagram pictures, anticipated scenarios of the use of *S*

Any of these prototypes can focus on only the main functionality or only the functionality over which there is least understanding or the most contention.

The rationale behind prototyping is IKIWISI. Many clients and users simply cannot describe what they want, but if they see what they want, they can recognize it as what they want immediately. Unfortunately, sometimes AYSTII (anything you show them is it), and *A* will have to judge whether what he or she is observing is IKIWISI or AYSTII.

One problem with the prototyping approach, particularly if it uses a running program, is that it can raise unrealistic expectations in *C* and the users, namely, that the guts of the software is already developed, that development of the production version will go as fast as the production of the prototype, or something else totally unrealistic. *A* must make clear and continually remind *C* and the users that what they see is *not* real software, that it is only a mock up, an empty shell, a wizard of Oz, *vel cetera*.

87.6.9 Joint Application Design

Joint application development (JAD) can be thought of as structured group brainstorming with the emphases on “structure” and “group” or as an extended focus group. The main idea of JAD is get all the stakeholders who matter and who can make binding decisions together in an isolated place to work intensively in a short time period to make the key requirements and design decisions, to which every stakeholder present commits, allowing implementation to proceed straightforwardly from the agreed to RS and design documents [52].

JAD for a CBS is carried out in two steps:

1. JAD/Plan, the RElic step
2. JAD/Design, the software design step

This chapter, being about RElic, focuses on the first step. Each step consists of three phases,

1. Preparing for the session
2. The session itself
3. Reporting on the session

There are six roles for each step:

1. Session leader, a JAD expert who organizes and facilitates the session
2. Analyst–scribe, who understands and develops the big picture and produces the session report
3. Executive sponsor, the manager who has ultimate responsibility for *S*, who understands *O*’s goals for *S* and can make *binding* decisions concerning *S* and its development
4. User representatives, a selection of knowledgeable users and managers
5. Information systems representatives, a selection of technical experts who understand the technology and its trade-offs
6. Specialists, a selection of experts on special topics deemed relevant to *S*, for example, security, the application domain, laws, regulations

Advance preparation is the key to the success of JAD. The executive sponsor picks the participants and invites them to the JAD session with explanations of what is to be done at the session and their roles. The session leader and the executive sponsor familiarize themselves with *P*, the problem at hand; the domain of *S*; and the stakeholders. They try to identify the possible issues and points of contention. They set the scope of the session. They prepare materials both for before the session, for example, reading material for the participants, and for during the session, for example, electronic slides, flip chart pads, markers for the whiteboards, food, etc.

The session is planned for, say, a full day or longer, at some place sufficiently isolated that participants will not be drawn away from the session to deal quickly with short matters. Cell phones should be turned off! Breaks for coffee, meals, and even some recreation are planned.

At the session itself, the session leader welcomes the participants and thanks them for agreeing to isolate themselves for the session period. He or she presents *P* and the goal for what is to be accomplished. He or she establishes the ground rules for the session and delimits the scope. Finally, he or she throws out some initial ideas.

The participants work on solving P , that is, doing the RELic that is needed. There will be brainstorming sessions as needed. The goal is to make decisions that everyone present can buy into and that have the power of the executive sponsor behind them.

Toward the end of the session or even very soon afterwards, the scribe writes up what has been decided, in the form of a RS if the session was for RELic. Everyone, including the executive sponsor, reads the write up, corrects it, and signs off on it.

JAD was developed at IBM and was found to be very successful because it is very effective at using the isolation and the short time available to get diverse stakeholders to agree to and buy into concrete decisions that have the power of an organizational executive behind them.

87.7 What Can Go Wrong during RELic?

There are a number of reasons that RELic can fail to lead to an adequate RS for S :

1. The existence of an unknown requirement: None of the stakeholders mentioned the requirement because none knew of it. Modeling helps expose the incompleteness of a set of requirements, as the known requirements fail to lead a complete model.
2. The existence of a known but undiscussed requirement: The requirement was known to several stakeholders, but each such stakeholder assumed that it was understood the same way by all and was therefore not worthy of mentioning. The only hope for exposing such requirements is the tendency for a person to say things that depend on unspoken, tacit assumptions, because he or she *knows* that the assumption is true. Having on the RELic team someone who is capable of being puzzled by things that different stakeholders describe differently—perhaps someone ignorant of S 's domain [4]—is helpful for exposing these tacit assumptions and undiscussed requirements. To the extent that an undiscussed requirement causes the discussed set of requirements to be incomplete, techniques for finding an unknown requirement can help expose known but undiscussed requirements.
3. The existence of a known, discussed, but undocumented requirement: The requirement was thoroughly discussed, but no one wrote it down, creating the possibility that if it is discovered again later, it will be understood differently from what was agreed to mean when it was first discussed. Having on the RELic team someone who is taking complete minutes and notes helps ensure that everything that is discussed ends up being documented properly.
4. The existence of a wrongly documented requirement. No stakeholder understood the requirement correctly and the incorrect understanding was documented, or it was understood correctly, but a saboteur documented it incorrectly, unbeknown to the other stakeholders.

87.8 Myths about RELic

The biggest myth about RELic is that A can just ask C and the users what they need and want and can expect to hear accurate answers. The fact is that S 's just asking C and users what they need and want does not always work.

Sometimes, C and the users know what they need and want but cannot describe it, for example, as few people who can ride a bicycle can describe how to ride a bicycle, at least in a way such that anyone hearing the description will be able to just get on a bicycle and start riding without falling. Instead, they have to *show* what they need and want, for example, by showing when, where, and how E should deviate from what it does and then showing with pictures what it should do instead.

Other times, they do not know what they need and want; they know only that what E does is not what they need and want. They might be able to put their fingers on only what is wrong with what E does, and A would have to take it from there.

Closely related to not being able to describe what they need and want is not being able to describe in detail what they need and want, the exceptions from the norm, and the responses to the exceptions. When most people are asked what they do, they will quote the official policy, and not what they actually do. Most of what they really do, which is not specified by the policy, is what they do in situations not covered by the policy. This quoting of official policy is not an example of conscious, politically safe mouthing of the policy. Many people simply do not remember the exceptions unless and until they actually come up. The official policy *is* their conscious model of what happens. Domain experts among these people, from their experience with *E* and their understanding of *O*'s goals, instinctively *know* what to do for each exception as it comes up. Ultimately, even with a prototype, *A* has to be watching when any exceptional situation happens during the operation of *E* to see what really happens.

Sometimes requirements information is simply not in the mind of *any* stakeholder. Joseph Goguen [20] observed in 1993 that

It is not quite accurate to say that requirements are in the minds of clients; it would be more accurate to say that they are in the social system of the client organization. They have to be invented, not captured or elicited, and that invention has to be a cooperative venture involving the client, the users, and the developers. The difficulties are mainly social, political, and cultural, and not technical*.

Finally, many people just do not know why they do something, saying only that it is done this way because the policy says so. They very often do not even know why the policy is the way it is. It could be that the reasons for the policy are lost in history and that they were in response to a situation that is irrelevant today. In other words, the policy once made sense, but the person who formulated the policy, the reasons for it, and the understanding of the reasons are long since gone. For example, many companies that have committed all data to a highly reliable data base continue to print out the summary in quintuplicate. Why? At the time of automation, the five most senior members of the company, who have since retired, refused to learn to use the computer to access the data directly!

87.9 Why Invention and Creativity Are Necessary for RELic

The quotation from Joseph Goguen in Section 87.8 pointed to the need to *invent* requirements. Invention requires creativity. Many others have observed the importance of creativity in RE, particularly for discovering and inventing requirements for *S* [17,20,21,24,29,30,31,33,35,36,43], for solving wicked [42] problems, and for addressing critical business challenges [14,19,41,42].

Creativity is a part of RELic because requirements have to be invented. Requirements have to be invented, because if not, we would never advance beyond what we do now. Anytime *S* is different from *E*, someone had to have invented some new requirement that made the difference. That someone could be *A* or *any* of the stakeholders, including *C* and the users.

87.10 Empirical Studies of RELic Techniques

A lot of what is said about RELic techniques is folkloric. That is, a lot is said without what is accepted as empirical evidence that it is true. A significant fraction of what is said is probably true. That is, experienced practitioners, for example, Gause & Weinberg and Beyer & Holtzblatt, have learned what works and have described the abstracted techniques, suggesting that others try them too.

Nevertheless, there is empirical work testing whether specific techniques work as expected and discovering what really works. For example, for brainstorming and other creativity enhancement techniques,

* Note that this quotation is from a draft of what was later published as a chapter in a book [21]. The quotation did not survive into the book chapter. However, by e-mailed personal communication, Goguen assured the author that he still believed in the contents of the quotation.

there are empirical studies about what works [2,25,32,46]. More empirical research is needed to validate RE methods in general and RElic methods in specific.

Dieste and Juristo have published a systematic review of research empirically validating RElic techniques [15]. Independent of the contents of the review, its bibliography is a gold mine of references to RElic techniques.

87.11 Conclusions

RElic is fundamentally the gathering of information about the CBS S to be built, from whatever sources the information is available, be it the client C ; other stakeholders in C 's organization, O ; the existing system, E , to be replaced by S , documentation about E ; and invention. Often times, the information does not come freely from stakeholders in O that do not fully understand the problem P to be solved by S or have a political agenda. This chapter describes techniques that can be used to help start the free flow of this information, so that eventually a good RS can be produced for S .

88.1 Underlying Principles

In the discipline of software engineering, the term *specification* has various possible interpretations. Whether applied to a simple routine, to a class, to a small subsystem, or a large system, it relates to the behavior of the entity as seen externally. Thus, how does its operation impact on the external environment, what is the effect of its operation, etc.? In this chapter, the focus will be on specifications for software systems and the term *software requirements specification* (often abbreviated to SRS) is typically used to capture this.

SRSs are relevant to different categories of interested parties. At an early stage, a very informal description can be used to inform users about the system—about what the system will do, what role it will play, and how users can interact with it. Such descriptions are very useful; they are typically accessible to many parties who can then react with helpful insights into providing improvements, amplifications, and clarifications.

Where the software is embedded and forms part of a much larger system, the software requirements are typically derived directly from the specification of the larger system. The functionality of the software is derived in this way together with the manner in which it interacts with the wider system and typically includes constraints and performance issues.

For software system designers and implementers, it is important to have an SRS document that describes the system in unambiguous terms. Such documents have to be written in a rather formal (i.e., precise and unambiguous) manner and are the subject matter of this chapter. These specifications have to be agreed among all interested parties. For large systems, such documents can themselves be relatively large.

For a general overview of different aspects of software specification (see Gehani and McGettrick, 1986 and Dorfman and Thayer, 1997).

88.2 Best Practices

88.2.1 Nature of Specifications

88.2.1.1 Typical Structure of Specifications

Central to the SRS will be two important aspects of specification: typically SRS documents will be couched in terms of

- The *functional specification* that captures the activities that the system has to perform. The various activities have to be identified and their functionality described.

- The *nonfunctional specification* that captures additional aspects such as timing constraints, reliability requirements, safety issues, security and privacy constraints, and recovery from exceptions.

Having said this, an SRS document will have to be far more comprehensive than just this. Such a document will need to capture the context for the software system in all its forms. Much will depend on practices within an organization but typically supplying all the relevant detail can occupy as much as 20%–25% of overall development time. The rationale for such major investment is that errors or omissions at this stage can typically be 10–20 times more expensive than errors at the design stage and 100–200 times more costly than coding errors.

From this perspective, great care should be taken to ensure that as much relevant detail is obtained at this stage and that it is an accurate reflection of what is required. Conversely all irrelevant detail ought to be excluded; for clarity, this refers to detail irrelevant for the explicit purpose of providing an SRS document that is as simple as possible. Having said this, such documents can often be very abstract and the provision of a number of illustrative use cases can be used to add clarity and assist with understanding.

To facilitate the provision of SRS document, guidelines are often supplied to provide a framework for a specification. In this spirit an industrial standard exists—see IEEE (1998). A typical SRS document will include

- An introduction that informally captures the goals and intent of the system.
- *Environmental factors* that capture the characteristics of the environment in which the system is to run, that is, the software, hardware, and communications infrastructure and human interaction issues.
- *Interface considerations* detail how the system will interact with other software and with the various users; this may well be amplified by use cases that capture the class of possible users and the manner in which they have to interact.
- The *functional specification*.
- The *nonfunctional specification*.
- Constraints on design: the languages to be used, standards to be followed, resource issues, policy considerations, etc.

The structuring of these specifications is an important matter. The principles associated with such structuring are similar to the guidance for structuring and organizing programs themselves. Thus, it should be clear where the need for particular parts of the requirements arose and then individual aspects of the specification should be grouped together in some natural and logical fashion, for example, those related to some event, to some data structure, and to some subsystem.

88.2.1.2 Some Fundamental Questions

At this stage there are two fundamental questions to be asked:

1. Is it possible to build this software system? Behind this comment lies the observation that it is possible to specify software systems that can never be built, not because of limitations of resources but because of basic theoretical considerations. For instance, it is just not possible to build a program that tells whether arbitrary programs will terminate or a system that tells whether two arbitrary arithmetic expressions are identical. There are also matters such as the possibility of stating very demanding performance requirements when the reliability of the underlying operating system or hardware makes this impossible.

A related matter is that, even if it is possible to build a particular system, the task may turn out to be enormously expensive, even far too expensive in retrospect. When this happens it is desirable to know well in advance so that unnecessary development does not occur. The SRS document is the definitive statement and so the input for any discussions or analysis on questions of feasibility. For such purposes, simplicity and clarity are desirable.

2. Are there software systems for which it is not reasonable to think of supplying a specification? Here the issue is not the ability of the person undertaking the task but it relates to the nature of the task itself. It is recognized that providing a specification for a sophisticated search engine falls into this category.

88.2.1.3 Usage of the SRS Document

Generally, the usage of the SRS document falls into several categories:

- It can be viewed almost as a legal document and the basis of a contract between a client and development team; it captures in succinct terms what has to be produced.
- It is a definitive statement that can be used to resolve questions, for example, between members of a development effort, about the final system.

It can be used to address certain (usually limited) questions about the feasibility of building such a system:

- It is the starting point for a serious development effort.
- It can be used as the basis of an evaluation of the resources required for the development effort and this includes costs, manpower, and timing.
- Importantly, it provides the basis for an independent testing effort, that is, an effort that can proceed independently of the work of the development team.
- Finally, it is a sound starting point for considerations of possible future enhancements to the system.

To fully meet these various demands, the SRS document should ideally possess certain desirable characteristics.

88.2.1.4 Desirable Characteristics of SRS Documents

A key characteristic is *simplicity*. This is a somewhat vague concept but in this context includes being easy to read and understand, easy to obtain answers to questions, is well structured and organized, and is free of obscurity and complexity. Ideally also it should be relatively compact and free of extraneous detail. For instance, an argument often given is that an SRS document should be free, for instance, of implementation detail; the latter is the concern of the implementation team who will wish to be free to make implementation decisions and choices.

Another important characteristic is *completeness*. Thus, there should be no areas of omission so that, for instance, all ways in which the system can be accessed by a user and all ways in which it interacts with other software are captured and the relevant functionality explained in detail. Importantly, the issue of completeness is relevant not just to the functional requirements but also to the nonfunctional requirements and the other dimensions of the SRS document. In safety critical systems, for instance, safety requirements need to be carefully clarified and then articulated. Under completeness, an often-neglected area relates to error situations, exception handling, and fault tolerance. It may be desirable that the SRS document should stipulate what happens in the event of exceptions taking place, an upper bound on time to recovery, etc. In safety critical systems, for instance, it can be vital to know how the system responds to exceptions so as to be comfortable that no life will be lost and the system will always be in a safe state.

Requirements need to be captured in such a way that the resulting document is *unambiguous*. All readers must be able to interpret the requirements in the same way; otherwise, there is scope for confusion and inefficiency. An aspect of this, of course, is *consistency* of the requirements; so, for instance, particular terms should be referred to in the same way throughout to avoid possible confusion. When natural languages are used, there is often scope for employing an associated glossary to capture meaning.

Another term often associated with specifications is *correctness*. The term *correctness* usually implies consistency between two entities, for example, in simple mathematics a known answer and a suggested answer. Given this interpretation, if two specifications are supplied, then consistency between these can be addressed and used to produce a definitive SRS document. Otherwise, notions of correctness tend

to take the form of comparing an SRS document and some abstract view of the system that resides in someone's mind. If the abstract view is just one person's view that can be problematic, that vision needs to be transmitted to a wider audience and group activity and discussion can facilitate that.

The term *verifiable* is also often used in the context of SRS documents. This is intended to capture the notion that requirements can easily be checked. To illustrate "fast response" is better captured in quantifiable terms so that a developer will know if this is being achieved. Likewise, reliability targets should be quantified.

The concept of *full referential transparency* is also highly relevant. Possessing this property implies that accessing the system for a particular purpose has the stated effect and does not have curious side effects in other parts of the wider system. The reverse is also equally relevant, that is, that activities in other parts of the system (e.g., in other locally resident software systems) do not have an impact on the software under consideration.

To emphasize the earlier text, an additional very important and related aspect relates not to what the final system should do but what it should not do. The possibility of the system producing unexpected or undesirable effects is often ignored. Of course, an implementer may choose to offer additional functionality (hopefully with the approval of the client) that proves to be exceedingly attractive and useful. But as well as implementing the agreed functionality, a devious implementation could include some malicious code that produces highly undesirable side effects. This can happen deliberately or accidentally, for example, through the reuse of code developed elsewhere. It is important to have an eye to such possibilities. Basically, the external impact of the system should not be beyond that captured in the SRS document.

Finally, although every effort has to be made to produce a final definitive SRS document, part of the reality of software systems is that they will need to be modified, perhaps several times. Consideration should be given to ensuring that a SRS document is written, organized, and structured so that it is readily amenable to modification and amplification.

88.2.2 Language of Specifications

An important consideration is the language in which a specification is described. There are various possibilities. Natural languages can be used although normally considerable care has to be taken to ensure precision. However, an important class of formal languages called *specification languages* exists. These are used for capturing what has to be done and not how implementation should proceed.

The motivation here is that a formal structure tends to bring additional rigor and a greater ability to reason about a system. An additional important consideration is that formal languages are amenable to processing by tools of different kinds. Included in these are tools to

- Check such matters as syntax, the proper use of types as appropriate, certain aspects of semantics.
- Assist with ensuring the desirable characteristics such as consistency and completeness mentioned earlier; this may even extend to reasoning about the system.
- Allow a certain amount of simple animation of the specification in the sense that certain inputs can be provided and appropriate outputs produced; this can include error situations.
- Possibly support aspects of the implementation activity; there are systems that aim to carry out correctness—preserving transformations that will ultimately lead to final executable code.

The class of specification languages is subdivided into various categories.

88.2.2.1 Model-Based Specifications

With *model-based* specification languages, a specification captures a system's behavior in terms of an abstract model; this is typically constructed using mathematical structures such as sets, functions, and relations. The functionality of the system is then defined in terms of changes to the model. Examples of these languages include the Z specification language (see Spivey, 1992), the Vienna Development Method (VDM) (see Dawes, 1991), and Milner's Calculus of Communicating Systems (CCS) (see Milner, 1980).

Some insight into the nature of these specifications and the benefits they bring is relevant. Using the formal specification language, an abstract model of a system is developed using the facilities of the language, usually sets relations, variables of particular types, etc. Of course these will be initialized in appropriate ways, for example, initially a particular set may be empty. The various activities that the system has to perform then take the form of functions or routines that change the state of the system in clearly defined ways. So basically, the system is state based. Through the application of functions, the system moves from an initial state through other states by the application of the various functions and routines. Beyond the basic requirements,

- Invariants capture those aspects of the state of the system that must remain unaltered throughout all changes of state, for instance, in a library system invariants may stipulate that all users of the library must be registered and that all books are classified as either on loan or available for lending.
- For each function, there will also be preconditions and post-conditions: the preconditions stipulate state characteristics that must pertain prior to certain state changes being attempted, for example, a book can be borrowed only if it is not already on loan; post-conditions capture the effect of invoking the function.

A key matter is that after the operation of each function, the system invariants must remain intact. This is to reflect the fact that the various states have desirable properties and no undesirable ones. This will typically require proof (for example, see Yang and Hawblitzel, 2011).

There is obvious scope for tools to check syntax, to carry out relevant type checking, to check that variables have been initialized appropriately, and to assist with proof.

88.2.2.2 Property-Based Specification Languages

Here the specification takes the form of system constraints on system behavior; typically the fewer the properties or constraints specified, the richer the range of possible design decisions to be made. This group of languages is typically subdivided as follows:

- The *axiomatic* that uses first-order logic to describe preconditions and post-conditions. The languages OBJ (see Malcolm and Goguen, 1996) and Larch (Gutttag et al., 1990) support this form of specification.
- The *algebraic* where data types and processes are captured in the form of an algebra and then axioms in the form of equations are employed.

88.2.2.3 Concurrent and Distributed Systems Specification

Concurrent and distributed systems pose an even greater set of problems for system developers. The timing issues, the potentially complex interactions, the problems of sharing, and the constraints pose a new set of very complex problems. Different approaches, different languages, and different formalisms are needed to address the challenges.

The topics here are not the main focus of this chapter. However, temporal logic has provided the basis for many developments in this area; this is in the form of a logic that permits arguments about happenings over time. Advances in model checking (see Clarke et al., 2009) have made many of the related problems of verifying properties of finite-state systems.

88.2.3 Specification of Nonfunctional Requirements

The specification of nonfunctional requirements is often ignored, and that can lead to serious disruption in project delivery. In reality the nonfunctional specification should be given similar prominence and attention as the functional specification part of an SRS document. It should possess desirable characteristics and be checked for such matters as feasibility and completeness.

88.2.3.1 Classification

Where they are addressed, it is customary to provide a classification of nonfunctional specifications. The IEEE standards (see Kotonya and Sommerville, 1998) use a classification that includes

- Process requirements that cover standards to be used as well as other implementation requirements and importantly delivery dates
- Product requirements that address matters such as efficiency, performance, reliability, and storage requirements as well as safety, security, and usability
- External requirements that address economic considerations, legal matters, etc.

The manner in which these requirements are stated is generally fairly obvious.

88.2.3.2 Reliability and Safety

In the context of reliability requirements, safety requirements, etc., a quantitative approach based on probability can be employed. For instance, in the context of safety, critical systems probability is typically employed to identify the criticality of the software and to capture the required safety levels. Safety integrity levels (SILs) are used to capture the level of criticality of the software and so the required measures of performance of the software. These ideas are captured within the standard IEC 61508—see IEC 61508 (2010).

To illustrate the SILs where the demands on the software are relatively low, the following captures the average probability of failure to perform on demand:

SIL	Maximum Average Probability of Failure (Low Demand)
4	$\geq 10^{-5}$ to $< 10^{-4}$
3	$\geq 10^{-4}$ to $< 10^{-3}$
2	$\geq 10^{-3}$ to $< 10^{-2}$
1	$\geq 10^{-2}$ to $< 10^{-1}$

On the other hand, if the demands on the software are very high, even continuous, the following may be more apt:

SIL	Maximum Average Probability of Failure (High Demand)
4	$\geq 10^{-9}$ to $< 10^{-8}$
3	$\geq 10^{-8}$ to $< 10^{-7}$
2	$\geq 10^{-7}$ to $< 10^{-6}$
1	$\geq 10^{-6}$ to $< 10^{-5}$

The comment should be made that higher SILs are deemed unachievable due to current limits of the technology; there is scope for change here as technology improves.

88.2.3.3 Specification of Security

An increasingly important matter is the specification of security requirements. Such requirements are normally concerned with the careful management and organization of data, but there are huge concerns over such practices as compromising the software that has access to the data.

Of course, this is an ever-changing landscape. Providing nonfunctional requirements in the general area of security is nontrivial. One way of approaching this is to stipulate that steps should be taken to exclude certain common security risks. The latter are known and in Owasp (2013), for instance, there is a list of the 10 most common security risks for 2013.

88.3 Research Issues

Although considerable progress has been made, the field of SRS remains one in which there are many challenges. Included in these is the wish to automate to some extent the process of going from an SRS document to code that meets the required objectives. Progress has been made in this regard but much more remains to be done.

The EU funded *Prospectra* project, for instance—see Hoffman and Kreig-Brueckner (1993)—had the ambitious goal of making software production a truly engineering discipline. It sought to support development from a formal specification to executable code through a sequence of correctness preserving transformations and in the process building up knowledge of program construction and the associated proof. There were many interesting developments here but a final usable system did not materialize.

Included among the challenges are

- How can high-quality (meeting the requirements of consistency, completeness, etc.) SRS documents that embrace all aspects of specifications including functional, nonfunctional, and other aspects be produced quickly? What guidance can be provided in this regard?
- Can better approaches be devised to ensure that nonfunctional requirements are captured systematically in a useful and complete manner?
- What guidance can be provided for ensuring that an SRS document can be the basis of the provision of a realistic measure of costs and more generally resources?
- How can formal specification languages and their habitual use in software development process be made ever more accessible to software engineers, with associated proof happening but in a manner that does not require deep insights into logic?
- How can better tools be provided to support the aim of ensuring that software engineering becomes a true engineering discipline, that is, complete with reuse of knowledge about program construction and proof?
- How can correctness preserving program transformations be developed starting with SRS documents, taking account of advances in multi-core?

88.4 Summary

There are differing approaches to the topic of SRS, ranging from the relatively informal through to the very formal. Having high-quality specifications tends to become more and more important as the size and complexity of a project increases and also as its significance (in terms of safety, security, etc.) increases. In all cases, high-quality specifications can dramatically enhance the efficiency of the software development process; the more formal approaches open doors for an increased use of support tools and rigorous approaches. Although these are gradually gaining support and favor, some continue to see the lack of skills in this area as a cause for concern and a source of risk.

In the background, there are serious systems issues that need to be addressed. Thus, high-quality specifications are the ultimate goal, but these need to be present in larger systems that are themselves of high quality (thus reliable) and the tools used to process specifications themselves need to be of high quality.

89.1 Introduction

This chapter provides an overview of techniques and tools for analyzing the correctness of software systems using *model checking*. After providing some background on traditional finite-state model checking and related tools (Section 89.2, we give an overview of two classes of techniques that have allowed model checking to be applied directly to the source code of large software systems: counterexample-guided abstraction refinement (CEGAR) using predicate abstraction (Section 89.3), and bounded model checking (Section 89.4). The chapter concludes with a brief survey of tools that leverage traditional model checking methods for the analysis of software systems (Section 89.5). Software model checking techniques based on CEGAR and bounded model checking are also treated in the *Software Verification* chapter of the Handbook of Satisfiability [73]; we believe these chapters complement one another.

89.2 Model Checking

We begin with some background on traditional model checking techniques for finite-state systems. For full coverage of this topic, we refer the reader to several excellent books and tutorials [3,35,66,78,79]).

The model checking problem can be stated as follows:

Given a finite-state model M and a logical property ϕ , does M satisfy ϕ ?

The finite-state model M under consideration is usually a *Kripke structure* consisting of a set of states, a transition relation over pairs of states, and a description of the logical formulas that hold in each state, while ϕ is a formula in some temporal logic, such as linear temporal logic (LTL) or computation tree logic (CTL).

A *model checker* is an algorithm for answering the model checking problem with respect to a specific temporal logic. A model checking algorithm either determines that the model satisfies the property,

or produces a *counterexample*: a sequence of state transitions through M which demonstrates that the property is violated. Among the many model checking tools that have been designed, perhaps the most notable are SPIN [66] and SMV [77]. Practical model checking tools allow models to be expressed using relatively high-level description languages, such as Promela (the input language for SPIN) or the SMV language.

Model checking can be used in the analysis of any kind of system (e.g., a hardware design, protocol specification or software program) if it is possible to express desired properties of the system as temporal logic formulas, and if it is possible to obtain a finite-state model that accurately describes behaviors of the system that are relevant to these properties. In this case a model checker can be used to prove that the system satisfies the properties of interest, or to yield counterexamples demonstrating that the system is incorrect. The production of counterexamples is a key benefit of model checking over other formal verification techniques: counterexamples can be invaluable aid to engineers in the process of debugging and fixing a system. In practice, model checking tools operate on models provided using high-level description languages which can be expanded automatically into Kripke structures.

The first algorithms for model checking date from the early 1980s [28,83]; see [27] for a retrospective on the birth of the field. The development of *symbolic model checking* [21,77] in the early 1990s led to model checking being used extensively in industrial hardware verification. The application of model checking to software verification, the focus of this chapter, has been more recent.

The main challenge associated with practical model checking is *state space explosion*. Typically a model is described as the composition of a number of components, for example variables or processes, each describing aspects of the system under consideration. The potential state space of the model grows exponentially with the number of components, and can quickly become too large to explore exhaustively using standard algorithms. A significant portion of model checking-related research has been on techniques for ameliorating state space explosion while maintaining soundness guarantees, including symbolic representation [21,77], partial order reduction [51,81], symmetry reduction [31,48,68,91], and abstraction [30,55].

The state space explosion problem is particularly relevant to software model checking because programs exhibit extremely large and often *infinite* state-spaces. This can stem from potentially unbounded allocation of heap data structures, and from recursive procedure calls. In some programming languages, numeric data types such as integers are regarded as having infinite range. In mainstream languages such as C, C++ and Java, all numeric types have finite (though often very large) domains.

89.3 CEGAR-Based Software Model Checking

Counterexample-guided abstraction refinement (CEGAR) [29] aims to leverage the power of traditional finite-state model checking techniques for the analysis of systems with very large or infinite state spaces. Model checking based on CEGAR was originally proposed for the analysis of finite-state transition systems with intractably large state spaces, based on the following idea:

1. Given a description of a finite state transition system C , compute an *abstract* transition system A such that A has a smaller state space than C and A *over-approximates* C : for every path through P there is a corresponding abstract path through A , thus A contains at least the behaviors of P .
2. Apply traditional finite-state model checking techniques to decide whether A is correct. If A is correct then, because A over-approximates C , correctness of C follows.
3. If A is *incorrect*, a *counterexample* π showing incorrectness of A is produced by the model checker. Examine π to determine whether it is also a counterexample to the correctness of C . If it is, incorrectness of C follows directly.

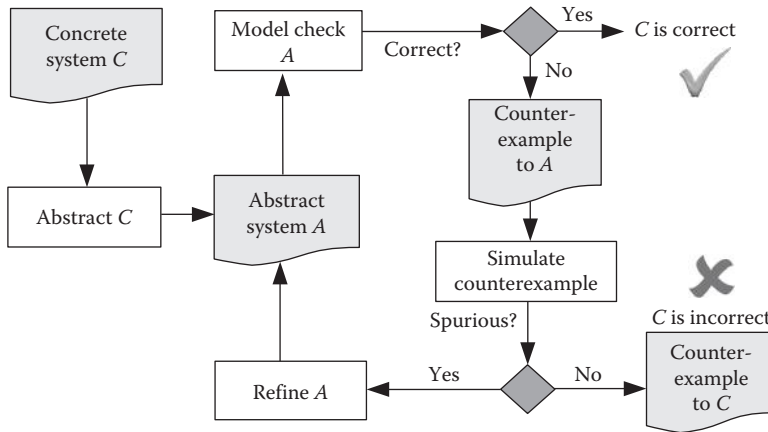

FIGURE 89.1 Counterexample-guided abstraction refinement.

4. If π is deemed *spurious* (it is a counterexample to the correctness of A but not to that of C) then extract information from π to *refine* the abstract program A such that π (and ideally a whole family of counterexamples to which π belongs) is no longer a counterexample to A , and continue from step 2.

The CEGAR process is illustrated in Figure 89.1.

The key motivations for CEGAR are that while there may *exist* an abstraction of a large transition system that facilitates sound, efficient verification, it may not be straightforward to directly pinpoint the required abstraction. CEGAR allows verification to start with a coarse abstraction and gradually refine this abstraction in response to counterexamples, driving the abstraction closer to a point where verification will succeed or, during this process, discovering a genuine counterexample to correctness.

For finite-state transition systems, the CEGAR process is guaranteed to terminate, though in the worst case the state-space of the abstract system may grow as large as that of the concrete system [29].

89.3.1 Predicate Abstraction

CEGAR-based model checking can also be applied to infinite-state systems, including software, but in this case there is no termination guarantee. Each time the abstract system is refined it is possible for new spurious counterexamples to manifest, and there is no limit to how large the abstract system can grow. Nevertheless, CEGAR-based model checking has proven successful in the analysis of infinite state software systems, as demonstrated by several tools including SLAM [10], BLAST [15], SATABS [33], MAGIC [25], and CPACHECKER [16].

The majority of software model checkers that employ CEGAR use *predicate abstraction* [55] as their abstraction method. Predicate abstraction involves choosing a fixed set of predicates over the state of a system and then representing a concrete state abstractly according to the truth values of these predicates when evaluated with respect to the state. For example, consider a simple system with two integer variables x and y . The state space of this system is infinite, consisting of all integer pairs. If we perform predicate abstraction over this state space with respect to predicates $p \triangleq x = 0$ and $q \triangleq y = 0$, then there are four abstract states, as depicted in Figure 89.2, corresponding to each of the four possible valuations of p and q .

A predicate abstraction technique for C programs was proposed in [7]. This method takes a C program together with a set of predicates, and produces a corresponding *Boolean program*. The Boolean

FIGURE 89.2 Predicate abstraction of a system with two integer variables x and y , with respect to predicates $x = 0$ and $y = 0$. The abstract state space comprises four abstract states, one for each valuation of the predicates.

program has identical control structure to the C program, but instead of operating over the original program it operates over a set of Boolean variables, one for each predicate.

We illustrate predicate abstraction for C programs using an example adapted from [10], and simplified further for presentation here. Consider the fragment of C code shown in Figure 89.3a, which is originally derived from a peripheral component interconnect (PCI) device driver [10]. The method `process` iterates through a queue of requests via global variable `req`. We omit details of the structure of requests, except that the `request_t` structure has a `next` field. Before accessing the request queue, the method acquires a lock, shown in Figure 89.3a for simplicity by setting variable `locked` to `true`. The lock is released by setting `locked` to `false`.

We wish to verify that the `process` function obeys correct locking discipline, that is that the lock is not acquired while it is already held, and that the lock not released unless it is held. In Figure 89.3a, we have instrumented the code with assertions about `locked` to check this.

Figure 89.3b is a Boolean program obtained by applying predicate abstraction to the program of Figure 89.3a with respect to the predicate `locked`. The only data tracked by the Boolean program, in addition to the program counter, is the truth of `locked`. This means that statement `locked = true` at line 11 of Figure 89.3a maps to an identical statement in Figure 89.3b, but statement `nPktsOld = nPkts` at line 13 is replaced with `skip` (a no-op), because this statement cannot affect the truth of `locked`. The condition `req` at line 14 is replaced with the *nondeterministic* condition `*`: the only data available to the Boolean program is the truth of `locked`, so whether `req` is null cannot be precisely determined. The Boolean program soundly over-approximates this condition by evaluating it non-deterministically. The translation of the remaining statements of Figure 89.3a to corresponding statements in Figure 89.3b is similar.

Notice that for every execution trace through the program of Figure 89.3a there is a corresponding trace through the program of Figure 89.3b such that the value of `locked` is identical throughout both traces.

(From Ball, T. and Rajamani, S. K., *The SLAM toolkit*, In Berry, G., Comon, H., and Finkel, A., eds., *CAV*, volume 2102 of *Lecturer Notes in Computer Science*, Springer, New York, pp. 260–264, 2001.)

As we shall see in Section 89.3.3, the reverse is not true: the Boolean program contains additional execution traces that are not feasible in the original program.

Now let us consider applying predicate abstraction to the program of Figure 89.3a with respect to the predicates `locked` and `nPkts==nPktsOld`. The resulting Boolean program is shown in Figure 89.3c. Predicate `locked` is treated as in Figure 89.3b. Boolean variable `nP_eq_nPO` tracks the predicate `nPkts==nPktsOld`. Initially the value of this predicate is unknown. At line 13 the predicate becomes true due to the assignment `nPkts = nPktsOld` in the original program. At line 21 the predicate is updated to model `nPkts` being incremented. It is clear that if `nPkts` and `nPktsOld` are equal then they will no longer be equal after `nPkts` is incremented. However, if the variables are *not* equal then incrementing `nPkts` may or may not lead to equality: if `nPkts==nPktsOld-1` holds then equality

will result after the increment, otherwise it will not. In the absence of any such further information about `nPkts` and `nPktsOld`, in this case the best we can say is that after the increment the value of the predicate becomes unknown. The statement:

```
nP_eq_nPO = nP_eq_nPO ? false : *;
```

at line 21 of Figure 89.3c reflects this reasoning.

The predicate `nPkts==nPktsOld` allows the guard of the `do..while` loop to be represented precisely at line 24 of Figure 89.3c. Because the two predicates under consideration say nothing about `req`, testing and updating `req` at lines 14 and 15 of Figure 89.3a still lead to a nondeterministic choice and no-op, respectively, at the corresponding lines of Figure 89.3c.

Boolean and Cartesian Abstractions: We have illustrated the process of predicate abstraction informally through an example. For a complete procedure for this translation, treating pointers and procedure calls, see [7].

Predicate abstraction can be applied with varying degrees of precision. At one extreme, the *Boolean abstraction* represents each program statement as the most precise possible predicate transformer [55]. In the worst case, for a set of n predicates, this can involve checking the feasibility of all $2^n \times 2^n$ potential predicate transformations. An alternative is the *Cartesian abstraction*, combined with the *maximum cube length approximation* [7], which allows faster but less precise predicate abstraction. The loss of precision may require additional refinement steps as described in Section 89.3.4. The relationship between the Boolean and Cartesian abstractions has been studied formally [8].

89.3.2 Boolean Program Model Checking

The Boolean program corresponding to a recursion-free C program has a finite state space. If the C program is recursive, then so is the corresponding Boolean program, in which case the Boolean program corresponds to a *pushdown system*, for which the model checking problem has been studied (see, e.g., [20,22,50]). Model checking tools for Boolean programs include BEBOP [9], MOPED [86], BoPPO [36], and BOOM [12] (though BoPPO and BOOM do not support recursive Boolean programs). Each of these tools uses symbolic model checking techniques based on binary decision diagrams to curb state explosion.

By construction, the Boolean program obtained from a C program is an over-approximation, thus if Boolean program model checking determines that the Boolean program is correct it follows that the C program is also correct. In the best case, it may be possible to prove correctness of an infinite-state C program by performing predicate abstraction and Boolean program model checking with respect to a small number of predicates. However, if model checking reveals that the Boolean program is not correct, this does not directly reveal anything about the original program; further analysis is required.

89.3.3 Counterexample Simulation

Continuing the example of Section 89.3.1, suppose that we have computed the Boolean program of Figure 89.3b with respect to the predicate `locked`. Model checking this Boolean program will result in a counterexample because the Boolean program is *not* correct. One counterexample that might be returned by a Boolean program model checker is the trace that, starting with `locked = false`, sets `locked` to `true` at line 11, enters the `if` statement at line 14, sets `locked` to `false` at line 19 and leaves the `do..while` loop at line 24. As a result, control reaches line 27 with `locked` set to `false`, and the assertion fails.

It is now necessary to decide whether this counterexample trace corresponds to a feasible trace of the original program. This can be achieved by building a logical formula describing the conditions for the Boolean program counterexample to be followed in the original program and ending in a state where the assertion does not hold. For the counterexample, we have just described the corresponding formula is as follows:

$$\begin{aligned} & !\text{locked}_0^5 \wedge \text{locked}_1^{11} \wedge \text{nPktsOld}_1 = \text{nPkts}_0^{13} \wedge \text{req}_0 \neq 0^{14} \wedge \text{req}_1 = \text{req}_1 \rightarrow \text{next}^{15} \wedge \\ & !\text{locked}_2^{19} \wedge \text{nPkts}_1 = \text{nPkts}_0 + 1^{21} \wedge \text{nPktsOld}_1 = \text{nPkts}_1^{24} \wedge !\text{locked}_2^{27} \end{aligned}$$

The superscripts in this formula are for illustration only and indicate from which line of Figure 89.3a each conjunct arises. Multiple assignments to variables are modeled in the formula by giving each variable a fresh index (indicated by a subscript) each time it is assigned, in the style of static single assignment form.

Satisfiability of the formula corresponding to a counterexample can be checked by a state-of-the-art theorem prover or SAT/SMT solver. If the formula is *satisfiable* then abstract counterexample does correspond to a concrete counterexample, and the satisfying assignment provides a test input to the program that will cause the bug to manifest. If the formula is *unsatisfiable*, the abstract counterexample is *spurious*: it does not correspond to a trace of the original program, and the abstraction must be refined to block the counterexample.

The aforementioned formula is easily seen to be unsatisfiable due to the unsatisfiable subformula:

$\text{nPktsOld}_1 = \text{nPkts}_0^{13} \wedge \text{nPkts}_1 = \text{nPkts}_0 + 1^{21} \wedge \text{nPktsOld}_1 = \text{nPkts}_1^{24}$ and thus the counterexample is spurious.

89.3.4 Abstraction Refinement

On discovering a spurious counterexample, it is necessary to *refine* the abstraction, making it sufficiently precise that the counterexample trace is blocked. Eliminating spurious counterexamples clears the way for either finding genuine bugs, or proving correctness.

Two complimentary approaches to abstraction refinement are used by CEGAR-based model checkers: *transition refinement* and *predicate discovery*.

As discussed in Section 89.3.1, it may be infeasible to compute a Boolean program that uses the most precise abstraction, the *Boolean abstraction*, with respect to a set of predicates. Instead, less precise abstractions can be used: the SLAM tool uses *Cartesian abstraction* with *maximum cube length approximation* [7], while SATABS [33] employs an extremely coarse method known in the community as *fast abstraction*. This source of imprecision can lead to spurious counterexamples, which can be refined away using *transition refinement* [5]. Transition refinement considers each abstract transition $a \rightarrow b$ occurring in the counterexample trace. Suppose that the transition $a \rightarrow b$ is associated with the abstract statement at program point i . We can check, using a theorem prover, whether there exists concrete program states s and t such that: s is abstracted by a , t is abstracted by b , and the concrete statement at program point i leads to a transition between s and t . If no such pair of concrete states exists, then the transition $a \rightarrow b$ is *spurious*: it does not belong to the Boolean abstraction of the program, and can thus be safely removed by adding constraints to the Boolean program. The process for obtaining and adding such constraints is described in detail in [5].

If a counterexample is spurious but contains no individually spurious transitions, then even the most precise Boolean abstraction is insufficient for proving the program with respect to the current set of predicates. In this case, the abstraction can be refined by adding further predicates. Some implementations choose to add further predicates before the possibilities for applying transition refinement have been exhausted [5]. Several schemes have been proposed to discover new predicates from counterexamples.

The simplest approach is to symbolically compute the weakest precondition from the failed assertion to the start of the program along the counterexample trace, and to add some or all of the atomic predicates occurring in the resulting formula to the set of predicates to be used for abstraction. This scheme is straightforward to implement and relatively predictable, but can lead to the generation of a large number of irrelevant predicates, and may generate predicates that are too counterexample-specific to facilitate verification. The problem of predicate explosion can be mitigated to some extent by alternating between weakest precondition and strongest postcondition-based analyzes [4], while interpolation techniques have shown success in the generation of relevant and general predicates [63,71].

Returning to our simple running example: transition refinement does not apply to the counterexample trace described in Section 89.3.3. Applying any of the commonly employed predicate discovery techniques identifies the predicate $nPkts=nPktsOld$. Adding this to our set of predicates leads to the Boolean program shown in Figure 89.3c which we already discussed in Section 89.3.1. Model checking for this Boolean program succeeds, thus we can conclude that the program of Figure 89.3a is correct.

89.3.5 Notes on CEGAR

The main bottlenecks for CEGAR-based verification using predicate abstraction are computing and model checking the abstraction. Adding further predicates to refine spurious counterexamples can quickly lead to an abstraction that is expensive to compute and infeasible to check. *Lazy abstraction* [64] aims to address this problem by localizing abstraction refinement. Rather than working with Boolean programs, this technique computes an *abstract reachability tree* (ART) with respect to a set of predicates. When a spurious counterexample through the ART is discovered, yielding new predicates, only portions of the ART relevant to the counterexample are refined. This avoids state explosion in the remainder of the ART.

The scalability of predicate abstraction can be improved by computing predicate transformers with respect to blocks of statements, rather than individual statements. This *large block encoding* technique [14] can dramatically reduce the size of the abstract state space, which is of prime importance for techniques based on ARTs, and facilitates the use of the more precise Boolean abstraction over Cartesian abstraction (see Section 89.3.1). The CPACHECKER tool [16] implements a generalization of the large block encoding technique [17].

CEGAR-based model checking for concurrent programs has been considered in several works. The MAGICis designed for analysis of concurrent programs where communication is by message passing [25]. An extension of the BLAST model checker focuses on the detection of data races in shared variable concurrent programs [62]. Two recent techniques and tools aim at verifying freedom from assertion failures in shared variable concurrent programs: THREADER [57,58] and SYMMPA [43,44]. THREADER applies thread modular reasoning to aim to combat state explosion arising due to concurrency, while SYMMPA employs a combination of symmetry reduction and BDD representation [13].

89.4 Bounded Model Checking of Software

Bounded model checking (BMC) is a method for performing depth-bounded verification of transition systems [18]. Given a transition system described by an initial state predicate $I(\mathbf{v})$ and a left-total transition relation* $T(\mathbf{v}, \mathbf{v}')$, and a predicate $P(\mathbf{v})$ describing a property that should hold in all reachable states (where \mathbf{v} and \mathbf{v}' denote vectors of system variables), BMC involves checking the following formula for some $k \geq 0$:

$$I(\mathbf{v}_0) \wedge T(\mathbf{v}_0, \mathbf{v}_1) \wedge \cdots \wedge T(\mathbf{v}_{k-1}, \mathbf{v}_k) \wedge (\neg P(\mathbf{v}_0) \vee \cdots \vee \neg P(\mathbf{v}_k)) \quad (89.1)$$

* A transition relation $T \subseteq S \times S$ is left-total if for every $s \in S$ there exists some $s' \in S$ such that $(s, s') \in T$. If we view T as a directed graph, this means that every node has at least one successor.

This formula encodes all paths of the transition system of length $k + 1$ that commence in an initial state, and along which the property is violated at some point. If the formula is satisfiable, then the satisfying assignment yields a counterexample demonstrating that the property can be violated. Unsatisfiability of the formula establishes that the property holds in all states that are reachable within the given depth bound; no guarantees are provided about deeper execution traces. The technique can also be used for bounded verification of certain temporal logic properties [18].

Bounded model checking has proved very successful as a technique for hardware verification due to the ability of modern SAT solvers to handle large Boolean formulas. We describe two methods by which BMC has been applied to the analysis of software.

89.4.1 Programs as Transition Systems

Traditional bounded model checking can be applied directly to the analysis of nonrecursive programs by inlining all procedure calls and then interpreting the program control flow graph (CFG) as a transition system. We illustrate this using the example program of Figure 89.4a. This simple program fragment initializes variables i and x to zero, then loops 100 times maintaining the invariant $x = 2 * i$. The program then asserts, incorrectly, that x and i are equal.

A possible CFG for this program is depicted in Figure 89.4b. Each block in the CFG is labeled with a unique number.

By using a *program counter* variable, pc , to record which CFG block is due to be executed next, we can encode the semantics of this program via the following formulas:

$$\begin{aligned}
 I(pc, x, i) &\triangleq pc = 1 \\
 T((pc, x, i), (pc', x', i')) &\triangleq pc = 1 \wedge x' = 0 \wedge i' = 0 \wedge pc' = (i' < 100 ? 2 : 3) \\
 &\quad \vee pc = 2 \wedge x' = x + 2 \wedge i' = i + 1 \wedge pc' = (i' < 100 ? 2 : 3) \\
 &\quad \vee pc = 3 \wedge pc' = end \wedge x' = x \wedge i' = i \\
 &\quad \vee pc = end \wedge pc' = end \wedge x' = x \wedge i' = i \\
 (pc, x, i) &\triangleq (pc = 2 \Rightarrow x = 2 * i) \wedge (pc = 3 \Rightarrow x = i)
 \end{aligned}$$

We have used a special program counter value, *end*, to indicate that execution has terminated. If $pc = end$ the transition system exhibits a self-loop; this ensures that the transition relation is left-total.

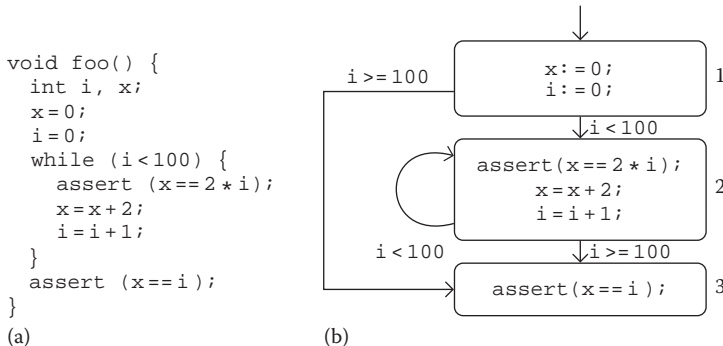

FIGURE 89.4 A simple program and its control flow graph. (a) Example program. (b) Control flow graph.

Equation 89.1 can now be applied using these formulas to check freedom from assertion violations up to any specified depth. To discover that the assertion at the end of the program can fail, a depth of at least 100 is required.

The F-SOFT [69] performs bounded model checking of C programs, treating the program CFG as a transition relation in a manner similar to the above.

89.4.2 Unwinding Loops in Control Flow Graphs

The disadvantage of the method described in Section 89.4.1 is that it does not exploit the structure of the program under consideration. An alternative to unwinding the transition relation associated with a program is to directly unwind loops in the program’s CFG.

We illustrate this using the example program of Figure 89.4. Figure 89.5a shows the result of unwinding two iterations of the CFG of Figure 89.4b. Observe that block 2 in Figure 89.4b, the body of the loop, has been duplicated as blocks 2 and 2’ in Figure 89.5a. The edge (2, 3) which leaves the loop in Figure 89.4b results in two edges, (2, 3) and (2’, 3) in Figure 89.5a. The back-edge (2, 2) in Figure 89.4b results in an edge connecting block 2 to block 2’ in Figure 89.5a. Because we have chosen to unwind the loop by just two iterations, the edge leaving block 2’ which corresponds to the back-edge leads to an empty block, 4, with no successors. This causes execution to terminate without error along paths that would exceed the bound of two loop iterations.

The result of this unwinding is a loop-free CFG encoding all program traces that execute at most two loop iterations. Using techniques for computing weakest preconditions [11], this loop-free CFG can be turned into a logical formula whose satisfiability reveals an assertion failure, and whose unsatisfiability implies that the program is correct up to this execution depth. There is clearly room for optimizing this procedure: a cheap static analysis reveals that in the example of Figure 89.5a all the edges guarded by $i \geq 100$ are infeasible, leading to the simpler CFG of Figure 89.5b in which node 3 is no longer reachable. Such an analysis allows the CFG to be simplified before it is turned into a formula.

The more general case of unwinding k iterations of an arbitrary loop is illustrated in Figure 89.6 (adapted from [41]). Figure 89.6a depicts an arbitrary CFG which contains a natural loop L (see, e.g., [1] for a formal definition of natural loops in control flow graphs). The head of L can be reached from outside

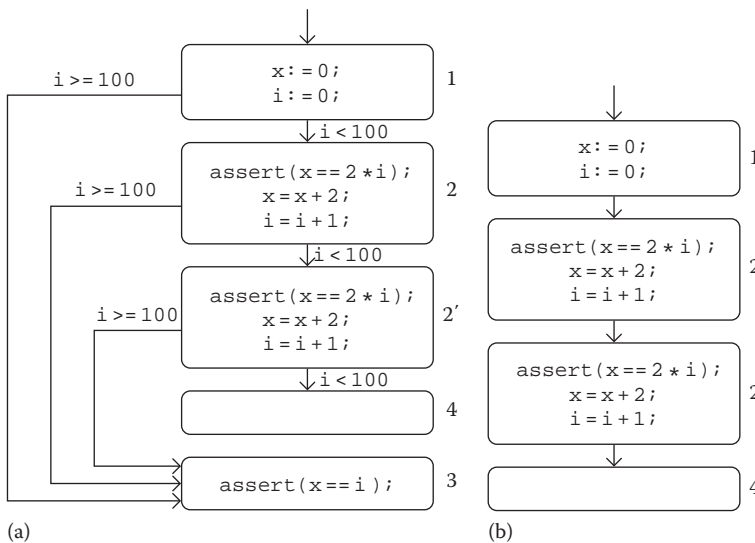

FIGURE 89.5 Unwinding the control flow graph of Figure 89.4b by two iterations. (a) Straightforward unwinding. (b) Unwinding and simplification.

FIGURE 89.6 Illustration of unwinding k iterations of an arbitrary natural loop in a control flow graph. (a) A program containing a loop L . (b) The program of Figure 89.6a after unwinding k iterations of loop L . Notice that loop back-edges which would lead to a further iteration have been cut.

the loop via a number of CFG edges (edges from *Program* to L). The loop contains a number of *back edges* (edges from nodes in L to the head of L), and a number of *exit edges* (edges from L to *Program*). Figure 89.6b illustrates the effect of unwinding k iterations of loop L . The result is a CFG containing the *Program* part of Figure 89.6a unmodified, together with k copies of the loop body L , denoted L_1, \dots, L_k . Exit edges of L are preserved in each L_i . A back-edge of L leads to an edge from L_i to the head node of L_j , for $1 \leq i < k$. In L_k , edges that would correspond to back edges of L are *not* present; this is indicated by crosses in Figure 89.6b. Omitting these edges restricts program executions to those involving at most k iterations of L , as desired.

Compared with the approach of applying BMC at the transition system level described in Section 89.4.1, loop unwinding has the advantage that different unwinding depths can be applied to different loops in the program. It may be the case that to discover a bug at least k iterations of a certain loop L must be explored, where k is large, while other loops need only be minimally unwound. By unwinding loops individually, it is possible to generate a minimal program unwinding that exposes the bug. Operating at the transition system level it would be necessary to unwind the *entire* transition system up to a bound proportional to k , the unwinding depth for loop L .

Unwinding a single loop by k iterations leads to a linear increase in the size of the CFG. However, if the unwound loop contains a nested loop then the nested loop will be duplicated k times in the unwound CFG. As a result, uniformly unwinding all loops in a loop nest by k iterations leads to $O(k^d)$ growth in the size of the CFG, where d is the depth of the loop nest.

Bounded model checking can be applied to recursive programs by inlining recursive calls up to a given bound.

The CBMC tool [32,34] performs bounded model checking of C programs via loop unwinding and inlining of recursive calls.

89.4.3 Notes on BMC

As discussed earlier, BMC provides no guarantees about program correctness beyond the given execution bound. In embedded software it is common for recursion to be absent and for loops to exhibit fixed upper bounds. In this case, sufficient unwinding of the program transition relation (Section 89.4.1) or loops (Section 89.4.2) is guaranteed to lead to consideration of all possible program behaviors. The loop unwinding method can be combined with the insertion of *unwinding assertions* to determine when sufficient unwinding has been performed to establish program correctness [32,34]: when unwinding k iterations of a loop, we insert an `assert(false)`; statement on execution paths that would execute a $(k + 1)$ st iteration. In the example of Figure 89.5a, this corresponds to placing

an `assert(false)`; in block 4. With respect to the general case of Figure 89.6b, adding unwinding assertions would involve extending each cross in loop copy L_k with an edge to a node containing an `assert(false)`; statement.

The k -induction method [87] enables BMC to be used for sound verification. In the context of transition systems, the method considers standard BMC to establish a *base case*, showing that all executions of length at most k , starting in an initial state are safe. Then, in addition, a *step case* is checked, in an attempt to show that an error-free execution trace of length k , starting from an *arbitrary* state, cannot be extended to an erroneous trace of length $k + 1$. Combining this with the base case establishes correctness of the transition system. The k -induction method has recently been applied in the context of software verification [41], allowing automatic verification of programs using weaker loop invariants than are required by traditional logic-based methods. Bounded model checking of software using k -induction has also been successful in establishing data race freedom for systems software that manipulates data using direct memory access (DMA) operations [45,46].

Bounded model checking techniques have proven effective in generating test cases for software (see, e.g., [2,61,65]). To generate a test vector that exercises a certain program behavior, one can instrument the program with assertions stating that the desired behavior is *not* possible. Applying BMC to detect violations of this assertion directly yields the desired test vector, if the behavior in question can be exhibited within a reasonable execution bound. Bounded model checking with k -induction has also been used for the detection of equivalent mutants in mutation-based testing [42].

BMC has been applied to the analysis of concurrent programs [39,84]. To limit state explosion arising due to concurrency these works employ the idea of bounding the number of thread context switches that are considered [74,82,88], in addition to bounding execution depth, based on the empirical observation that many concurrency bugs can be exposed using only a small number of thread context switches [76].

A technique closely related to BMC is dynamic symbolic execution, as implemented by tools such as EXE [24] and KLEE [23]. The key difference is that dynamic symbolic execution techniques maintain distinct formulas for different paths through a program, forking execution whenever a branch instruction is encountered such that both branch alternatives are feasible under the current set of constraints. In contrast, a bounded model checker unwinds the entire program, yielding a *single* formula that encodes all execution traces up to a given depth. The disadvantage of exploring execution paths separately, as in dynamic symbolic execution, is *path explosion*: the number of paths that must be considered to guarantee defect freedom up to a given depth k is in the worst-case exponential in d . An advantage is that the formula associated with a specific path remains relatively small and has a conjunctive form for which constraint solvers are highly optimized. The formula generated by program unwinding during bounded model checking can quickly exceed the capacity of state-of-the-art constraint solvers.

89.5 Tools Based on Traditional Model Checking

We conclude the chapter with a brief survey of notable tools that directly employ techniques based on traditional finite-state model checking for the analysis of software.

Bandera and Bogor: The BANDERA tool allows model checking of Java programs through a process of finite-state model extraction [37]. Program slicing is used to first simplify a Java program with respect to the property under consideration. The program state-space is then restricted through the application of user-provided abstraction functions. This leads to a sound over-approximation, as long as the given abstraction functions are sound. Then, if necessary a *component restriction* phase is used to make the resulting model tractable. This involves, for example, limiting the ranges of variables, or limiting the number of objects that can be allocated in the heap. Component restriction sacrifices soundness, but can allow the detection of subtle errors. The resulting finite-state model is represented in

the Bandera Intermediate Language (BIR). A BIR model can then be translated to the input language of any finite-state model checker; translators exist for variety of model checkers, including SPIN [66], dSPIN [40], nuSMV [26], and Java PathFinder [89]. Bandera provides a rich specification language for stating properties to be checked [38] and has been applied in the context of analyzing concurrent Java programs [59].

The BOGOR framework [85] aims to provide an extensible platform for designing software model checkers, motivated by the BANDERA project, during which the often large gap between features of full-blown programming languages and the input languages of finite-state model checking tools proved to be a major source of inefficiency in verification. The core of BOGOR is a model checker for an extended version of the BIR language, where the extensions allow direct encoding of high-level programming constructs.

Java PathFinder: The Java PathFinder (JPF) tool [75,89] supports model checking of Java byte-code, allowing it to be applied to compiled Java programs for which source code is not available. A combination of state compression, partial order and symmetry reduction, abstraction and program slicing is used to combat state space explosion. An earlier version of JPF tool translated Java source code directly to Promela for model checking using SPIN [60].

JPF also provides support for symbolic execution [72], which facilitates test case generation for Java programs [90].

Spin: The SPIN model checker [66] allows fragments of C source code to be included directly in a Promela verification model, and for selected C program variables to be tracked as part of the model state during verification. This allows users of SPIN to extract verification models from C programs, either manually or with the assistance of automated model extraction tools [67].

As discussed earlier, SPIN has been employed as a back-end model checker for a variety of software model checking tools.

VeriSoft: The VeriSoft model checker [53] is geared toward analysis of concurrent C and C++ programs, checking for coordination problems (such as deadlocks), as well as for violations of user-supplied assertions. Based on the observation that the state of C and C++ programs is typically large and complex, VeriSoft employs a *stateless* search approach in which a set of previously visited states is *not* maintained. This dramatically reduces memory consumption during model checking, but means that individual states may be visited many times during exhaustive exploration. VeriSoft employs symmetry and partial order reduction techniques to mitigate this problem to some extent [52]. The VeriSoft approach shares similarities with recent techniques for concurrency testing such as the CHESS tool [80].

89.6 Conclusion

We have surveyed two of the most successful techniques for practical software model checking: predicate abstraction and CEGAR, and bounded model checking, and have provided an overview of other key model checking techniques that are geared towards software analysis.

A common technology shared by many of these techniques is *constraint solving*: the abstraction, counterexample simulation and refinement processes in the CEGAR methods we have studied all involve invoking a constraint solver to decide formulas, and bounded model checking works by unwinding a program into a formula to be checked by a SAT or SMT solver. Thus, a key factor in future scalability of software model checking and other verification techniques will be the extent to which advances in constraint solving continue to improve performance.

Dramatic improvements in the capability of software model checkers have been made over the last 15 years, and there has been some uptake by industry. Arguably the biggest success story for software model checking has been technology transfer from Microsoft's SLAM tool, which is based on predicate abstraction and CEGAR, to Static Driver Verifier (SDV) that ships with the Windows Driver Development kit [6].

Despite this success, it is fair to say that software model checking, and verification in general, is *not* employed widely in industry at present. In our view, there are three main barriers to widespread industrial adoption of these techniques, and thus areas for further research:

- *Scalability*: Model checking complex systems is typically expensive; it is not unusual for a verification run to take hours or days to complete.
- *Lack of specifications*: Formal analysis of software depends on the existence of meaningful properties to check. Such specifications are usually not present in general-purpose software.
- *Lack of automation*: Unlike lightweight approaches to improving software reliability, such as regression testing or basic type checking, applying a software model checker is rarely a “push-button” process; significant manual intervention and expertise is usually required.

90.1 Introduction

The design of a software artifact is a critical step in making the move from the vision of a system to reality. First in the life cycle comes the vision, then the business case for the vision, then the business case is turned into requirements, and then the artifact is designed, implemented, tested, deployed, and released into the environment. These phases are usually not disjoint in time—the business case informs the vision, the requirements inform the business case and so forth, but the design should reflect the preceding phases (the vision, the business case, and the requirements). It is also influenced by the following phases: the design must be implementable, it should be easily testable, and it should be changeable when the artifact must be modified to reflect environmental changes.

One assumption underlying any design is that the design will satisfy some set of requirements. These requirements may be explicit or implicit, known or unknown, but it is the requirements that drive the design strategy. A consequence of this is that a designer is not looking for an optimum design but rather one that is “good enough” in that it satisfies the requirements. A complication is that some requirements may not be known to the designer during the design process but these requirements, nevertheless, must be met by the design.

Requirements can be categorized into three categories:

- The functional requirements—what the artifact should do.
- The quality requirements—how well the artifact will do what it is designed to do. These requirements are frequently called the nonfunctional requirements or the “ilities.” Quality requirements can be run time requirements such as performance or availability or they can be development time requirements such as an enumeration of expected modifications or a requirement that the development be distributed across specific teams in specific locations.
- The business requirements—what constraints the various stakeholders add to the other requirements.

We now turn to the principles underlying various design strategies.

90.2 Underlying Principles

A design is a point within a “design space.” This is a space formed by considering all possible decisions that might be made within the design process. Since nontrivial systems can have on the orders of thousands of decisions, each with multiple alternatives, arbitrarily searching this space is clearly not feasible. Thus, a systematic method for navigating the design space is critical to produce acceptable designs in a reasonable amount of time.

We begin by discussing two background concepts—views or viewpoints and patterns and tactics. Then we move to the two basic principles of a systematic design strategy—decomposition and generate and test.

90.2.1 Views

Complicated systems such as software systems are difficult to describe because the static version of the system (the code) can have very different structure and properties than the dynamic version of the system (the system in execution). A description of a set of element types in a computer system and their relationships is called a view (Clements et al. 2010). The perspective from a stakeholder who is interested in some properties of the system is called a viewpoint (ISO/IEC/IEEE 2011).

Common types of views are the module views, those that represent the code structures (see Figure 90.1); the component and connector views, those that represent dynamic behavior involving processes,

FIGURE 90.3 A sample allocation view.

threads, and components (see Figure 90.2); and the allocation views, those that represent the mapping between software elements and non-software elements such as processors (see Figure 90.3).

90.2.2 Architectural Patterns and Tactics

A pattern is a known solution to resolve conflicting forces (requirements) on a system. Patterns derive from the work of Alexander et al. (1977) and have been widely accepted by the software engineering community (Gamma et al. 1995, Buschmann et al. 1996). It is common to see patterns used in design strategies although the composition of patterns remains an unresolved problem.

Architectural tactics are transformations on a design to improve its performance with respect to a single quality attribute (Bachmann et al. 2002). Whereas patterns resolve conflicting requirements, tactics are intended to improve a design with respect to a single quality attribute requirement. Patterns are a coarse-grained mechanism to enable the meeting of certain requirements and tactics are a fine-grained mechanism.

90.2.3 Decomposition

Decomposing a difficult problem into its component portions is a basic engineering tenet. Each portion is independently solved and the various solutions are integrated together. We examine four different strategies for decomposition. Structured Analysis and Design (SADT) and object orientation decompose the system into modules, whereas using preconstructed components and architecturally significant requirements may decompose the system into combinations of module, component and connector, and allocation views.

90.2.3.1 Using Preconstructed Components

This strategy was first articulated by McIlroy at the 1968 NATO conference on software engineering (McIlroy et al. 1968). The strategy is to determine a solution through the composition of preexisting components. The analogy is with the composition of physical components. The assumptions under which this is an effective strategy are that there exists a framework into which all of the components will fit and that there exist components that together provide all of the appropriate functionality with the correct set of quality characteristics. This vision is still being explored; see Kung-Kiu and Zheng (2007) for a survey of the current state. It is possible, for example, to quickly build a web site using preexisting components and tools but only for relatively simple and common needs. Most software development still involves a substantial amount of component design and construction.

90.2.3.2 SADT

SADT was the next decomposition strategy to be articulated (Marca and McGowan 1987). It is based on considering a hierarchy of function. SADT considers the user-visible functions and derives an organization of those functions. That is, it groups functions that are similar, identifies the core functionalities that underlie a group of functions, and arranges them in a hierarchical structure.

The problem with SADT is that it does not accommodate future modifications to the system very well. Consider a financial system. Business processes are based around workflow, individual specialties, and a separate common database. Modifications such as changing the concept of a customer will be far ranging and will impact many portions of the system.

SADT lives on into the modern world in two manifestations. First, it has some similarities to feature modeling used in product lines (Kang et al. 1990) although product lines consider a collection of systems, whereas SADT is used for a single system. Second, SADT has similarities to the user stories used in some agile methodologies (Cohn 2004). The difference is that user stories are linked to a development methodology that involves rapid delivery and future refactoring to accommodate the problems associated with modifiability.

90.2.3.3 Object Orientation

Object-oriented design (Wirfs-Brock and McKean 2002) is a design strategy that builds on the ideas of objects in object-oriented programming (Goldberg and Robson 1989). Object-oriented design's basic decomposition strategy is to decompose the system into objects where the objects represent concepts that are likely to change over time. These objects are determined through examination of scenarios of use (use cases) (Cockburn 2000).

Each object is specified through the allocation of "responsibilities" to the object. A responsibility is an action the object will accomplish, a decision the object will make, or a piece of information the object will retain.

Objects are encapsulated (Parnas 1972) to hide certain data and expose other data. The choice of data to hide is dictated partially by consideration of assumed changes. Any data that are likely to change over time should be hidden so that changing the data will not have ripple effects to the remainder of the system. This prevention of ripple effects is one of the main goals of encapsulation.

Object-oriented design is still a viable design strategy and is taught and written about. The problem with object-oriented design is that it privileges modification among the quality attributes. That is, the decomposition strategy is based on consideration of modification. As we will see in the next section, modifiability is one possible source of a decomposition strategy but there are others.

90.2.3.4 Architecturally Significant Requirements

Object-oriented decomposition makes two assumptions:

1. The primary design drivers are potential changes.
2. Potential changes can be identified through the identification of objects.

Decomposition based on identification of architecturally significant requirements removes those two assumptions. Architecturally significant requirements (Obink et al.) are those requirements that drive the design. Typically, these are quality or business requirements that pertain to either run time or development time.

When one examines a design after it has been completed, one can see the primary requirements that the design is attempting to achieve. This is a *post facto* recognition of the architecturally significant requirements. The assumption behind decomposition based on architecturally significant requirements is that the architecturally significant requirements can be discovered *a priori*. These requirements may be change requirements based on objects but they could also be specific change requirements or other quality attribute requirements such as performance or availability requirements. In this way, decomposition based on architecturally significant requirements can be seen as a generalization of object-oriented decomposition. In Section 90.3.1, we will describe a technique for discovering the architecturally significant requirements.

90.2.4 Generate and Test

Generate and test is a basic strategy of problem solving. An initial hypothesis is generated, it is tested against some set of criteria, and, depending on the results of the test, another hypothesis is generated and tested. In order for this strategy to be effective, successive hypotheses should converge to a solution. Hofmeister et al. 2007 describe this process as one of analysis (understanding the architecturally significant requirements), synthesis (creating a hypothesis), and evaluation (test).

Viewing the design strategy as a process of generate and test leads to three questions:

1. How is the initial hypothesis generated?
2. How is the hypothesis tested and when is the process complete?
3. How are the results of the tests used to generate the next hypothesis?

90.2.4.1 Generating the Initial Hypothesis

The initial hypothesis depends on the context of the particular design. Some possibilities for generating the initial hypothesis are as follows:

- Base the initial hypothesis on an existing system. Many systems are similar to an existing system and basing the initial hypothesis on that existing system will enable the exploitation of the similarities. The differences will come out in the test phase.
- Base the initial hypothesis on an existing framework. A great many software frameworks are available in a wide variety of domains ranging from automotive to web services to content management to gaming. These frameworks provide generic functionality within the domain and must be specialized for the particular system under design.

- Base the initial hypothesis on an object-oriented decomposition. Although the object-oriented decomposition assumes that modifiability is the most important quality attribute, it typically is one of the most important. The testing phase will discover the shortcomings of a purely object-oriented decomposition for the particular system being designed.
- Base the initial hypothesis on patterns or tactics. Basing the initial hypothesis on either patterns or tactics will lead to a very sparse design compared to the final design since patterns consider only a few requirements and tactics even fewer. Patterns and tactics do provide a place to begin, however, as opposed to a strictly random hypothesis.

90.2.4.2 Testing the Hypothesis

Three activities are included in the test phase of generate and test—selecting the test cases, performing the tests, and deciding when the process is complete:

1. Selecting the test cases is a matter of choosing those requirements, both explicit and implicit, that will have the most impact on the design, that is, the architecturally significant requirements. Other test cases will depend on particular usage aspects of the system. For example, a mobile application should have a test case that specifies what happens when the application becomes disconnected and then is reconnected. Start up and shut down are specific usage test cases that are relevant for many large operations. Upgrading the system is relevant for those systems that require 24/7 access, and so forth.
2. The actual process of testing produces one of two outputs. Either the current hypothesis is satisfactory for the test or some problems are determined. These problems are carried forward to the “generate next hypothesis.” The tests can be performed through means of increasing fidelity and cost. The choice of which type of test to perform depends on the costs and benefits of the testing type. The cheapest tests have the least fidelity. We present the tests in increasing order of cost and fidelity. The types of tests are as follows:
 - a. Thought experiments. These are the most common forms of performing tests on a design. A thought experiment is a walk-through of the design in response to particular stimuli. This is the fastest, cheapest, and the type of test with the least fidelity.
 - b. Analytic modeling. Creating a model of the current design will enable a variety of “what-if” types of analyses. Being able to create an analytic model depends on the type of requirement that one is testing. Well-accepted analytic models can be created for performance, for modifiability, and for availability (see, e.g., Smith and Williams 2001). Other quality attributes are more difficult to model and the creation of these models is an active area of research. The fidelity of an analytic model will determine the accuracy of the model’s predictions.
 - c. Simulation. Creating a simulation of the current design enables more fidelity to be incorporated into the test than through an analytic model. Simulations allow what-ifs to be explored in much the same fashion as do analytic models. Analytic models may be difficult to solve and so creating a simulation will generate the test results through mimicking the operation of the system rather than through generating a closed form solution.
3. Deciding when the generate and test process has completed is the easy portion of the test step. The process is complete when either the requirements are satisfied or the budget for the design portion has been exhausted. In the latter case, the hypothesis that best satisfies the requirements is the hypothesis carried forward to the implementation phase.

90.2.4.3 Generating the Next Hypothesis

The output of the testing phase is essentially a list of requirements that are not met by the current hypothesis. For each requirement not met, there will be either or both of responsibilities that are not covered in the current design and a measurement of how far the current design diverges from the quality attribute requirement.

The next hypothesis should incorporate both responsibilities not covered in the current hypothesis and adjustments to improve the hypothesis with respect to quality attribute requirements:

- Additional responsibilities are either added to modules in the current hypothesis or to newly created modules. If a new responsibility has coherence with the existing responsibilities in a module, it should be added to that module. If the new responsibility does not have coherence with the responsibilities in any existing module, then possibly a new module should be created for the new responsibilities. Since modules also act as work assignments for teams, a new module should only be created when there are sufficient responsibilities within it to assign to a team. Responsibilities that are left dangling because they do not cohere with existing responsibilities and are not large enough to justify the creation of a new module can be assigned arbitrarily.
- Adjusting the current hypothesis to improve its quality attribute performance is the reason for architectural tactics. Each architectural tactic provides additional responsibilities; movement of responsibilities from one module to another; combining, splitting, or creation of a new module; or adjustment of the properties of responsibilities, modules, or components.

One or more tactics are chosen and applied to improve the design, the responsibilities discovered missing from the testing phase are added to the current architecture, and the next test can be performed.

90.3 Best Practices

A major practical problem for a designer is dealing with the masses of detail both in the requirements and in the design. This problem is manifested in three fashions—a designer must abstract the detail to enable the designer to have an overall grasp of the system and its requirements, the designer must produce the design incrementally since designing for all of the requirements at once is not possible for large systems, and design decisions must be recorded, ideally with rationale, since the designer makes too many decisions to remember them all.

Abstracting the masses of detail in the requirements is discussed in Chapter 86. Abstracting the detail from a design perspective is discussed in the next section and appropriate tooling is discussed in Section 90.3.3.

90.3.1 Finding Architecturally Significant Requirements

Architecturally significant requirements are those requirements that drive the design, that is, they are the most important requirements. Deconstructing “important” yields two types of importance—business and structural:

- From a business perspective, a requirement can be essential (the system is unacceptable if the requirement is not met), important (the system is acceptable but not as good as desired if the requirement is not met), and nice to have (the system is fine without it but the meeting of this requirement adds incremental value).
- From a structural perspective, a requirement can be overarching (the design would be substantially different without this requirement), significant (the design would be somewhat different without this requirement), or insignificant (the design would be essentially the same without this requirement).

Using these two types of criteria provides a means for discovering architecturally significant requirements. For each requirement (both explicit and implicit), assign it a business rating and a structural rating as previously mentioned. Those requirements that are both essential and overarching are the architecturally significant requirements. Using a construct called the utility tree (Clements et al. 2002) enables the designer to structure the requirements based on the type of quality attribute that they support. The utility tree is not essential to discovering the architecturally significant requirements, but it

provides a structure that is useful for discovering requirements that are essentially the same from a quality attribute perspective. For example, if two requirements have the same required response time and take essentially the same path through the current hypothesis, the utility tree would enable the designer to discover the duplication.

90.3.2 Combining Generate and Test and Decomposition

Both generate and test and the decomposition strategies we discussed as basic principles are motivated by limitations of humans. Generate and test is motivated by the reality that people cannot solve multivariate problems in their head where the number of variables is large. Viewing each requirement as a variable that the design must satisfy means that the design problem is one with thousands of degrees of freedom. Decomposition is also motivated by human limitations. The details of any design are dealt with through the use of abstraction. The initial decomposition is a solution to the most abstract form of the requirements and each subsequent decomposition provides solutions to more detailed forms of the requirements although for a smaller portion of the overall solution.

The two techniques can be combined. Generate and test decomposes the system. Restricting the requirements that drive generate and test to architecturally significant requirements will provide an initial decomposition. Each element of the initial decomposition can then, in turn, be further decomposed by finding the architecturally significant requirements for that element and using generate and test to decompose that element. This leads to the following approach:

1. Determine the architecturally significant requirements.
2. Use generate and test to determine the initial decomposition of the system to satisfy the architecturally significant requirements.
3. For each element of the current decomposition, do the following:
 - a. Determine the architecturally significant requirements that pertain to that element.
 - b. Use generate and test to develop a solution for the restricted architecturally significant requirements.
4. Iterate until either the requirements are satisfied or the time allocated for designing has elapsed.

The attribute directed design method (Bass et al. 2003) is a method that utilizes this combination of the two techniques.

90.3.3 Tooling

Tooling is essential to support the design of a complicated system. There are three types of functions that a tool or tool chain must support:

1. *The recording of design decisions and their rationale.* Recording of decisions is done in two forms depending on the audience. During the execution of the design process, many decisions are being made. These decisions should be recorded but the audience for this recording is the designers during the design process. The mass of detail in the design will overwhelm any individual's memory, even from day to day. This is especially true when the choice between two decisions is essentially arbitrary. One option must be chosen to move forward but recalling which one was chosen the next day when a similar situation arises may be problematic. Almost any means can be used to record this class of decisions—an engineering notebook, a word processing system, or other ad hoc means. Since the only point of these recording is to supplement the designer's short-term memory, the form does not matter. Tools for recording of design rationale have received renewed attention in recent years (Jansen and Bosch 2005, Kruchten et al. 2009).

At particular milestones during the design, especially after the completion of the design, decisions will be exposed to a broader audience. The design will be evaluated, it will be presented to developers as a blueprint, and the designers will revisit it after some period of time. In this

situation, more formality is needed in the recording of the design and the tooling should support this formality. Different views of the design are presented using different notations and the tool used should support much more formality than needed for the short-term recording of the design decisions. See Clements et al. (2010) for a discussion of various types of notations. Bachmann (2011) proposes using frequent and focused design reviews as a means for encouraging development teams to develop documentation in an incremental fashion.

2. *Traceability to requirements.* A design is intended to provide a solution for a set of requirements. Some requirements will be explicit and others implicit. The explicit requirements will be recorded in some form and a tool should support the tracing of particular sets of design decisions back to the explicit requirements. This will enable review of the design to determine if it satisfies at least those requirements that have been made explicit.
3. *Integration with the development tools.* Creating a design is one step in the development process. The tool chain used in the development should provide a smooth integration from one step to the next and, perhaps more importantly, back. One problem with designs is that they diverge from the code. This happens over time because maintenance activities are performed on the code, frequently without simultaneously updating the design. An integrated tool chain would support the reflection of code modifications in the design (backward integration) as well as the movement from the design to the code (forward integration). How to accomplish this integration is a research question.

90.4 Research Issues

The research issues involved in design revolve around tools and models. Models are necessary for automatic and semiautomatic design. Even with manual design, however, design tools need to be integrated into a coherent tool chain.

90.4.1 Automatic/Semiautomatic Design

One research question is the extent to which a design process can be automated or semiautomated. Several factors make the problem of intelligently supporting the design process a difficult question:

- The size of the design space is huge. Every decision that is made during the design process adds another sub-tree to the set of possible solutions. Since a serious design may encompass thousands of decisions, the tree that represents the design space is huge. Also adding to the size of the design space is the fact that decisions are not commutative. That is, decision to split a module and then deciding to add a particular responsibility to one sub-module may yield a different result than adding that responsibility to the module prior to splitting it. From this, it is clear that any automatic or semiautomatic design engine must have a very sophisticated method for navigating the design space.
- The navigation of the design space must be driven by the requirements. These include the quality and the business requirements as well as the functional requirements. The navigation engine must have models that will guide its decisions in considering its next moves. These models must be able to both deduce the properties of a hypothesis and relate these properties to the satisfaction of requirements and suggest transformations of the hypothesis to improve its behavior with respect to the requirements. For example, a particular hypothesis may be deficient in performance and the design engine must have a menu of options that will improve the performance of the next hypothesis with respect to that particular requirement. See Bachmann and Bass (2003) for one example of a semiautomated tool that relies on human intervention for navigation but provides information to the human based on quality attribute models to guide the navigation.
- Improving the performance of a hypothesis with respect to one requirement will have an impact on how well other requirements are satisfied. This puts any tool for navigating the design space in the realm of multi-attribute optimization. See Makki et al. (2008) for a discussion of how the design process can be cast as a multi-attribute decision process.

90.4.2 Models

As the discussion about automated or semiautomated tool support for design indicated, models are critical to support the design process. The models must relate requirements to the design. The type of requirements that affect the design, as was discussed in the section on architecturally significant requirements, are the quality attribute and the business requirements:

- *Quality attribute models.* The maturity of models for the different quality attributes is very different. Performance has the best models. Queuing models have existed for networked computer systems since the 1970s (Kleinrock 1975) and real-time scheduling models have existed at least since the early 1990s (Harbour et al. 1993). Models for other quality attributes are much less mature and applicable. Security, for example, has no models that relate the design of the system to the probability of a successful attack.
- *Business models.* Models that relate business requirements to design are currently restricted primarily to cost models. Different design choices may be made depending on costs. Many business requirements are manifested as quality attribute requirements, for example, requirements for long-lived systems can usually be translated into modifiability requirements. Other business requirements that impact design decisions, for example, improve the skill set of our employees, have no models that can be used to support various design decisions.

90.4.3 Tool Chain

Design sits between requirements elicitation and implementation in the life cycle. There are a large number of tools to support requirements elicitation and tracing and also a large number of tools to support implementation and testing. Designs are frequently not kept up to date because modifications done to the code are not easily reflected back into the design. What is needed is a tool that supports the design process and integrates well with both the requirements tools and the implementation tools so that the designer and implementer can seamlessly move between their various activities. The design of such a tool is a research problem. IBM has experimented with the Architect's Work Bench (Abrams et al. 2006) but that effort has ended. In addition to the process integrations attacked by the Architect's Work Bench, there is an additional question of the most effective method for reflecting modifications to the code back to the design.

90.5 Summary

Designing a system is a crucial step to realizing the vision articulated for that system. Humans are good at creative activities and computers and processes are good at organizing these activities. Design strategies are built around recognition of human limitations and an understanding of the forces that drive design.

Research issues in design are motivated by increasing the models of important elements of the design process and embedding those models in tools.

91.1 Underlying Principles

The term *architecture* has been used for centuries to denote the art and science of designing buildings and structures. The term is applied in various different domains scope including building architecture, town planning, urban design, and landscape architecture. One of the earliest written works on the topic of architecture is *De Architectura* (On Architecture), which was published as Ten Books on Architecture, by the Roman architect Vitruvius in the early first century CE [10]. The work is a treatise on architecture and served as a guide for building projects. Currently, the work is one of the most important sources of knowledge of Roman building methods and the planning and design of both large and small structures, including buildings, aqueducts, baths, harbors, and machines. The concept of architecture has further evolved in the history through various traditions and regions.

The software engineering community has also adopted the term architecture to denote the gross-level design of software-intensive systems. The importance of high-level architectural structure was already acknowledged early in the history of software engineering. The first software programs were written for numerical calculations using programming languages that supported mathematical expressions and later algorithms and abstract data types. Programs written at that time served mainly one purpose and were relatively simple compared to the current large-scale diverse software systems. Over time, due to the increasing complexity and the increasing size of the applications, the global structure of the software system became an important issue.

Currently, it is not the algorithms and data structures that constitute the major design problems, but the construction of the systems from many components and the organization of the overall system [16]. Already in 1968, Dijkstra proposed the correct arrangement of the structure of software systems before simply programming [13]. He introduced the notion of layered structure in operating systems, in which related programs were grouped into separate layers, communicating with groups of programs in adjacent layers. Later, Parnas argued that the selected criteria for the decomposition of a system impact the structure

of the programs and several design principles must be followed to provide a good structure [27,28]. Within the software engineering community, there is now an increasing consensus that the architectural design of software systems is important to cope with the increased complexity and meet the stakeholder requirements properly. Without loss of generality, we can state that software architecture is recognized as a key determinant of project success. Without the right architecture, the project will likely fail.

91.1.1 Definition

In tandem with the increasing popularity of software architecture design, many definitions of architecture have been introduced over the last decade, though a consensus on a standard definition is still not established. We think that the reason why so many and various definitions on software architectures exist is because every author approaches a different perspective of the same concept of software architecture and likewise provides a definition from that perspective. Notwithstanding the numerous definitions, it appears that the prevailing definitions do not generally conflict with each other and commonly agree that software architecture represents the gross-level design of the software system consisting of components and relations among them.

The ISO/IEC 42010 (formerly IEEE 1471) Recommended Practice for Architectural Description of Software-Intensive Systems provides the following definition for software architecture [19]:

Architecture is the fundamental organization of a system embodied in its components, their relationships to each other, and to the environment, and the principles guiding its design and evolution.

Another recent definition is given in [8]:

The software architecture of a program or computing system is the structure or structures of the system, which comprise software elements, the externally visible properties of those elements, and the relationships among them.

There are plenty of other definitions, each focusing on different aspects. Based on the definitions in the literature, we consider the following definition of software architecture that includes the important aspects:

Architecture represents the gross level structure of software intensive systems, which consists of software components and relationship among these components, including systemic design decisions and the rationale for these design decisions, to meet the set of concerns for the stakeholders.

The aforementioned definition has in fact three parts: (1) the structure and behavior of the system, (2) the design decisions that have led to the structure together with the rationale behind these design decisions, and (3) the stakeholder concerns that govern the design decisions and shape the architecture. The term component here is used as an abstraction of different interpretations and likewise may refer to subsystems, processes, software modules, hardware components, or any element that has systemic behavior. In a similar sense, relations may refer to data flows, control flows, call relations, part of relations, etc.

91.1.2 Rationale for Architecture

Software architecture is an abstract representation that serves various purposes. We list the following:

- *Architecture helps to understand the system*

An important concern in software projects is the understanding of the system and its properties. Software architecture is a high-level abstraction of the system that abstracts away from the irrelevant details and as such can facilitate the understandability.

- *Architecture supports communication among stakeholders*
Software architecture can be used as a common abstraction that stakeholders can use to communicate and discuss the system properties. A stakeholder is defined as an individual, team, or organization with interests in, or concerns relative to, a system. Each of the stakeholders' concerns impacts the early design decisions that the architect makes. *Architectural drivers* [26] define the concerns of the stakeholders that shape the architecture.
- *Architecture serves as a basis for the subsequent phases of the life cycle process*
Architecture defines the gross-level structure of the system to which the subsequent life cycle detailed design and code artifacts should conform. Likewise, architecture defines the boundaries of the system and provides the constraints for the implementation. Further, the software architecture is used to guide the subsequent life cycle activities and help to achieve integrity of the system.
- *Architecture supports the quality requirements*
It is important that the architecture design supports the software system quality requirements that are required by the various stakeholders. Since software architecture represents the earliest design decisions about a system, architecture can be used to define and reason about the quality attributes. In addition, software architecture can be used to analyze the risks, sensitivity points, and trade-offs.
- *Architecture serves as a means for supporting the organization*
The motivation for architecture-driven development is not just for technical reasons but also for organizational reasons. Architecture defines the gross-level structure of the system that can be used to support work allocation, budget planning, and development structure of the project.

91.2 Architecture Modeling

Every system has an architecture whether it is complex or not. If the architecture is modeled, we can control it and benefit from an architecture-driven development. Initially, software architecture was represented using arbitrary box-and-lines notations leading to ambiguous interpretations. As such, very soon, it was acknowledged to provide more formal support for architectural modeling, both visually and textually. Together with the quest for more formal approaches, a widespread awareness has established stating that architecture should be modeled based on *architecturally significant requirements (architecture drivers)*. These requirements are systemic in nature and usually concern the overall system or the large part of the system. Modifiability and performance requirements are examples of architecturally significant requirements. This need for modeling the architecture for different stakeholders has led to the notion of *architectural views* that is a representation of a system for a particular concern. Having multiple views of the architecture helps to separate the concerns and as such support the modeling, understanding, communication, and analysis of the software architecture for different stakeholders. Architectural views conform to *viewpoints* that represent the conventions for constructing and using a view. It is now common practice to model and document different architectural views for describing the architecture according to the stakeholders' concerns [4,8,11,17,22,32,33,37]. An architectural view is a representation of a set of system elements and relations associated with them to support a particular concern. Having multiple views helps to separate the concerns and as such support the modeling, understanding, communication, and analysis of the software architecture for different stakeholders. Architectural views conform to viewpoints that represent the conventions for constructing and using a view. An *architecture framework* is defined as the coordinated set of viewpoints that are used to define the views. A more precise definition of architecture framework is given in the ISO standard [21]:

Conventions, principles, and practices for the description of architectures established within a specific domain of application and/or community of stakeholders

Different architectural frameworks have been proposed in the literature. Examples of architectural frameworks include Kruchten's 4+1 view model [22], the Siemens Four View Model [17], and the Views and Beyond (V&B) approach [8]. An example list of architecture frameworks is shown in Table 91.1.

TABLE 91.1 Example Architecture Frameworks

The computational viewpoint describes the functionality provided by the system and its functional decomposition 4. The engineering viewpoint describes the distribution of processing performed by the system to manage the information and provide the functionality 5. The technology viewpoint describes the technologies chosen to provide the processing, functionality and presentation of information

Initially, architectural frameworks were proposed with a fixed set of viewpoints. Because of the different concerns that need to be addressed for different systems, the current trend recognizes that the set of views should not be fixed but multiple viewpoints might be introduced instead. As such, recent architectural frameworks such as the V&B approach provide mechanisms to adapt existing viewpoints or to add new viewpoints. Organizing the system as a set of viewpoints has also been addressed in enterprise application system using the so-called enterprise architecture frameworks. Examples include the early Zachman Framework for Enterprise Architecture [39], The Open Group Architecture Framework (TOGAF) [38], and the ISO (ISO/IEC 10746) Reference Model of Open Distributed Processing (RM-ODP) [30].

So far, most architectural viewpoints seem to have been primarily used either to support the communication among stakeholders or at the best to provide a blueprint for the detailed design. From a historical perspective, it can be observed that viewpoints defined later are more precise and consistent than the earlier approaches but a close analysis shows that even existing viewpoints lack some precision. Moreover, since existing frameworks provide mechanisms to add new viewpoints, the risk of introducing imprecise viewpoints is high. The development of a proper and effective architecture is highly dependent on the corresponding documentation. An incomplete or imprecise viewpoint will impede the understanding and application of the viewpoints to derive the corresponding architectural views and likewise lower the quality of the architectural document.

In Figure 91.1, we show the conceptual model for architectural view modeling that is based on the ISO/IEC 42010 recommended standard for architectural description [19]. The left part of the figure shows basically the definition of the architectural drivers. A system has one or more stakeholders who have interest in the system with respect to one or more concerns. Concerns can be functional concerns or quality concerns. The right part of the figure focuses on the architectural views for the different concerns. Each system has an architecture, which is described by an architectural description. The architectural description consists of a set of views that correspond to their viewpoints. Viewpoints aim to address the stakeholder's concerns. Functional concerns will define the dominant decomposition

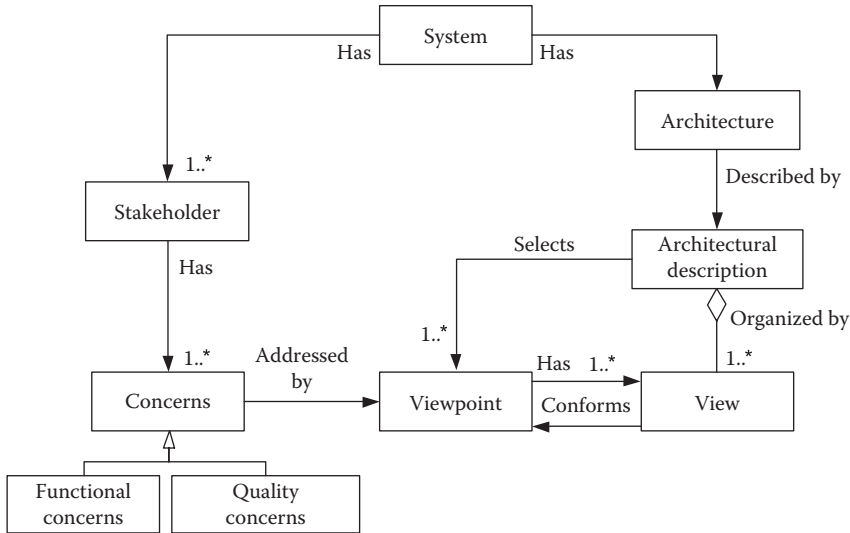

FIGURE 91.1 Conceptual model for architectural views based on ISO/IEC 42010.

along architectural units that are mainly functional in nature. On the other hand, quality concerns will define the dominant decomposition of the architecture along architectural units that explicitly represent quality concerns.

91.3 Architecture Design Methods

Various different software architecture design methods have been published in the literature. In general, the architecture design process is defined early in the software life cycle process. The main activities and a global architecture design process are given in Figure 91.2.

The process is typically defined as an iterative process in which one can iterate to previous activities if needed. In the succeeding text, we describe the activities.

91.3.1 Analyze Concerns

As stated before, architecturally significant requirements define the concerns of the stakeholders that shape the architecture. To analyze the concerns, first, the stakeholders must be identified and their concerns must be elicited. After analyzing and consolidating the elicited concerns, the concerns must be explicitly represented for guiding the subsequent architecture design activities.

91.3.2 Analyze Domain

Domain analysis can be defined as the process of identifying, capturing, and organizing domain knowledge about the problem domain with the purpose of making it reusable when creating new systems [1,9]. The UML glossary provides the following definition of the term domain:

Domain: An area of knowledge or activity characterized by a set of concepts and terminology understood by practitioners in that area.

A survey of domain analysis methods shows that these methods include the similar kind of activities. Figure 91.3 represents the common structure of domain analysis methods as it has been derived from survey studies on domain analysis methods [1,9].

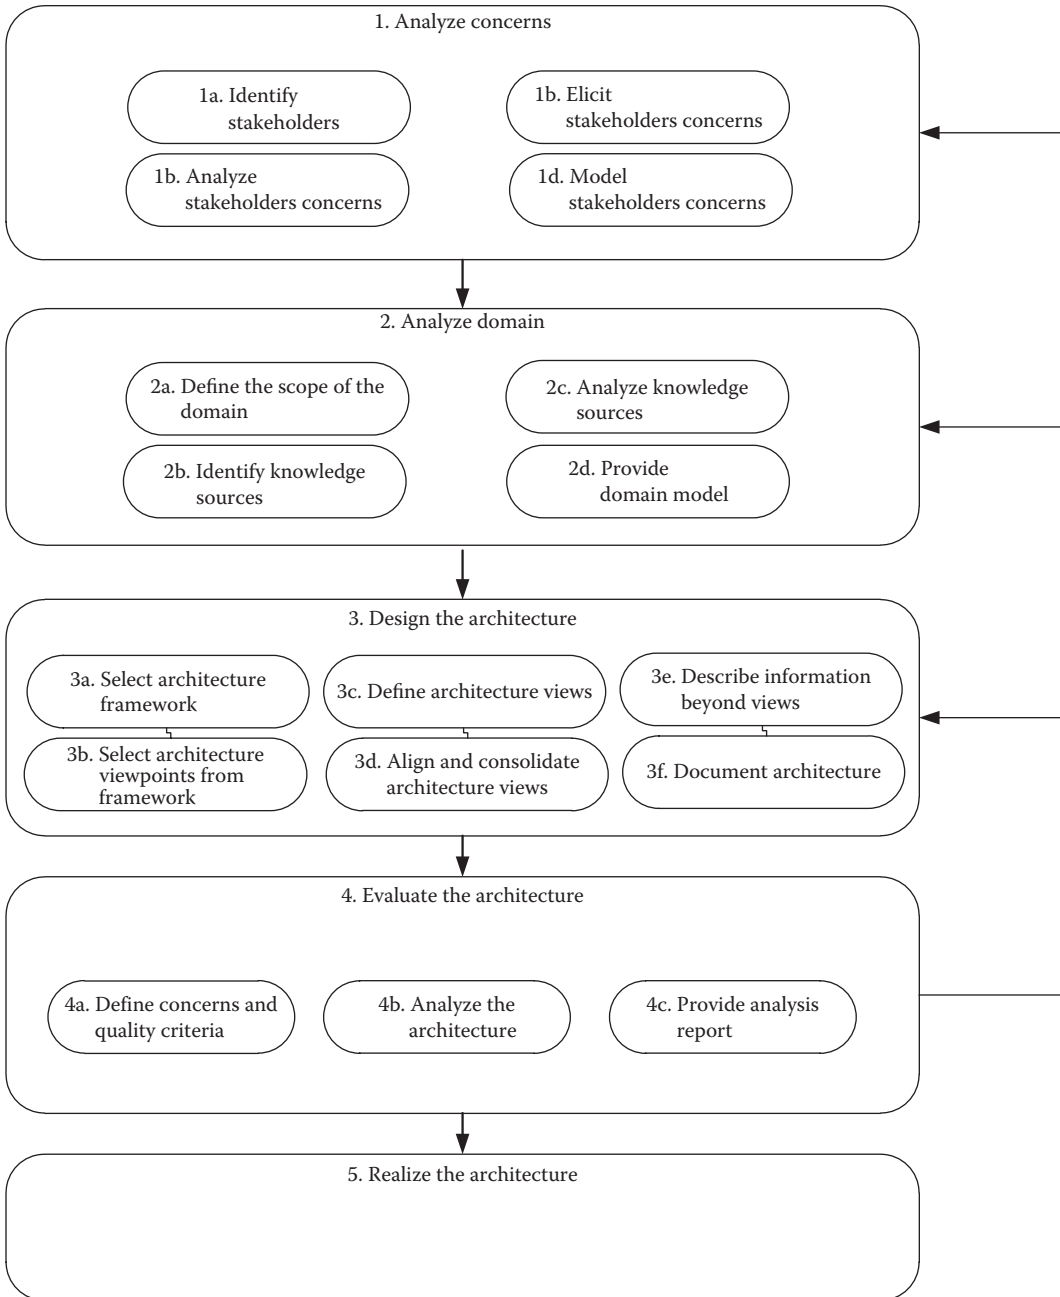

FIGURE 91.2 Example software architecture design process.

Conventional domain analysis methods consist generally of the activities *Domain Scoping* and *Domain Modeling*: *Domain Scoping* identifies the domains of interest, the stakeholders, and their goals and defines the scope of the domain. *Domain Modeling* is the activity for representing the domain, or the *domain model*. The domain model can be represented in different forms such as object-oriented language, algebraic specifications, rules, and conceptual models. Typically, a domain model is formed through a commonality and variability analysis to concepts in the domain. A *domain model* is used as a basis for engineering components intended for use in multiple applications within the domain.

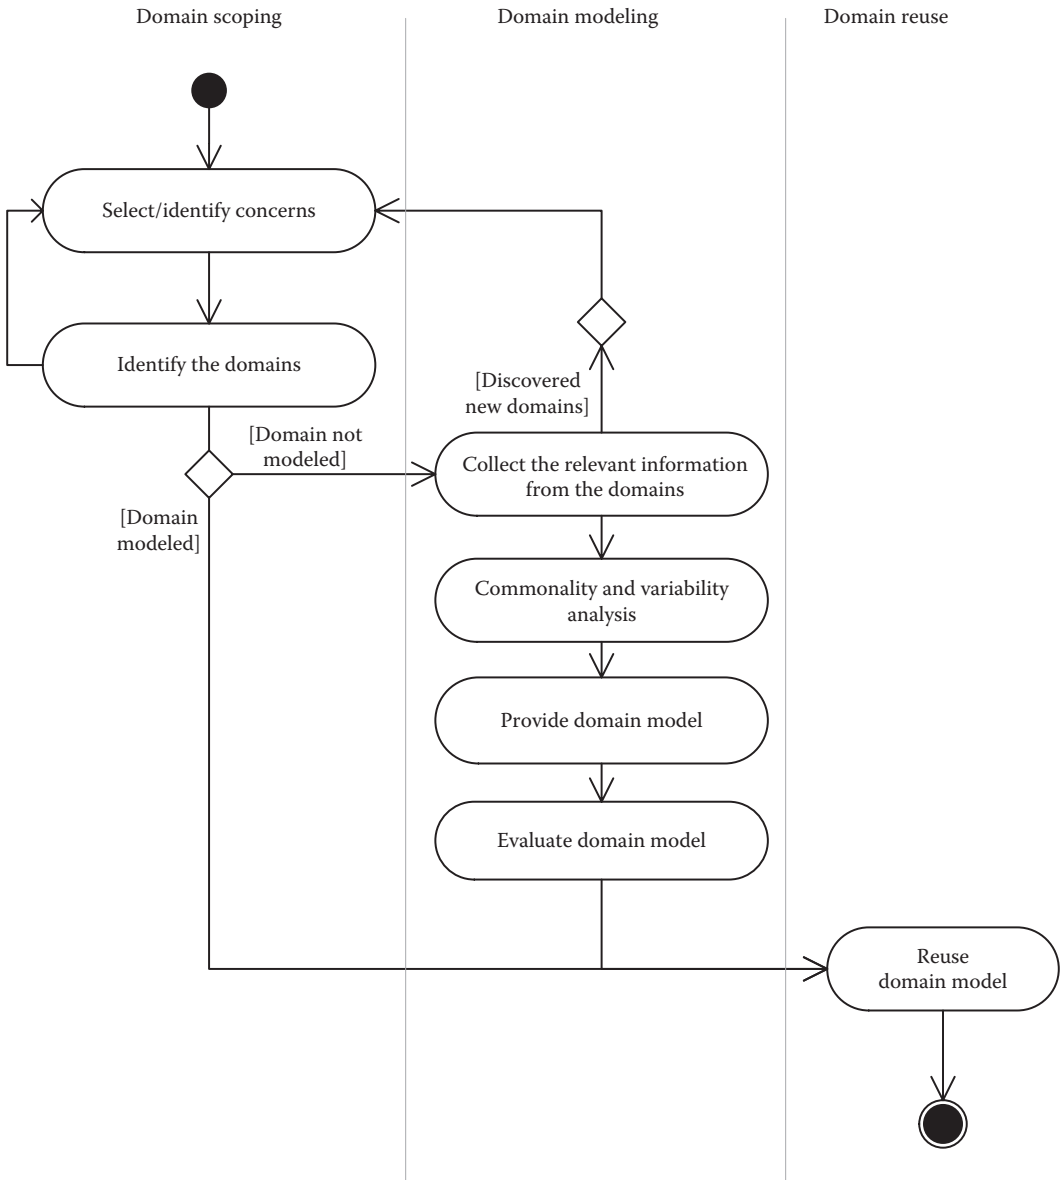

FIGURE 91.3 Common structure of domain analysis methods.

This activity results in a thorough understanding of the domain in which new concerns that were overlooked in the previous activity can be identified. For this, one can iterate back to the previous activity of concern analysis to update the identified concerns.

91.3.3 Architecture Design

Once the stakeholder concerns and the domain has been understood and modeled, the architecture design can be started. In this context, as stated before, the notion of viewpoint plays an important role in modeling and documenting architectures. Before the design process can begin, an architecture framework needs to be selected that contains the viewpoints with which the architecture views

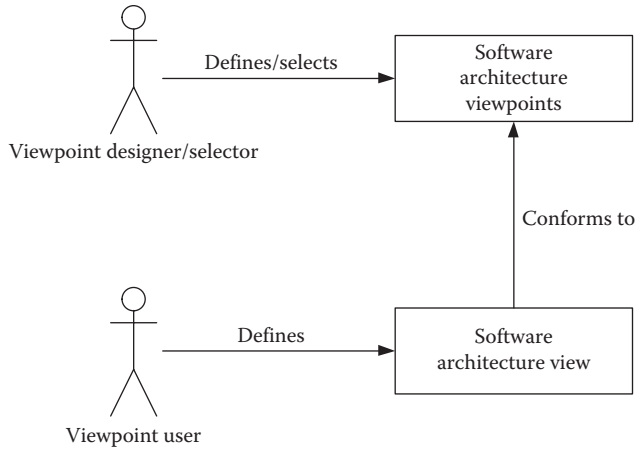

FIGURE 91.4 Viewpoint definition and view development for MPL.

will be modeled. Sometimes, new viewpoints might need to be added if the existing viewpoints are limited in modeling the stakeholder concerns. In this respect, we can distinguish between *viewpoint designer* and *viewpoint user* (Figure 91.4). The viewpoint designer either designs new viewpoints or selects viewpoints from an existing architecture framework. The viewpoint user is the software architect who uses the viewpoints to document the architecture. Viewpoint designer and viewpoint users are roles and can represent the same architect or architecture team.

After the selection of the viewpoints, the architecture views need to be aligned with each other for consistency [39]. Typically, this includes checking whether the elements in each view map to other elements of related views.

During the design, one might identify the need for new concerns or analysis of domains that were not identified before. As such, iterating to the activity *Analyze Concerns* and/or *Analyze Domain* can be necessary.

91.3.4 Architecture Evaluation

The architecture forms one of the key artifacts in the entire software development life cycle since it embodies the earliest design decisions and includes the gross-level components that directly impact the subsequent analysis, design, and implementation. The key concerns of an architecture are defined by stakeholders, an individual, team, or organization with interests in, or concerns relative to, a system. Each of the stakeholders' concerns impacts the early design decisions that the architect makes. To ensure that the concerns have been properly addressed, the architecture needs to be evaluated with respect to the defined concerns. For this, the concerns and the quality criteria are identified. Based on these, the architecture will be evaluated and an impact analysis report will be provided. The result of the evaluation process might require iteration to activities *Analyze Concerns*, *Analyze Domain*, and *Architecture Design*. We elaborate on the evaluation process in Section 91.4.

91.3.5 Architecture Realization

The final step of the architecture development cycle is the realization of the architecture.

To realize the important architecture design concerns, one of the key goals of software architecture design is to serve as a guideline for the subsequent life cycle activities. Based on the architecture design, the detailed design and subsequent activities can be carried out. Figure 91.5 shows the relationships among these concepts. An architecture description is defined using architecture views and addresses a set of concerns. The architecture is followed by the detailed design that realizes the architecture and that

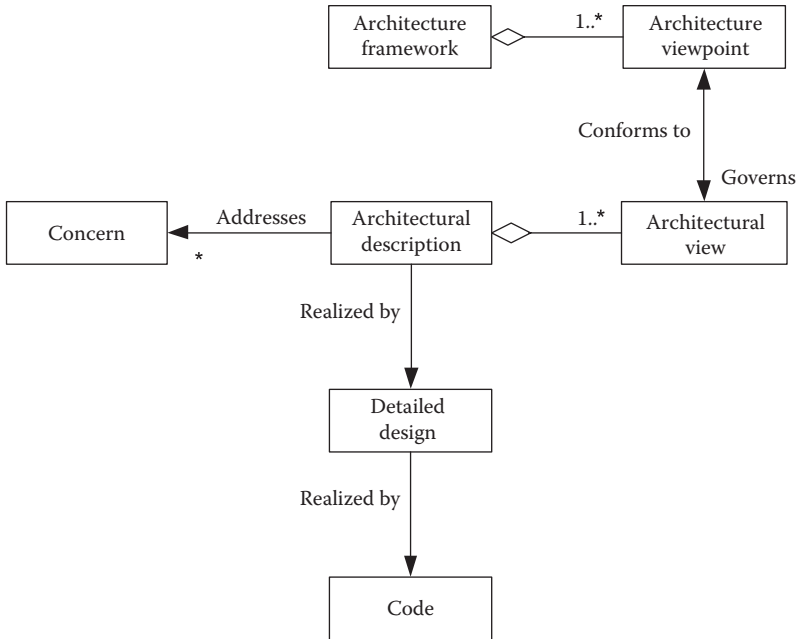

FIGURE 91.5 Relation between architecture viewpoint, architecture view, and detailed design.

is subsequently realized by code. To preserve the benefits of the architecture, it is important to keep the life cycle artifacts consistent with the architecture.

Software systems are rarely static and need to evolve over time due to bug fixes or new requirements. These required changes might lead to a situation in which the realization of the architecture (in the detailed design and code) is different from the architecture description itself. As such, the benefits of an architecture-driven software development approach will be lost. A proper documentation of the architecture is important to minimize the cost of software maintenance. Despite this, the evolution of the system and likewise the discrepancy between the architecture description and the resulting implementation will be highly probable. The discrepancy between the architecture description and the architecture realization is usually referred to as *architectural drift* or *architecture degeneration*. This architecture drift can be even introduced during the initial implementation of the architecture due to lack of knowledge about the architecture or stringent time-to-market constraints. Even if the initial implementation of the architecture is properly aligned with the architecture description, the constant need for new requirements very often leads to a situation that can lead to architecture drift.

The existence of discrepancies among the architecture description and its implementation is not a mere theoretical issue, but it may directly lead to increased maintenance time and cost, because the original design goals have been lost. In the extreme cases, a system’s architecture may even deteriorate to a degree where further development is not feasible, leading to a complete system reimplementa-tion. As such, preferably conformance checking of the architecture description and the implementation should be exercised over the architecture of a system during development and maintenance, with the aim of enforcing architecture consistency.

91.4 Architecture Evaluation

In the previous section, we have discussed the generic approach for designing software architecture. Various other architecture design approaches can be found in the literature. In this context, Hofmeister et al. [18] also provide a model of software architecture design approaches. The aim of

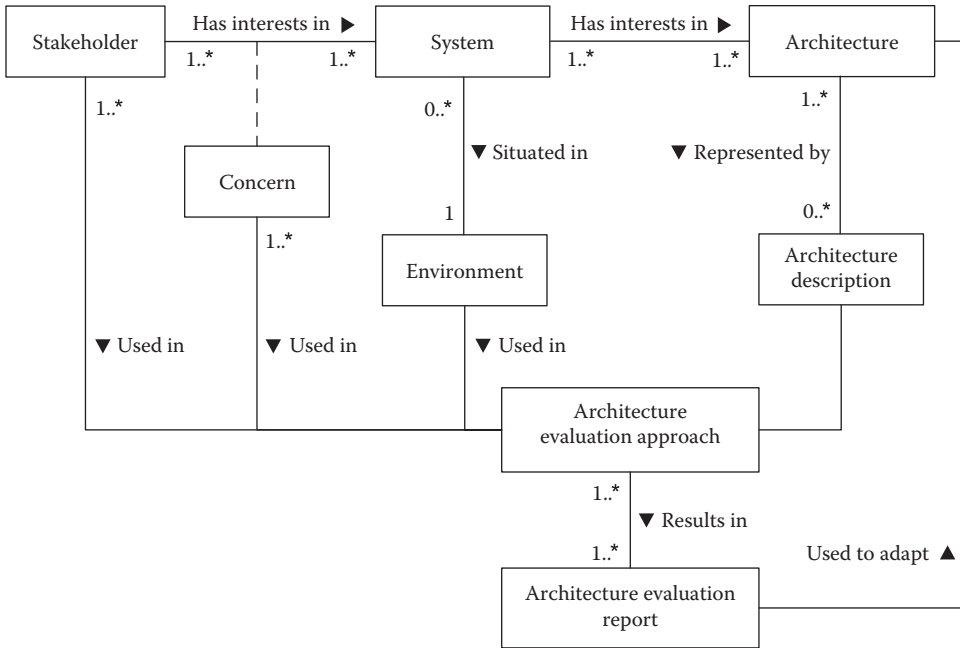

FIGURE 91.6 Conceptual model for software architecture analysis.

all these architecture design approaches is to design a software architecture that meets the stakeholder goals. Since architecture is critical for the success of a project, different architectural evaluation approaches have also been introduced to evaluate the stakeholders’ concerns. A comprehensive overview and comparison of architecture analysis methods have been given by, for example, Dobrica et al. [10], and Babar et al. [2]. Kazman et al. [20] have provided a set of criteria for comparing the foundations underlying different methods, the effectiveness and usability of methods. Figure 91.6 provides a conceptual model that relates the architectural concepts with the architecture evaluation approach. Although different architecture evaluation approaches have been proposed in the literature, we can state that most of these follow the model as defined in Figure 91.6. In essence, each architecture evaluation approach takes as input the stakeholder concerns, the environment issues, and the architecture description. Based on these inputs, the evaluation results in an *architecture evaluation report*, which is used to adapt the architecture.

Figure 91.7 shows the generic conceptual process for architecture evaluation that has been based on the proposed architecture evaluation approaches. Each architecture evaluation approach appears to take as input the architecture and the quality criteria that need to be evaluated. If the architecture meets the criteria, then a decision can be made to realize the architecture, if not, then a refactoring of the architecture is required. Architecture evaluation approaches usually differ with respect to, for example, the goal of the approach, the type of inputs, the evaluation techniques, the addressed quality attributes, the stakeholders involvement, the ordering of activities, and the output results [2,20].

91.5 Research Issues

It is now generally accepted that software architecture design plays a fundamental role in coping with the inherent difficulties of the development of large-scale and complex software systems. Research on architecture design in the last two decades has resulted in different useful techniques and approaches. Different architectural modeling approaches for representing multiple views of the architecture have been proposed. Multiple architectural patterns have been introduced in literature to support the quality

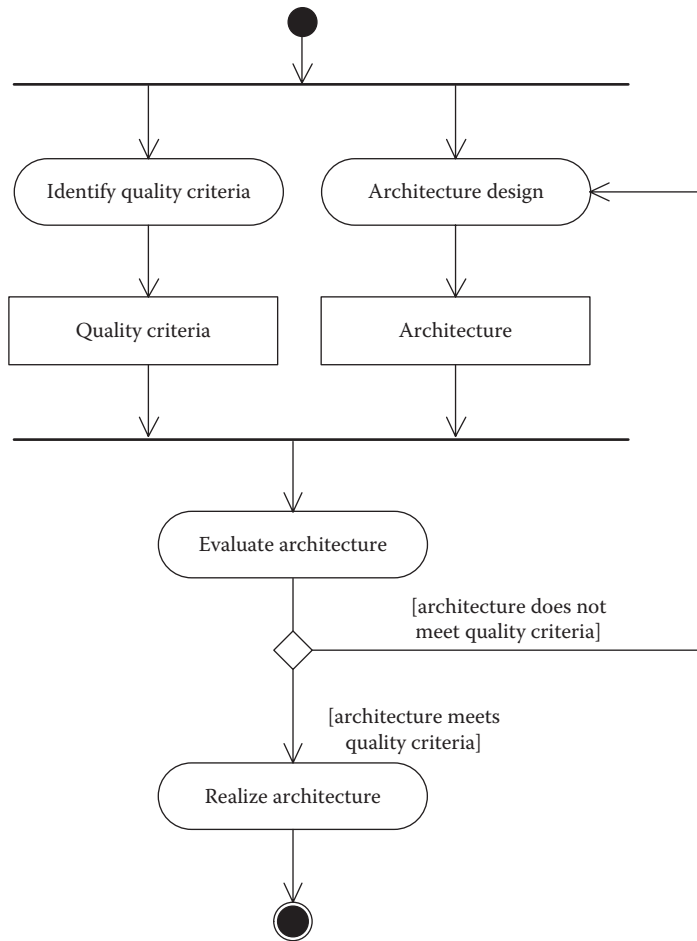

FIGURE 91.7 Generic architecture evaluation process.

of architecture [3,6,22]. A broad range of architecture analysis approaches has been proposed to analyze the architecture before it is implemented [15,34]. We can state that the software architect is now equipped with a broad set of techniques to design a software architecture that aims to meet the stakeholder concerns. Using these approaches, the software architect makes a wide range of design decisions that leads to the selection of a particular design alternative. Yet, there are indeed still challenging issues in the state of the practice and different research questions need to be tackled in the architecture design community [35]. We list some of the important research directions:

91.5.1 Modeling Quality Concerns

In the literature, initially a fixed set of viewpoints has been proposed to model and document the architecture. Because of the different concerns that need to be addressed for various systems, the current trend recognizes that the set of views should not be fixed but *open-ended*. An important example in this context is the V&B approach as proposed by Clements et al. [8]. Hereby, the authors propose the notion of architectural style that is a specialization of architectural element types and relationship types, along with any constraints. The notion of styles makes the V&B approach adaptable and open-ended since the architect is not bound to a fixed set of views but can in principle define any style that is needed. Certainly, existing architectural modeling approaches are important for representing the structure and

functionality of the system and are necessary to document the architecture systematically. An analysis of the existing multiview approaches reveals that they are primarily focused on functional concerns and appear to be incomplete when considering nonfunctional concerns [40]. The ISO/IEC 42010 standard is intentionally not specific with respect to concerns that can be addressed by views. In approaches such as the V&B approach, nonfunctional concerns appear to be implicit in the different views but no specific style has been proposed for this yet. One could argue that for addressing nonfunctional concerns, software architecture analysis approaches have been introduced. The difficulty here is that these approaches usually apply a separate quality model, such as queuing networks or process algebra, to analyze the quality properties. Although these models represent often precise calculations, they do not depict the decomposition of the architecture, and an additional translation from the evaluation of the quality model needs to be performed. To represent nonfunctional concerns more explicitly, architectural views should also be able to model the decomposition of the architecture based on the required nonfunctional concern. Viewpoints for nonfunctional concerns will typically overlap or crosscut existing viewpoints based on functional concerns. The crosscutting nature of nonfunctional concerns can be both observed *within* an architectural view and *across* architectural views. Aspect-oriented software development (AOSD) promotes the separation of crosscutting concerns to increase modularity. Hereby, crosscutting concerns are separately represented as first-class abstractions (aspects) and woven into the *base code*. To cope with the crosscutting concerns at the architecture design level, we believe that AOSD techniques are necessary [6].

Appropriate models for quality concerns can support the architecture design process to design for quality. In addition, different approaches have been defined that provide guidelines for designing for various qualities. *Architectural Perspectives* [32] are a collection of activities, tactics, and guidelines to modify a set of existing views to document and analyze quality properties. Architectural perspectives as such are basically guidelines that work on multiple views together. An important observation hereby is that the crosscutting nature of quality concerns can be both observed *within* an architectural view and *across* architectural views. Architectural tactics [3] aim at identifying architectural decisions related to a quality attribute requirement and composing these into an architecture design. Defining explicit viewpoints for quality concerns can help to model and reason about the application of architectural tactics.

91.5.2 Model-Driven Approach for Architecture Design

Architecture design is basically about *modeling* the system from different perspectives. Historically, *models* have had a long tradition in software engineering and have been widely used in software projects. The primary reason for modeling is usually defined as a means for communication, analysis, or guiding the production process. Models are different in nature and quality and different classifications of models have been provided in the literature. Mellor et al. [25] make a distinction between three kinds of models, depending on their level of precision. A model can be considered as a *sketch*, as a *blueprint*, or as an *executable*. According to [25], an executable model is a model that has everything required to produce the desired functionality of a single domain. Executable models are more precise than sketches or blueprints and can be interpreted by model compilers. A similar classification of models is defined by Fowler [15] who suggests a distinction based on three levels of models, namely, *conceptual models*, *specification models*, and *implementation models*.

In model-driven software development, the concept of *models* can be considered as executable models as defined by the aforementioned characterization of Mellor et al. [25,34]. In model-driven software development, models are not mere documentation but become “code” that are executable and that can be used to generate even more refined models or code. This is in contrast to model-based software development in which models are used as blueprints at the most.

The language in which models are expressed is defined by metamodels. As such, a model is said to be an instance of a metamodel, or a model *conforms to* a metamodel. A metamodel itself is a model that

conforms to a meta-metamodel, the language for defining metamodels [12,13,23]. Given the different levels in which the models reside in model-driven development, models are usually organized in a four-layered architecture. The top (M3) level in this model is the so-called meta-metamodel and defines the basic concepts from which specific metamodels are created at the meta (M2) level. Normal user models are regarded as residing at the M1 level, whereas real-world concepts reside at level M0.

In fact, we can state that the current architectural modeling practices can be categorized as *model-based development*, rather than *model-driven development*. In the last two to three decades, architectural modeling and the corresponding notations have evolved from simple sketches to more precise models as defined by architectural view concept. Yet, the view models can usually not be considered as executable models. Moreover, the link between architectural models and the link from architectural models are merely implicit and not formal [12].

In architecture modeling literature, the notion of metamodel is not explicitly used. Nevertheless, the concepts related to architectural description are formalized and standardized in ISO/IEC 42010:2007, a fast-track adoption by ISO of IEEE-Std 1471-2000, *Recommended Practice for Architecture Description of Software-Intensive Systems* [21]. The standard holds that an architecture description consists of a set of *views*, each of which conforms to a *viewpoint*, but it has deliberately chosen not to define a particular viewpoint. Here, the concept of view appears to be at the same level as the concept of *model* in the model-driven development approach. The concept of viewpoint, representing the language for expressing views, appears to be on the level of metamodel. Although the ISO/IEC 42010 standard does not really use the terminology of model-driven development, the concepts as described in the standard seem to align with the concepts in the metamodeling framework. In Figure 91.8, we provide a partial view of the standard that has been organized around the metamodeling framework. An *Architecture Description* is a concrete artifact that documents the *Architecture* of a *System of Interest*. The concepts *System of Interest* and *Architecture* reside at layer M0. *System of Interest* defines a system for which an *Architecture* is defined. *Architecture* is described using *Architectural Description* that resides at level M1. *Architectural Description* includes one or more *Architectural Views* that represent the system from particular stakeholder concern’s perspective. Architectural views are described based on *Architectural Viewpoint*, the language for the corresponding view. *Architectural Viewpoints* are organized in *Architectural Framework*. The latter two reside at level M2. The standard does not provide a concept that we could consider at level M3, and as such we have omitted this in Figure 91.8.

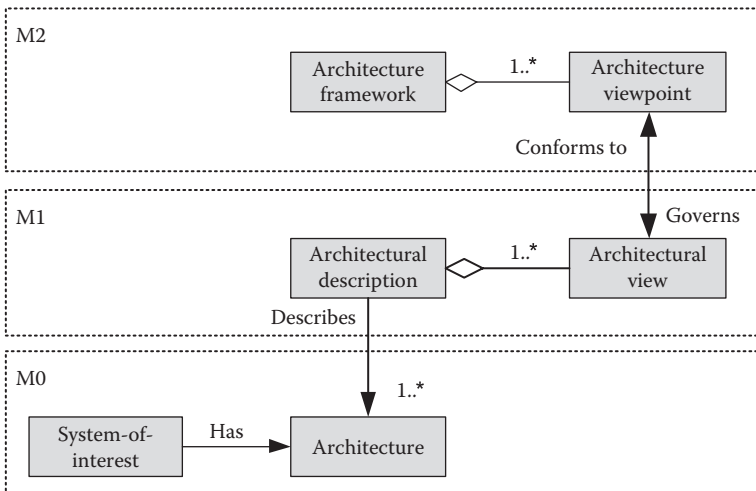

FIGURE 91.8 Architectural description concepts from a metamodeling perspective.

91.6 Summary

In this chapter, we have defined an overview of software architecture design. We have focused on three basic topics including software architecture modeling, software architecture design methods, and software architecture evaluation.

Software architecture modeling has evolved from informal box-and-line drawings to extensive architecture frameworks that include various viewpoints for modeling the architecture based on the concerns of stakeholders. Different architecture frameworks have been introduced in the literature, each with its own set of viewpoints. Earlier frameworks assumed a fixed set of viewpoints from which the architect can select the required ones to model the architecture. Recent approaches such as the V&B approach adopt an open-ended approach in which new viewpoints can be designed if deemed necessary.

The process of software architecture design usually starts in the early phases of the software development life cycle. Various architecture design methods have been introduced. We have identified five key activities that can be observed in most architecture design methods. The activities include *Analyzing Concerns*, *Analyze Domain*, *Architecture Design*, *Evaluate Architecture*, and *Architecture Realization*.

Once the architecture is designed, it can be evaluated based on quality criteria. The evaluation results in impact analysis report that might require refactoring the architecture to align it with the defined quality criteria.

Key Terms

Architectural (architecture) pattern: “An architectural pattern expresses a fundamental structural organization schema for software systems. It provides a set of predefined subsystems, specifies their responsibilities, and includes rules and guidelines for organizing the relationships between them” [5, p. 12].

Architecture description language (ADL): A language for representing a software and/or system architecture. ADLs are usually graphical languages that provide semantics that enable analysis and reasoning about architectures, often using associated tools.

Architecture framework: “Conventions and common practices for architecture description established within a specific domain or stakeholder community” (ISO/IEC 42010:2007). TOGAF and DoDAF are examples of architecture frameworks.

Architecture stakeholder: An individual, team, or organization with interests in, or concerns relative to, a system.

Concern: Any matter of interest that is held by a stakeholder.

Module: An implementation unit of software that provides a coherent set of responsibilities.

Relation: A definition of how elements cooperate to accomplish the work of the system. The description of a relation names the relations among elements and provides rules on how elements can and cannot be related.

Resource: A function, method, data stream, global variable, message end point, event trigger, or any addressable facility within an interface.

Software architecture: The fundamental organization of a system embodied in its components, their relationships to each other, and to the environment, and the principles guiding its design and evolution.

View: A representation of a set of system elements and relations among them.

Viewpoint: ISO 42010 defines a viewpoint as a work product establishing the conventions for the construction, interpretation, and use of architecture views and associated architecture models.

92.1 Speech Interface Design

A speech application is considered effective if it simulates the core aspects of human conversation. Language is deeply entrenched in human behavior; therefore, a successful speech interface should be based on the different ways that people use speech to communicate. Language conventions that help people know what they should say next should be adopted when creating speech applications (Weinschenk, 2003).

92.1.1 Introduction to Speech Application Development

Human–computer interaction (HCI) focuses on the interaction between humans and computers. This can be done by studying the current design of technology and how it could be redesigned to make technology more user-friendly, more interesting, and engaging. One of the best ways to achieve this is through speech. Integrating speech in an application is a vast benefit because speech is natural. Speaking is a skill humans acquire at an early age and is something we as humans practice quite frequently. The naturalness of a conversation refers to the way that people cooperate with each other in order to ensure successful communication. A speech application is considered effective if it simulates the core aspects of human–human conversation. Language is deeply entrenched in human behavior; therefore, a successful speech interface should be based on the different ways that people use speech to communicate. Language conventions that help people know what they should say next should be adopted when creating speech applications (Weinschenk, 2003).

92.1.1.1 When Is Speech Used?

When determining the success of a speech application, whether or not using speech input is beneficial is a crucial factor. When using a speech application, the user’s expectations are high; therefore, speech only needs to be used when the need is clear. When the users are enthusiastic about cooperating, a speech application is most successful (Weinschenk, 2003). For example, airline companies successfully use speech recognition to automate checking flight statuses. People checking flight statuses want to do this as quickly as possible, so they listen and answer the prompts very carefully. People checking flight statuses are also motivated to cooperate, because they do not want to miss any important information, such as a gate change. Automated systems assist the users and save companies’ money as well. Speech is suitable for some tasks, but not for others. Table 92.1 lists when speech input and output are appropriate to use (Weinschenk, 2003).

92.1.1.1.1 Speech Challenges

According to Weinschenk et al., using a speech application poses many substantial challenges, and understanding these challenges and the various trade-offs help to produce an effective interface. Six challenges were identified, which are as follows:

- *What did you say?* Once it has been heard or said, it’s gone. Since speech is transient, only a limited number of items in a list can be remembered and a user may forget important information that were given at the beginning of a sentence. This is also true when speaking to a dictation system. The users sometimes forget what they have just spoken. The ability to remember transient information has substantial implication for speech interface design.

TABLE 92.1 When Is Speech Input Appropriate?

Use When	Avoid When
Users have a physical disability (e.g., seizures)	Users work in noisy environment
No keyboard is available (e.g., phone)	Task can be accomplished more efficiently using keyboard and mouse
Users are unable to type or are not comfortable with typing	Task requires users to engage in conversation with others while using the application
Task requires the user’s hands to be occupied (e.g., driving)	Information is personal or confidential
Task requires user’s eyes to be looking at something other than the screen	Large amounts of information need be presented
Situation requires getting the user’s attention	Task requires the user to do a comparison

- *What can I say?* In a speech application, the lack of visibility makes it challenging to communicate the functional boundaries of the application to the user. Furthermore, it is challenging to tell the user what actions can be performed and what words or phrases they can use to perform these actions.
- *Asymmetry.* People are able to speak easily and quickly, but cannot listen as easy and quickly. This means that we as humans can speak faster than we type but listen more slowly than we can read. Asymmetry produces an implication for “the type and the amount of information to speak” when designing speech interfaces.
- *Feedback and Latency.* Timing is very important when having a conversation. People read into the meaning behind pauses. Pauses in places where they naturally do not belong causes unfortunate processing delays in speech applications. For example, a user may reply to a prompt and because the system may take a long time to respond, then the user will think the system did not hear them and repeat the response again. This will cause the system to return the wrong response or the user to miss the systems response.
- *Prompting.* Well-designed prompts in a speech application provide the user with a smooth interaction. When designing prompts, many things have to be considered. Good design is accomplished by assessing the trade-off between performance and flexibility. The more the user is constrained on what they can say to an application, the chances of recognition errors are decreased. However, allowing the users to answer flexibly can speed up the interaction and makes the conversation feel more natural.
- *Handling Errors.* The quality of users experiences depend on how a system is able to handle recognition errors. If the users or the application notices an error, the speech interface should be able to provide a way for correcting the error. The most important thing not to do when handling these errors is to repeat the same error message if the users encounter the same rejection error in a row.

92.1.1.2 Speech Recognition

Today, when we call most companies, a person does not answer the phone, an automated machine does. The automated machine instructs the user how to move through the menu of options using touchtone keys or voice, allowing the user to say certain commands or keywords. This is done by speech recognition, the technology that enables computers or other electronic systems to understand human speech (Sharma, 2002). Speech recognition systems have two main functions: to understand the words spoken by the user and convert the spoken words to text for future use and to convert text to speech (TTS) for information access (Weinschenk, 2003). Speech recognition can be divided into two different categories: continuous and discrete.

92.1.1.2.1 Continuous versus Discrete

Continuous recognition allows the user to engage with the system in an everyday manner without using specific commands. Using this type of recognition makes the system error prone and extremely expensive. Discrete recognition allows the user to use a limited vocabulary of single words and phrases. Discrete vocabulary is easy to learn and produces higher accuracy rates; however, it is not as natural (Weinschenk, 2003).

92.1.1.2.2 Recognition Challenges

Speech application design, with its concerns for understanding human language, interpreting different dialects, intonations, and speaking speed, makes speech application design a great research area. The difficulties just listed are a few of the challenges faced for understanding human utterances. The following sections explain the challenges of recognition performance and flexibility versus accuracy.

92.1.1.2.2.1 Performance When designing a speech application, a big challenge is working with an imperfect speech recognizer. The biggest challenges for recognition performance are background noise, accents, and ambiguity. Background noises and utterances can interfere or distort the input that user gives to the system. The variations of different users’ voices such as accents can also decrease the

accuracy of the speech recognition system (Carroll, 2009). The larger the vocabulary or grammar of a speech recognition system the chances of ambiguity increases. Although the strings may be different when spoken by the user, they might sound alike and therefore the wrong output will be given (Cohen, 2004). Even though speech recognizers are improving consistently, it is very unlikely that in the foreseeable future it will be as robust as they are in science fiction movies. There are some recognition systems that over time adapt to their users, but in order to have good recognition performance, the system needs users who are willing to adapt their speech needs to the recognition system (Weinschenk, 2003).

92.1.1.2.2.2 Flexibility versus Accuracy The more flexible an application is, the more likely errors are to occur. Flexible systems allow the users to speak a command in various ways. When designing a speech application, there must be a balance between flexibility and recognition accuracy (Weinschenk, 2003). For example, a car application may allow the user to change the radio station as follows:

- Change to one oh one point three f m please.
- Can you please go to one hundred one point three?
- Go to station one oh one point three f m.
- Please change the station to one hundred one point three.

In theory, this may be the natural but if the recognition performance is poor, users will not be in favor of using the application. Accepting a variety of ways to complete a task can offer flexibility without causing the recognition performance to decrease (Weinschenk, 2003).

92.1.1.3 Speech Synthesis

A speech synthesizer, synonymous with TTS, converts written TTS (Sharma, 2002). Speech synthesis is complementary to speech recognition (Carroll, 2009). The history of speech synthesis surpasses that of speech recognition but is still progressing today. It is used as a screen reader and provides verbal instruction, feedback, or assistance (Weinschenk, 2003). Speech synthesis can be broken into two categories: concatenated and formant.

92.1.1.3.1 Concatenated versus Formant

Concatenated synthesis uses segments of recorded human speech and pieces them together to produce meaningful speech output (Sharma, 2002). Using concatenated synthesis produces a more natural sound. Having a human reader read segments of speech and storing the segment of speech is the process for creating concatenated synthesizers. This type of synthesis is used for systems that require a small vocabulary (Weinschenk, 2003). Formant synthesis uses a set of guidelines that control audio waveforms that simulate human speech. Formant synthesis creates true machine-generated speech that often sounds like a robot. This form of synthesis is used in most TTS applications (Sharma, 2002).

92.1.1.3.2 Synthesis Limitations

Speech synthesizers can make errors at any given time. Here is a list of some of the sources of error in producing TTS output (Weinschenk, 2003).

- *Structure analysis*: The beginning and end of paragraphs and sentences are inconsistently indicated due to punctuation and formatting.
- *Text preprocessing*: The speech synthesizer cannot know all the possible abbreviation and acronyms. It also cannot determine all the ways things such as time and dates can be written.
- *Text-to-phoneme conversion*: Although speech synthesizers can pronounce a lot of words correctly, there are still some words that it has to guess.
- *Prosody analysis*: Speech synthesizers try to guess the emphasis that a human uses on correctly phrasing a sentence and sometimes the output sounds artificial and unnatural.
- *Waveform production*: Due to the fact that speech synthesizers do not have lips, mouths, lungs, and other things used in human speech, they often produce speech that is mechanical.

92.1.1.3.3 Evaluating Synthesis

Being able to evaluate speech synthesis quality and understanding the factors that can affect the output are important in the utilization of speech synthesis (Weinschenk, 2003). The measures of the quality of synthesized speech are (Cohen, 2004) as follows:

- **Intelligibility:** An indication of how well the listener understands the words and sentences spoken by the synthesizer.
- **Naturalness:** An indication of the extent of how much the synthesized speech sounds like a human.
- **Accuracy:** An indication of how correct the speech synthesizer is at converting TTS.
- **Listenability:** An indication of how long and well the users can listen to the speech synthesizer for an extended amount of time without becoming tired.

92.1.2 Application Development Process

A voice-user interface (VUI) is an application with which a person interacts using her or his voice (Guang-li, 2011). These interfaces are evaluated based on how well they perform when interacting with various people. A system is said to perform well when it returns the correct responses to a user without lagging, making mistakes, and/or causing frustration. Other vital factors to consider are solving the problem, communicating naturally, and user satisfaction (Cohen, 2004). The accuracy of VUIs depends heavily on how well the application was designed and on how well the speech recognizer can parse through the input. Because most people speak, and speak often, designing an application to respond well to natural speech is often severely underestimated. Designing a machine that understands and communicates using natural language to provide a seamless user experience is a major undertaking. Responding well to natural speech is one of the most substantial challenges a VUI designer faces. Approaching VUI design in a similar way as a software engineer approaches designing software enables quicker development time, and upon application, completion results in a better user experience.

92.1.2.1 Think about the Problem: Requirements Analysis

In order to develop an application, the requirements must first be understood. Requirements Engineering (RE) is the systematic process of developing requirements through an iterative cooperative process. The process entails analyzing the problem, documenting the resulting observations in a variety of representation formats, and checking the accuracy of the understanding gained (Loucopoulos, 1995).

This section of the development process often begins with a mission statement and becomes more elaborate through studies and meetings with prospective clients (Rosson, 2002). The result of this effort is a full list of all functions and features the system must satisfy. Requirements analysis is an ongoing process but many users cannot declare or understand their real needs until they see what kind of options are available. According to (Rosson, 2002), “Usability engineers participate in requirements analysis by studying how work currently takes place to see if they can identify problems or opportunities that might be addressed by new technology.”

Scenarios or narratives are also often used during requirements analysis because they evoke reflection and conversation. Additionally, scenarios foster mutual understanding among the different groups who participate in the analysis (Rosson, 2002).

92.1.2.2 VUI Design

Once the problem is clear, designers can begin to envisage solutions. “The field of human-computer interaction (HCI) is concerned with the joined performance of tasks by humans and computational machines” (Hewett, 1996). Some would say that HCI’s major contribution to the field of computer science is the design, evaluation, and implementation of interactive computing systems for human use (Hewett, 1996).

Speech technology has improved significantly within the last decade where it has become possible and rather preferable to integrate voice into applications. Using voice as a means of interaction with a technology has its advantages over the traditional input/output modalities. Certain environments such as applications developed for in-vehicle use encourage the use of voice over the traditional input/output modalities. Designing VUIs differs from graphical user interface (GUI) design (Yankelovich, 1995).

While visual sketches are fundamental in GUI design to mock up user experience with an application, designers of VUIs find it vital to understand people's natural conversational styles and communications. A well-designed voice interface dialogue does not violate natural conversation behaviors. A natural dialogue would be one that simulates a natural conversation with the user without influencing the voice input. For example, a system would say, "what would you like to eat?" instead of prompting the user with "do you want an apple or an orange?" While the latter is restricting, the first example simulates more natural interaction. It is vital that VUI designers put together a dialogue that prompts and allows for natural navigation. The design of such a dialogue would consist of scenarios represented by a flowchart of in/output prompts.

As with any other input modality, using voice to place information into an application isn't perfectly reliable. Errors in speech input are encountered in myriad ways. Noise is one of the more troublesome challenges for speech application input. Another major challenge is the limitations of the applications grammar. A well-designed VUI allows a seamless workaround for these major challenges that does not frustrate the user (Yankelovich, 1998).

A VUI should be intuitive and complement human communication. A user would be easily frustrated if miscommunication and misunderstanding were too frequent while interacting with a VUI. Humans are wired to use speech to communication needs and desires among each other. A voice application should be able to attend to that need and deal with miscommunications smoothly. A VUI design fails if the user could detect the application's inefficiency in handling errors and completing tasks for which it was designed.

As aforementioned, errors occur when interacting with voice applications. A designer should incorporate prompts in the application to sympathetically aid the user. The user, with the systems help, should be able to backtrack to the point before miscommunication and continue interactions.

92.1.2.3 Implementation

One of the main aspects of speech application design is the grammar. The grammar tells your speech recognition application that to which it should listen. Once the system knows that to which it should listen, you can program an application to respond to utterances. Because humans generally communicate through speech, a good grammar is designed to process natural language. In order to implement a speech design, you need a speech recognition application and be able to build a grammar.

92.1.2.3.1 Grammar

A grammar consists of an organized list of rules specifying the words or phrases that can be used for that particular speech recognition system. The list of rules gives the guidelines for the applications spoken input. These guidelines are used to predict the possible speech input that the user will give and also restricts the words or phrases that the system can recognize. Grammars can be written in one of two forms: a grammar file or an inline script. A grammar file is an external file that holds the words and phrases for your speech recognition system. An inline script is within the actual code of the speech recognition application (Microsoft, 2004a).

A grammar limits vocabulary, filters response recognition, matches speech, and identifies rules. The grammar only contains the words or phrases that the system needs to successfully match the user's speech input. An application might only need to recognize a small set of words and the grammar prevents the system from having to search an entire dictionary. By specifying a group of words in

TABLE 92.2 Grammar Specification Language Operators

* Kleene closure	*D	Zero or more repetitions of D

a grammar, the recognition accuracy may also increase. Using a grammar also filters the results by only returning a successful recognition event only if the grammar is matched. Even though grammar structures need to be flexible for the user, it also needs to restrict the users input for a specific situation or task. Grammars have rules or entities that define and give order to the possible words, phrases, or utterances of the user. The rules can be referenced repeatedly within the particular grammar or rules in other grammars. Grammars can define all combinations of how to say a phrase in a single rule (Microsoft, 2004b).

Grammars can be written in various formats such as GSL, XML, JSGF, and ABNF. All grammars are constructed by using five basic operators. Table 92.2 describes how the operators are used in GSL (Nuance, 2001). The symbols A, B, C, and D denote a grammar or word name in the table.

Here are some GSL expressions and some of the phrase they describe: [coffee juice tea] *matches* “coffee,” “juice,” or “tea;” (I would like [coffee juice tea]) *matches* “I would like coffee,” “I would like juice,” or “I would like tea;” (?I would like) [coffee juice tea] *matches* “I would like coffee,” “I would like juice,” “I would like tea,” or simply “coffee,” “juice,” or “tea;” and (thanks + very much) *matches* “thanks very much,” “thanks very very much,” etc.

92.1.2.3.2 Highlighted Speech Platforms and APIs

Some easily available tools that enable speech application design for the web and desktop are Web-Accessible Multimodal Applications (WAMI) by MIT and Dragon NaturallySpeaking by Nuance. These tools are highlighted because of their good reputation and their ability to aid in the design of speech applications. WAMI is a speech platform that is available to use for free online. Dragon NaturallySpeaking is considered the state of the art for personal speech recognition. The following paragraphs further explain how WAMI and Dragon NaturallySpeaking can aid speech application design.

92.1.2.3.2.1 Web WAMI is a JavaScript API that allows a user to add speech recognition capabilities to a website. WAMI was developed by MIT’s Computer Science and Artificial Intelligence (CSAIL) Spoken Language Systems group. WAMI provides developers with a sufficient set of components to build a web-based multimodal interface. WAMI is designed to ease the development of multimodal interfaces with modest natural language understanding needs. Grammars are written using the Java Speech Grammar Format (JSGF) standard. WAMI can be used to produce applications on recent versions of Firefox, Opera, Safari, or Internet Explorer on a Windows, Linux, or OS X system (McGraw, 2008).

92.1.2.3.2.2 Desktop Dragon NaturallySpeaking is a speech platform created by Nuance. It allows the user to converse with the computer instead of typing. While the user is talking, whatever they are saying is transcribed to the screen and into documents or e-mail messages. Dragon can be used to compose letters and memos and send e-mail message. Dragon can also be used to do things such as enter data in forms or spreadsheets, work on the web, start programs, and open menus. Using Dragon boosts the productivity of your application. Personalizing Dragon’s vocabulary is easy and very important for productivity because it preempts recognition errors. Correcting Dragon’s errors will also help it learn. The more Dragon is used, the more it learns and adapts to the user in terms of acoustics and vocabulary (Nuance, 2012).

92.1.2.4 VUI Evaluation

A VUI designer should have a clear understanding of what the purpose of the application is and what needs to be accomplished when accessing the application. Any interruption that stops a user from accomplishing the task would negatively affect the experience. VUI designers should always aim to achieve higher user satisfaction. User satisfaction could be evaluated and measured via questionnaires, interviews, and focus groups. There are two ways to evaluate a VUI, a summative and a formative evaluation. A summative evaluation is one that takes place once after the application has been developed. Data collected from this evaluation are used to improve the next version of the VUI. A formative evaluation is one that takes place several times while the system is being developed and appears as part of the prototyping application. There are several ways to measure task succession. One is running a number of pilot studies to smooth out any wrinkles in interaction flow. A designer should calculate task completion time and evaluate the system's ability to fix errors.

92.1.2.5 Wizard of Oz

The Wizard of Oz (WOZ) is a method of system prototyping where a human experimenter sits behind the scenes and interacts with the user on behalf of the system. This method is useful in trying to understand the interaction that the user would expect under near perfect conditions. Since system prompts are simulated via the human experimenter, the interaction behavior between both the participant and the experimenter depends heavily on the believability of the wizard. Therefore, the user would have different interactions based upon the believability of the wizard. The two major ways of evaluating a VUI are summative and formative. Summative evaluation is an informal and is performed at the end of the interface development phase. The data collected are usually used at the next major release. Formative evaluations are more formal procedures that occur during prototyping.

92.1.2.6 Usability Measures

The best method for measuring the usability of a system is through observation. This method requires analyzers to observe the system during broad situations that closely match the predicted usage patterns. One issue with this method is the amount of effort needed to construct a robust prototype (Campos, 2003).

Obviously, analytical methods do not solve usability issues, but they do help generate early feedback about interactive systems. It is valuable to attain as much feedback as possible before expensive decisions are made. Analytical techniques can be used with informal representations of the design, such as a storyboard or wireframes. It should be noted that the feedback attained from this method alone is seldom enough to provide adequate specifications for programming the system (Campos, 2003). There are a few issues associated with informal methods. Informal methods are difficult to perform systematically and should only be used by someone who has sufficient expertise.

Two common methods for measuring usability include usability inspection and cognitive walkthrough. The inspection involves an examination of the design representation using a sequence of standard questions. Although both methods involve a systematic set of questions, the walkthrough actually requires an initial representation of how the system will be used. This is due to the fact that the walkthrough questions are related to the task representations (Table 92.3).

TABLE 92.4 Microsoft's Lessons in the Art of Automated Conversation

Selected Best Practice Guidelines for Speech Interfaces
<p>1. Make It Real</p> <p>Users come with their own set of terminologies (?), metaphors, and organizational structures in mind. This is known as their <i>mental model</i>, or expectation of the interaction. Usable applications tap into this knowledge to give users a head start in understanding how to interact with the application.</p> <p>2. Clearly and Consistently Communicate System Capabilities</p> <p>VUIs must be carefully designed to help users understand the capabilities of the system. Interfaces need to unobtrusively guide users to speak predictable utterances and avoid the unconstrained conversational speech that we use talking to another person. The goal is to achieve a natural conversation within the technological boundaries of speech recognition.</p>

The usability inspection method uses heuristic evaluation. This approach systematically inspects the system using a set of best practice guidelines. A team of evaluators, preferably not those involved in the design process, is assembled to perform the heuristic evaluation (Table 92.4). A sample of best practice guidelines used by Microsoft can be found in the succeeding text. Once the team of expert evaluators is assembled, they perform their assessment based on the design guidelines and aggregate the results. By aggregating results from multiple evaluators, a more comprehensive evaluation is created.

Because the usability inspection method does not explicitly mention how the system is to be used, a cognitive walkthrough is sometimes useful (Campos and Harrison, 2003). The purpose of a cognitive walkthrough is to assess how well an interface will guide users in performing a task. In order for this to be effective, the expected tasks must be identified and there must be a model of the interface that allows these tasks to be performed. According to Campos and Harrison (2003), the assessment is achieved through answering the following three key questions at each stage of interaction:

- Will the correct action be made sufficiently evident to users?
- Will users connect the correct action's description with that they are trying to achieve?
- Will users interpret the system's response to the chosen action correctly?

They also state usage models documenting predicted courses of action for the user is a prerequisite. If "no" is an answer to any of these questions, it exposes a problem that will be addressed.

92.2 Research Issues and Future Development

Previous sections of this chapter have introduced design strategies and tools targeted toward developers. In this section, however, user-focused applications take center stage. Here, we present a general overview of the speech technology application landscape with signs pointing toward more specialized readings. Broad classes of real-world applications of VUIs in the past and present are explored, and based on the trajectory defined by these developments, a brief glimpse into the future of speech applications is described.

92.2.1 Speech Technology Applications: Then

When referring to speech applications "then," we refer to applications that accomplish the most fundamental tasks that allow for the existence of speech systems. Stored voice applications allow for the recording and playback of recognizable human language. Synthesized speech applications are enabling applications that allow for the mechanic or digital production of human-like speech. The final type of fundamental speech application, or speech application "then," is those that are able to listen to human speech and in some form understand utterances. Speech applications "then" consist of systems that store voice information for later listening, synthesize speech, and recognize words or interactive voice response (IVR) systems.

92.2.1.1 Stored Voice and Interactive Voice Response Systems

Among the most widely used speech technology systems are those that permit both the storage and the playback of human (or human-like) voices. Systems of this kind, in fact, have been in existence for at least 150 years (Feaster, 2009). Stored voice applications use limited speech collections as “read only” data in which individual sounds, or responses, are mapped to specific user actions, or input (Schmandt, 1993). Stored voice applications are most appropriately used when the set of acceptable responses is finite. Example categories of stored voice applications, which may use either synthesized speech or digitally recorded human speech as output, are the following: playback-only applications, interactive record and playback applications, dictation applications, and multimedia/multimodal applications (Rodman, 1999; Schmandt, 1993, 1999).

92.2.1.1.1 Interactive Voice Response Systems

The deployment of VUIs, especially for use over the telephone, has grown rapidly over the past decade, and incentives for both corporations and their clients have stimulated this growth (Cohen, 2004). The quintessential example of this general observation is the IVR system, or call center.

92.2.1.2 Speech Synthesis Applications

Speech synthesis is one of the oldest branches of speech technology research. Speech synthesis (i.e., TTS) systems have applications in many different domains, including telecommunications (see Section 92.1.1), public safety, entertainment, and education (Rodman, 1999). In addition, aid for the disabled is a small, but very important, application niche. Synthetic speech systems can be used by the blind or visually impaired. These systems provide computer access, to read, and to manage personal productivity (Schmandt, 1993). Those who have lost the ability to speak by traditional means can also use synthetic speech systems. Theoretical physicist Stephen Hawkins, who lives with a form of amyotrophic lateral sclerosis (ALS), or “Lou Gehrig’s disease,” is one of the most famous users of speech synthesis technology (Lange, 2012).

92.2.2 Speech in the Automobile: Speech Applications “Now”

Speech technologies “now” refer to speech applications that take the fundamental speech applications and allow a person to interface with devices. One of the main thrusts of a lot of speech application design research for speech technologies “now” is for speech applications in the automobile.

The increase in the electronics within many vehicles can be attributed to the fact that automobiles have become more than just a means of transportation and for many people have become a multifunctional living space (Kern, 2009). Reducing distraction and cognitive load is the main thrust for designing speech application in the automobile.

92.2.2.1 Reducing Distraction

Any task whether cognitively, physically, or visually demanding can have a significant influence on driver distraction (Young, 2007). However, unlike other input modalities, like direct touch or gestures, the speech input does not require drivers to take their hands off the steering wheel and eliminates much of the overall difficulty of manual device interactions (Gruenstein, 2009). Even more, researchers have found speech to perform better than other input modalities for text input (Ablassmeier, 2006; Camilli, 2011; Maciej, 2009). Ford motor company has done a considerable amount of work in developing a VUI for their vehicles (Rana, 2010).

92.2.2.2 Design to Reduce Cognitive Load

Speech as an input modality is very effective; however, if improperly designed, it can increase cognitive loads. When used as an output modality, Christiansen et al. demonstrated that even though auditory feedback had the fewest eye glances, it had the longest completion times, and the authors state that

“listening to audio output while driving causes an increase in the cognitive load of the driver, thereby drawing mental resources away from the task of driving” (Christiansen, 2011).

92.2.2.2.1 *Evaluating Speech Interfaces in the Vehicle*

Usability measures should be collected using standardized tools such as the system usability scale (Lewis, 2009) or the technology acceptance model (Venkatesh, 2003). These questionnaires assess the overall perception of the system from the user’s perspective and are decisive indicator of the possible acceptance of the system in real-life scenarios.

92.2.2.3 **Toward Tomorrow**

It has also been noted that many auditory and speech alerts are clearly useful when the driver is not looking at an interface. However, additional research will be necessary to ensure that these alerts are not masked by other auditory information (Kramer, 2007).

Currently, handling speech in the automobile is a rich area of research and with increased developments in natural language processing and automotive user interfaces, speech research and developments in the automobile will flourish.

92.2.3 **Future of Speech Application Design**

Like most technologies, speech application design can be improved by incorporating aspects of complementary technologies. Current speech application design is limited. A limit is the inability of current speech applications to distinguish one person from another and the inability to determine a speaker’s mood in order to manage their affect. Integrating biometrics and affective technologies, speech application design can be improved.

In order to make speech applications more acceptable for users of all kinds, it is necessary to use them in conjunction with other technologies. As HCI designers, we want to use technologies that improve and enhance the usability of our applications. Adding security features and basing responses on user affect are two fantastic ways to improve the efficacy of speech applications. Voice biometrics is the modality that uses spoken utterances, as do speech applications, and affective technologies can use voice, facial expressions, body language, and many other human responses and physiological factors. One of the main things that biometrics and affective computing have in common is they take physiological aspects of humans and find patterns from these aspects that help recognize or understand people. The next couple of sections will speak to the usage of voice biometrics and affective computing in conjunction with speech interfaces.

92.2.3.1 **Biometrics**

Biometrics is the science of measuring the patterns of life. Biometrics is quantitatively taking measurements of physiological and behavioral aspects of humans and using them for tasks of identification or classification. Biometrics can be physiological or behavioral. A single type of biometric reading, physiological or behavioral, is referred to as a modality. Some of the physical modalities are fingerprint, iris, face, periocular, hand, finger geometry, odor, ear, and DNA (Jain, 2004). Some of the behavioral modalities (those included in direct and indirect HCI biometrics) are keystroke dynamics, mouse dynamics, haptic, programming style, audit logs, GUI interaction, and call stack. Yampolskiy and Govindaraju have come up with a definition for direct and indirect HCI biometrics and give examples of several modalities. Direct HCI biometrics are modalities that evaluate a person based on abilities, style, preference, knowledge, and strategy. Indirect HCI biometrics are those deduced from behaviors recorded when a person interacts with technology (Yampolskiy, 2007).

92.2.3.1.1 *Biometrics HCI Concerns*

Biometrics is a science that can make people uncomfortable because it learns them on a very intimate level. For example, fingerprint is a modality that makes people uncomfortable because law enforcement

uses it when registering people upon arrest. Hence, making people submit their fingerprint in order to access a location or service has negative connotations.

Considering HCI concerns with respect to biometrics allows us choose modalities whose connotations are not inherently negative and helps find uses of negative modalities in a manner that are less abhorrent to users (Wertheim, 2010). Gamboa and Fred also use HCI techniques to create behavioral biometric modalities. Given the previous work with respect to HCI and biometrics, how do we leverage the research to improve speech application design (Gamboa, 2003)? The most obvious way is incorporate voice biometrics into speech application design practices.

92.2.3.1.2 Voice Biometrics

The biometric modality that makes the most sense to use with speech applications is voice. Voice biometrics is a science that leverages the intricacies of the voice for the purposes of recognition and classification.

Voice biometrics, like most biometric modalities, comes in two recognition-based flavors: speaker verification and speaker identification. Voice has the four main requirements to be a biometric modality: distinctiveness, universality, permanence, and collectability. The systems employing this biometric modality operate similarly to all biometrics systems, which have four major components: sensor, feature extractor, matcher, and system database (Jain, 2004). In order to use voice biometrics with speech application design, these components must be included.

92.2.3.1.3 Speech Application Design Using Voice Biometrics

A speech application can prompt the user for their name and after making sure this name is in the system database prompt for other information, but the system may also be able to verify the speaker with the identity claim alone. Once the speaker is verified, they will be privy to using the system further. Markowitz writes about a case study involving a company *Girl Tech, Inc.* that makes products *Door Pass* and *Password Journal* (Markowitz, 2000). Both *Door Pass* and *Password Journal* use speaker verification to keep a door locked or a journal closed.

Obtaining useful information from a biometric signature that is or isn't adequate for authentication or identification is referred to as soft biometrics (Ross, 2007). Soft biometrics deals with the classification of people into groups based on similar attributes. Incorporating voice biometrics in speech applications takes speech applications to the next level.

92.2.3.1.4 A Look at the State of the Art

Voice biometrics has been steadily improving for over a decade (González-Rodríguez, 2008; Markowitz, 2008; Miller, 2012). Recently, a company has improved speaker verification using state-of-the-art recognition technology in conjunction with a smartphone (Miller, 2012). This new technology boasts that it accepts the incorrect user (false accept rate—FAR) once out of 10,000 times and rejects the correct user (false rejection rate—FRR) five times out of one hundred. Affective computing isn't a biometric modality, but using it in conjunction with voice biometrics can provide more secure and usable applications than voice biometrics alone.

92.2.3.2 Affective Computing

Affective computing attempts to recognize emotions and uses what it recognizes to improve a user's computing experience (Wu, 2010). Affective computing uses sensors to capture information. From the sensors, algorithms analyze the information in the context of the situation in which the data were captured (Healey, 1998). Because the data are analyzed in context, it can be labeled to match emotions and feelings a user has when his or her data are recorded. A system is created that uses the information learned from previous sensor readings and is able to understand what a user is feeling. Facial expression

is an important and often used indicator of mood. Galvanic skin response (GSR) is another popular indicator of mood. Facial expression information can be captured by camera, whereas specialized sensors must be attached or worn to capture GSR data.

92.2.3.2.1 Affect Improving Speech Applications

Affect can improve speech applications in a couple of ways. There are sensors that can be worn similar to wristwatches or gloves that record GSR data (Affectiva, 2012; Strauss, 2005). Using a wireless version of one of these sensors in conjunction with a speech application, the system would be able to cause the voice to respond to changes in a user's mood. Affective technology can improve speech applications and design by keeping track of user engagement or alertness. There are many more ways affective technology can improve and complement speech applications but that is for future research.

93.1 Introduction

In this chapter, we introduce software assurance, discussing the impact of software on our lives, the risks associated with software vulnerabilities, and some basic definitions of software assurance. We then introduce modern principles of software assurance, along with historical principles of software assurance. With this background in hand, we were able to identify a number of process models, frameworks, and best practices that were relevant to software assurance. Finally, we identify a research framework that could be used to support current research and to identify gap areas for future research.

93.2 What Is Software Assurance?

Formal practices to ensure correct software date back at least 40 years (Royce 1970). America's official interest in secure software dates back 9 years to Action Recommendation 2–14 in the *National Strategy to Secure Cyberspace* (DHS 2003). So if the aim of the prior 40-year practices was not to ensure that our code was secure, what *were* we trying to do? That work was to ensure the *quality* of the software product. To serve that aim, practices to validate product correctness have become an integral part of the industry. Likewise, because of the long history of software quality assurance, there is a seemingly endless list of assurance practices, which have always been considered part of the software life cycle. Activities such as

design practices (adopted in 1972), inspections (1976), change management (1979), incremental integration (1979), branch coverage testing (1979), and source code control (1980), which predate today's interest in security by decades, are often included in the steps for developing secure code (McConnell 2005).

What has happened over the past decade to change the emphasis from quality assurance to security assurance? The answer to that question lies in the appearance of the adversary. Prior to 2000, developers' only concern was to develop products that worked right under ordinary circumstances. Therefore, the aim of the software engineering process was to ensure properly functioning code. The fact that defects might be present did not matter as long as the product satisfied user requirements and functioned properly. However, when every bad actor on the planet began using the Internet as an avenue of attack, it became insufficient that the code only works right. Now software has to be free of all exploitable defects. Defects that might not have been worth fixing in the past if they did not affect operation may now represent a pathway for trouble. That changes the focus of the software assurance process from quality to security. This chapter will center on the shift in the definition of terms that results from this change in focus as well as the newest models and methods for finding and fixing exploitable defects in software.

93.2.1 Changing the Assurance Focus to Security

According to the US Committee on National Security Systems' (CNSS) *National Information Assurance (IA) Glossary*, software assurance is "the level of confidence that software is free from vulnerabilities, either intentionally designed into the software or accidentally inserted at any time during its life cycle, and that the software functions in the intended manner" (CNSS 2010, p. 56). In addition, a report from the USC Center for Systems and Software Engineering (CSSE) says that software assurance amounts to the addition of concrete functionality to secure the product (Colbert and Yu 2006). That includes the complete set of additional development activities from specification through design and on to code that are aimed at ensuring security functionality. Finally, a Department of Homeland Security (DHS) report suggests that the purpose of the assurance process is to build software-based systems that "limit the damage resulting from any failures caused by attack-triggered faults, ensuring that the effects of any attack are not propagated, and recover as quickly as possible from those failures as well as ensuring that the software will continue to operate correctly in the presence of most attacks by resisting the exploitation of weaknesses in the software by the attacker, or by tolerating the failures that result from such exploits" (Redwine et al. 2007). For the purpose of developing a curriculum model for software assurance in the *Master of Software Assurance Reference Curriculum* report, the CNSS definition was expanded as follows (Mead et al. 2010):

Application of technologies and processes to achieve a required level of confidence that software systems and services function in the intended manner, are free from accidental or intentional vulnerabilities, provide security capabilities appropriate to the threat environment, and recover from intrusions and failures.

The expanded definition emphasizes the importance of both technologies and processes in software assurance, observes that computing capabilities may be acquired through services as well as new development, recognizes that security capabilities must be appropriate to the expected threat environment, and identifies recovery from intrusions and failures as an important capability for organizational continuity and survival.

These definitions all suggest that software assurance involves the execution of a well-defined process to ensure that all vulnerabilities are identified and actively mitigated and that the everyday software development, sustainment, and acquisition processes always follow good security practices. However, in addition to finding and fixing faults in the product and process, another important software assurance role is to field software-based systems that limit the damage resulting from any failures caused by attack-triggered faults. The objective of this activity is to ensure that defects that represent vulnerabilities are identified, that the effects of any subsequent attack are not propagated, and that the system recovers as

quickly as possible from those attacks. The aim of this type of assurance is to ensure that the system continues to operate correctly in the presence of most attacks. This correct operation can be achieved by either establishing functions to resist the exploitation of weaknesses in the software or by building software functions that will tolerate the failures that result from such exploits. This shifts the purpose of the software assurance process from the simple identification and remediation of identifiable vulnerabilities to the establishment of real-time survivability and recovery in the product. Thus, for our purposes, the goal of software assurance is to ensure comprehensive organizational capability in the specification, design, and coding of the software, as well as in the development of specific security functionality to minimize damage from any unforeseen attacks and ensure a systematic recovery.

93.3 Why Does Software Assurance Matter?

The General Accounting Office (GAO) summarized the security concerns associated with software organizations in a March 2012 report. Software issues fall into five categories. Each category has slightly different implications for product integrity: “Installation of malicious logic on hardware or software, installation of counterfeit hardware or software, failure or disruption in the production or distribution of a critical product or service, reliance upon a malicious or unqualified service provider for the performance of a technical service and installation of unintentional vulnerabilities on software or hardware” (GAO 2012, p.1).

Embedding a malicious object in a product is always a hostile act that fulfills some specific purpose. Malicious objects are by definition not part of the intended functionality. Therefore, in order to find and eliminate any instance of malicious objects, which should be a high priority for any software customer, rigorous testing and inspection is required. Because it is hard enough to ensure the quality and security of the functions that should be present in a piece of software, it is asking a lot to expect that functions that should *not* be present are also identified and eliminated. Therefore, it is almost impossible to estimate how much malicious code currently resides in software products. Because the decision to embed a piece of malicious logic in a product is intentional, one of the most effective ways to ensure against the presence of such objects is to maintain strict oversight and control over the software development, sustainment, and acquisition work.

Some suppliers use counterfeit parts to save money or supply a feature that the maker is otherwise incapable of providing. Counterfeit parts can appear at any stage in the development and sustainment of any information and communication technology product. While counterfeits execute product functions as intended, they threaten product security and integrity because they are not the same as the actual part. As a result, counterfeits embody shortcuts in product quality or security that can fail in many ways. Because they function like the original part, it is often hard to spot a counterfeit in a large array of legitimate components. Consequently, it is critical that the customer for the part fully and completely understands their suppliers’ business and technical practices prior to engaging in any use of their products. A capability model is particularly helpful in enforcing that understanding since it establishes a common and auditable basis among both organizations.

The problems caused by breakdowns in the supply chain mirror the problems encountered in conventional manufacturing, in that the failure lies in the inability to do the work because a component is missing. From the standpoint of product security, a failure to deliver a critical part prevents the software product from being used, which is the equivalent of a denial of service in conventional security terms. So efforts to mitigate security risks or risks to product integrity tend to concentrate on identifying and managing single points of failure. Capability models help in that respect because they establish common management functions designed to monitor and control the overall process of construction or maintenance.

From a technical service standpoint, the focus is on learning whether the supplier’s operation is capable of delivering the product as specified. Since supplier capability is at the center of any acquisition or outsourcing decision, it is important to find out in advance if the contractors that comprise the supply

chain possess all of the capabilities required to do the work. Specifically, suppliers have to prove that they are capable of developing and integrating a secure product. Overall capability is usually demonstrated by the suppliers' past history with similar projects as well as their documented ability to adopt good software engineering practices. The presence of a commonly accepted model of best practice that is shared between customer and supplier and that is fully auditable helps to cement that assurance.

The issue of unintentional vulnerabilities is a result of the overall development and sustainment problem in that defects in software and hardware occur because of failure in the process. By definition, the installation of unintentional flaws is not a hostile act. However, because the problem is so pervasive, the sheer number of exploitable vulnerabilities placed in software products makes it a major concern. There is an extensive body of knowledge (BoK) in software product assurance; however, because the steps necessary to ensure product integrity have to be instituted, managed, and sustained in a logical way, best practices are often not followed or are performed halfheartedly. The result is that common defects in software products are exploited by a growing array of criminal and other bad actors. The installation and sustainment of a commonly accepted capability model addresses this concern directly. However, it is critical that the activities in that model be executed in a continuous and disciplined fashion.

93.4 Software Assurance Principles

93.4.1 Historical Principles for Information Protection

Much of the information protection in place today is based on principles established by Saltzer and Schroeder (1974) in their paper titled "The Protection of Information in Computer Systems," which appeared in *Communications of the ACM* in 1974. They defined security as "techniques that control who may use or modify the computer or the information contained in it" and described the three main categories of concern: confidentiality, integrity, and availability (Saltzer and Schroeder 1974). Their proposed design principles that focus on protection mechanisms to "guide the design and contribute to an implementation without security flaws" (Saltzer and Schroeder 1974) are still taught in today's classrooms. They established eight principles for security in software design and development (Saltzer and Schroeder 1974):

1. *Economy of mechanism: Keep the design as simple and small as possible.*
2. *Fail-safe defaults: Base access decisions on permission rather than exclusion.*
3. *Complete mediation: Every access to every object must be checked for authority.*
4. *Open design: The design should not be secret. The mechanisms should not depend on the ignorance of potential attackers, but rather on the possession of specific, and more easily protected, keys or passwords.*
5. *Separation of privilege: Where feasible, a protection mechanism that requires two keys to unlock it is more robust and flexible than one that allows access to the presenter of only a single key.*
6. *Least privilege: Every program and every user of the system should operate using the least set of privileges necessary to complete the job.*
7. *Least common mechanism: Minimize the amount of mechanism common to more than one user and depended on by all users.*
8. *Psychological acceptability: It is essential that the human interface be designed for ease of use, so that users routinely and automatically apply the protection mechanisms correctly.*

Time has shown the value and utility in these principles; however, it is appropriate to consider that these were developed prior to the Morris worm that generated a massive denial of service by infecting more than 6000 UNIX machines on November 2, 1988 (Wikipedia 2012a). To provide a technology context, consider that the IBM System 360 was in use from 1964 through 1978 and the IBM System 370 came on the market in 1972. The advanced operating system Multiple Virtual Storage (MVS) was released in March 1974 (Wikipedia 2012b).

These principles were assembled prior to the identification of the more than 46,500 software vulnerabilities and exposures that are currently exploitable in today's software products as described in the Common Vulnerabilities and Exposures (CVE) database at <http://cve.mitre.org/> (MITRE 2012). When these principles were developed, "buffer overflow," "malicious code," "cross-site scripting," and "zero-day vulnerabilities" were not part of the everyday vocabulary of operational software support personnel. Patches were carefully tested and scheduled to minimize operational disruption instead of pushed into operation to minimize attack vectors.

While these principles are still usable today to address security within an individual piece of technology, they are no longer sufficient to address the complexity and sophistication of the environment within which that component must operate. We must broaden our horizon to consider the large-scale, highly networked, software-dependent systems upon which our entire critical infrastructure depends, from phones, power, and water to industries such as banking, medicine, and retail.

93.4.2 Modern Principles for Software Assurance

There are vast lists of practices and procedures that describe what should be done to address software assurance.* There are also an equal number of complaints that effective assurance is not being addressed in today's software. We posit that some of the inaction stems from a general lack of understanding about why this additional work is needed. In our scrutiny of the wide range of materials published, the case for why to focus on software assurance has not yet been addressed. We proposed the following seven principles in response in our paper "Foundations for Software Assurance" (Woody 2012):

93.4.2.1 Risk

Risk drives assurance decisions: A perception of risk drives assurance decisions. Organizations without effective software assurance perceive risks based on successful attacks to software and systems and usually respond reactively. They may implement assurance choices such as policies, practices, tools, and restrictions based on their perception of the threat of a similar attack and the expected impact should that threat be realized. Organizations can incorrectly perceive risk when they do not understand their threats and impacts. Effective software assurance requires that risk knowledge be shared among all stakeholders and technology participants; however, too frequently, risk information is considered highly sensitive and is not shared, resulting in uninformed organizations making poor risk choices.

93.4.2.2 Interactions

Risk is aligned across all stakeholders and all interconnected technology elements: Highly connected systems like the Internet require alignment of risk across all stakeholders and all interconnected technology elements; otherwise, critical threats will be missed or ignored at different points in the interactions. It is no longer sufficient only to consider highly critical components when everything is highly interconnected. Interactions occur at many technology levels (e.g., network, security appliances, architecture, applications, and data storage) and are supported by a wide range of roles. Protections can be applied at each of these points and may conflict if not well orchestrated. Because of interactions, effective assurance requires that all levels and roles consistently recognize and respond to risk.

93.4.2.3 Trusted Dependencies

Dependencies are trusted: Because of the wide use of supply chains for software, assurance of an integrated product depends on other people's assurance decisions and the level of trust placed on these dependencies. The integrated software inherits all of the assurance limitations of each interacting component. In addition, unless specific restrictions and controls are in place, every operational component including infrastructure, security software, and other applications can be affected by the assurance of

* For a starting point see <https://buildsecurityin.us-cert.gov/swa/> (DHS 2012a).

every other component. There is a risk each time an organization must depend on others' assurance decisions. Organizations should decide how much trust they place in dependencies based on a realistic assessment of the threats, impacts, and opportunities represented by an interaction. Dependencies are not static, and trust relationships should be regularly reviewed to identify changes that warrant reconsideration. The following examples describe assurance losses resulting from dependencies:

- Defects in standardized pieces of infrastructure (such as operating systems, development platforms, firewalls, and routers) can serve as widely available threat entry points for applications.
- Using many standardized software tools to build technology establishes a dependency for the assurance of the resulting software product. Vulnerabilities can be introduced into software products by the tool builders.

93.4.2.4 Attacker

There are no perfect protections against attacks: A broad community of attackers with growing technology capabilities are able to compromise the confidentiality, integrity, and availability of an organization's technology assets. There are no perfect protections against attacks, and the attacker profile is constantly changing. The attacker will use technology, processes, standards, and practices to craft a compromise (known as a socio-technical response). Attacks are crafted to take advantage of the ways we normally use technology or designed to contrive exceptional situations where defenses are circumvented.

93.4.2.5 Coordination and Education

Assurance is effectively coordinated among all technology participants: Protection must be applied broadly across the people, processes, and technology in an organization because the attacker will take advantage of all possible entry points. Authority and responsibility for assurance must be clearly established at an appropriate level in the organization to ensure the organization effectively participates in software assurance. This assumes that all participants know about assurance and that is not usually a reality. There is much to be done to educate people on software assurance.

93.4.2.6 Well Planned and Dynamic

Assurance is well planned and dynamic: Assurance must represent a balance among governance, construction, and operation of software and systems and is highly sensitive to changes in each of these areas. An adaptive response is required for assurance because the applications, interconnections, operational usage, and threats are always changing. Assurance is not a once-and-done activity. It must continue beyond the initial operational implementation through operational sustainment. Assurance cannot be added later; it must be built to the level of acceptable assurance that organizations need. No one has resources to redesign systems every time the threats change, and assurance cannot be readily adjusted upward after the fact.

93.4.2.7 Measurable

A means to measure and audit overall assurance is built in: That which is not measured cannot be managed. Each stakeholder or technology user will address only the assurance for which they are held accountable. Assurance will not compete successfully with other competing needs unless results are monitored and measured. All elements of the socio-technical environment, including practices, processes, and procedures, must be tied together to evaluate operational assurance. Organizations with more successful assurance measures react and recover faster, learn from their reactive responses and that of others, and are more vigilant in anticipating and detecting attacks. Defects per lines of code, a common development measure, may be useful for code quality but are not sufficient evidence for overall assurance because they provide no perspective on how that code behaves in an operational context. Both focused and systemic measures are needed to ensure that the components are engineered with sound security and that the interaction among components establishes effective assurance.

93.5 Software Assurance Process Models and Practices

93.5.1 Putting Capability into Practice

The GAO report presents these three common sense principles based on process capability: “control the development and sustainment work using common best practice,” “adopt rigorous assurance practice at the component level,” and “rationally plan for failure” (GAO 2012). A very large percentage of the counterfeiting, supply-chain-critical point-of-failure breakdowns and capability concerns can be mitigated by simply ensuring that every one of the entities up and down the supply chain is under strict management control. In addition, unwanted functionality and development failures should be addressed by rigorous product assurance from the time of inception to the time of acceptance. Then, when the inevitable failure does occur, there is a well-defined strategy in place to ensure that the problem is resolved in a rational fashion.

Control processes that satisfy these three principles are specified in a range of capability models, which we will discuss in the next section. These are called “capability models” because they provide a complete classification structure of best practices and standards for every aspect of software product development and sustainment work. Because those standards are highly authoritative, their recommendations provide a coherent and logical high-level framework to ensure both the logic and relevance of all the elements of fundamental best practices.

93.5.2 Why Use a Process Model?

The role of software assurance is to ensure that faults do not occur in the first place. However, since managers don’t actually do the software development work, they have to use some sort of generic management process to ensure product integrity. The aim of that management process is to establish order, or system, to the way the organization conducts its software work. System, or orderliness, is important because at present, there is no explicit, standard set of best practices for software development work in most technology organizations. Instead, there is some sort of “customary” approach, which is probably not even written down. And whether that approach is agile development, extreme programming, or the waterfall, there is extensive evidence to indicate that software products in general continue to have defects.

A capability-based process directly addresses the problem with defects. Increasing an organization’s capability ensures that reliability and integrity are designed and built into the products in the first place rather than added on at the end. Process capability improvement standards provide a given organization with a template for setting up and running an effective management system. The assumption is that a software management system that is based on and follows a commonly accepted model of best practice, or conforms to a formal best practice standard, ensures successful management. Most leading-edge corporations have had such a management system in place for years. Now, with the current set of generic software best-practice standards, any organization can implement the successful practices that more advanced corporations employ.

93.5.3 Best Practices: Software Security Frameworks, Models, and Roadmaps

In addition to considering process models for software development and acquisition, a framework for building assured systems needs to build upon and reflect known, accepted, common practice for software security. There are a growing number of promising frameworks and models for building more secure software. For example, Microsoft has defined their security development life cycle (SDL) (Howard 2006) and made it publicly available (Microsoft 2010a). In version 2, the authors of the Building Security In Maturity Model (BSIMM) (McGraw, Chess, and Miguez) have collected and analyzed software security practices in 30 organizations (McGraw et al. 2010).

In this section, we summarize seven models, frameworks, and roadmaps, excerpting descriptive information from publicly available websites and reports. This section summarizes each effort to show the current state of the practice in building secure software and to aid in identifying promising research opportunities to fill gaps.

93.5.3.1 Building Security in Maturity Model

The BSIMM introduction states the following (McGraw et al. 2010):

The Building Security In Maturity Model (BSIMM) is designed to help an organization understand, measure, and plan a software security initiative. The BSIMM was created through a process of understanding and analyzing real-world data from nine leading software security initiatives and then validated and adjusted with data from twenty-one additional leading software security initiatives. Altogether, the BSIMM collectively represents the wisdom and knowledge of thirty firms with active and successful software security initiatives. Though particular methodologies differ, such as the Open Web Application Security Project (OWASP) Comprehensive, Lightweight Application Security Process (CLASP), the Microsoft SDL, or the Cigital Touchpoints, many initiatives share common ground. This common ground is captured and described in the BSIMM.

BSIMM is appropriate for an organization whose overall business goals for software security include

- Informed risk management decisions
- Clarity on what is “the right thing to do” for everyone involved in software security
- Cost reduction through standard, repeatable processes
- Increased code quality

BSIMM is not a complete “how to” guide for software security, nor is it a one-size-fits-all model. Instead, BSIMM is a collection of good practices and activities that are in use today.

93.5.3.2 CMMI Assurance Process Reference Model

The DHS Software Assurance (SwA) Processes and Practices Working Group developed a draft process reference model (PRM) for assurance in July 2008 (DHS 2008). This PRM recommends additions to CMMI for Development (CMMI-DEV) v1.2 to address software assurance. The “assurance thread” description includes Figure 93.1 (DHS 2012b).

The DHS SwA Processes and Practices Working Group’s additions and updates to CMMI-DEV v1.2 are focused at the specific practices level for the following (Table 93.1) CMMI-DEV process areas (CMMI Product Team 2006).

93.5.3.3 Open Web Application Security Project Software Assurance Maturity Model

The following discussion of OWASP SAMM is from *SAMM v1.0* (OWASP 2009):

The Software Assurance Maturity Model (SAMM) is an open framework to help organizations formulate and implement a strategy for software security that is tailored to the specific risks facing the organization. The resources provided by SAMM will aid in

- Evaluating an organization’s existing software security practices
- Building a balanced software security assurance program in well-defined iterations
- Demonstrating concrete improvements to a security assurance program
- Defining and measuring security-related activities throughout an organization

SAMM was defined to be flexible so that small, medium, and large organizations can use it with any style of development. Additionally, this model can be applied organization wide, for a single line of business, or even for an individual project. Beyond these traits, SAMM was built on the following principles (OWASP 2009):

- *An organization’s behavior changes slowly over time*—A successful software security program should be specified in small iterations that deliver tangible assurance gains while incrementally working toward long-term goals.
- *There is no single recipe that works for all organizations*—A software security framework must be flexible and allow organizations to tailor their choices based on their risk tolerance and the way in which they build and use software.

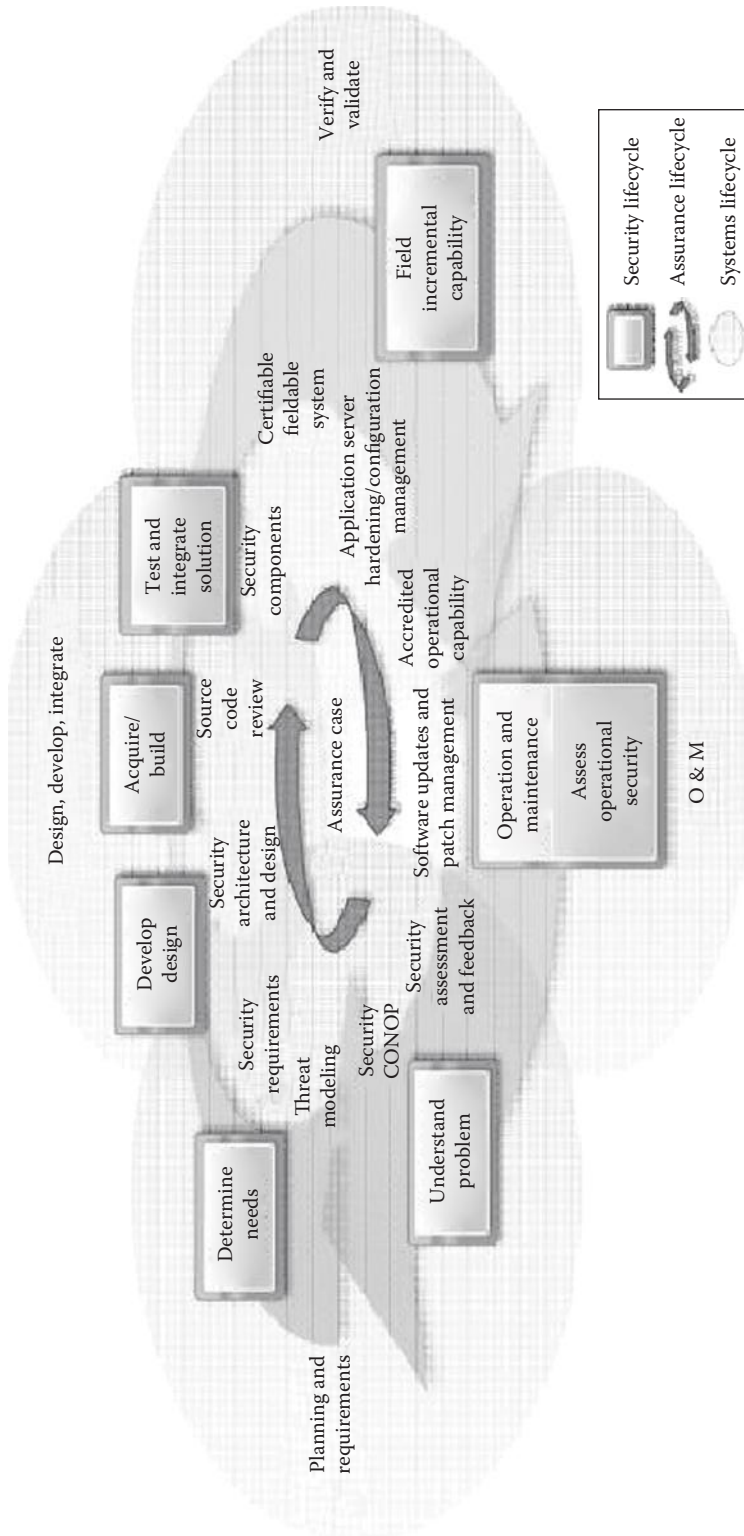

FIGURE 93.1 Summary of assurance for CMMI efforts.

TABLE 93.1 CMMI-DEV Process Areas

CMMI-DEV Process Area	Specific Practices
Process management	Organizational process focus Organizational process definition Organizational training

Measurement and analysis	

- *Guidance related to security activities must be prescriptive*—All the steps in building and assessing an assurance program should be simple, well-defined, and measurable. This model also provides roadmap templates for common types of organizations.

The foundation of the model is built upon the core business functions of software development with security practices tied to each. The building blocks of the model are the three maturity levels defined for each of the 12 security practices. These define a wide variety of activities in which an organization could engage to reduce security risks and increase software assurance. Additional details are included to measure successful activity performance, understand the associated assurance benefits, and estimate personnel and other costs.

93.5.3.4 DHS SwA Measurement Work by Bartol and Moss

According to the DHS SwA Measurement Working Group (DHS 2010),

Practical Measurement Framework for Software Assurance and Information Security (Bartol 2008) provides an approach for measuring the effectiveness of achieving software assurance goals and objectives at an organizational, program, or project level. It addresses how to assess the degree of assurance provided by software, using quantitative and qualitative methodologies and techniques. This framework incorporates existing measurement methodologies and is intended to help organizations and projects integrate SwA measurement into their existing programs.

The Practical Measurement Framework focuses principally, though not exclusively, on the information security viewpoint of SwA. Many of the contributing disciplines of SwA enjoy an established process improvement and measurement BoK, such as quality assurance, project management, process improvement, and safety. SwA measurement can leverage measurement methods and techniques that are already established in those disciplines and adapt them to SwA. The *Practical Measurement Framework* report focuses on information assurance/information security aspects of SwA to help mature that aspect of SwA measurement.

This framework provides an integrated measurement approach, which leverages the following five existing industry approaches that use similar processes to develop and implement measurement:

- Draft National Institute of Standards and Technology (NIST) Special Publication (SP) 800-55, Revision 1, *Performance Measurement Guide for Information Security*
- ISO/IEC 27004 information technology—security techniques—information security management measurement
- ISO/IEC 15939, *System and Software Engineering—Measurement Process*, also known as Practical Software and System Measurement (PSM)

- CMMI measurement and analysis process area
- CMMI GQ(I)M—Capability Maturity Model Integration Goal Question Indicator Measure

The framework describes candidate goals and information needs for each stakeholder group. The framework then presents example supplier measures as a table, with project activity, measures, information needs, and benefits as the columns. Example measures for acquirers are similarly presented in the framework and are intended to answer the following questions:

- Have SwA activities been adequately integrated into the organization's acquisition process?
- Have SwA considerations been integrated into the SDLC and resulting product by the supplier?

93.5.3.5 Microsoft Security Development Life Cycle

The Microsoft SDL* is an industry-leading software security process. A Microsoft-wide initiative and a mandatory policy since 2004, the SDL has played a critical role in embedding security and privacy in Microsoft software and culture. Combining a holistic and practical approach, the SDL introduces security and privacy early and throughout all phases of the development process.

The reliable delivery of more secure software requires a comprehensive process, so Microsoft defined *Secure by Design*, *Secure by Default*, *Secure in Deployment*, and *Communications* (SD3+C) to help determine where security efforts are needed. The guiding principles for SD3+C are identified in the following subsections, which are excerpted from *Microsoft SDL version 5.0* (Microsoft 2010b):

Secure by Design

- *Secure architecture, design, and structure.* Developers consider security issues part of the basic architectural design of software development. They review detailed designs for possible security issues, and they design and develop mitigations for all threats.
- *Threat modeling and mitigation.* Threat models are created, and threat mitigations are present in all design and functional specifications.
- *Elimination of vulnerabilities.* No known security vulnerabilities that would present a significant risk to the anticipated use of the software remain in the code after review. This review includes the use of analysis and testing tools to eliminate classes of vulnerabilities.
- *Improvements in security.* Less secure legacy protocols and code are deprecated, and, where possible, users are provided with secure alternatives that are consistent with industry standards.

Secure by Default

- *Least privilege.* All components run with the fewest possible permissions.
- *Defense in depth.* Components do not rely on a single threat mitigation solution that leaves users exposed if it fails.
- *Conservative default settings.* The development team is aware of the attack surface for the product and minimizes it in the default configuration.
- *Avoidance of risky default changes.* Applications do not make any default changes to the operating system or security settings that reduce security for the host computer. In some cases, such as for security products, it is acceptable for a software program to strengthen (increase) security settings for the host computer. The most common violations of this principle are games that either open firewall ports without informing the user or instruct users to open firewall ports without informing users of possible risks.
- *Less commonly used services off by default.* If fewer than 80 percent of a program's users use a feature, that feature should not be activated by default. Measuring 80 percent usage in a product is often difficult because programs are designed for many different personas. It can be useful to consider whether a feature addresses a core/primary use scenario for all personas. If it does, the feature is sometimes referred to as a P1 feature.

* More information is available in *The Security Development Lifecycle* (Howard 2006), at the Microsoft Security Development Lifecycle website (Microsoft 2010a), and in the document *Microsoft Security Development Lifecycle version 5.0* (Microsoft 2010b).

Secure in Deployment

- *Deployment guides.* Prescriptive deployment guides outline how to deploy each feature of a program securely, including providing users with information that enables them to assess the security risk of activating non-default options (and thereby increasing the attack surface).
- *Analysis and management tools.* Security analysis and management tools enable administrators to determine and configure the optimal security level for a software release.
- *Patch deployment tools.* Deployment tools aid in patch deployment.

Communications

- *Security response.* Development teams respond promptly to reports of security vulnerabilities and communicate information about security updates.
- *Community engagement.* Development teams proactively engage with users to answer questions about security vulnerabilities, security updates, or changes in the security landscape.

93.5.3.6 CERT® Resilience Management Model (RMM) Resilient Technical Solution Engineering Process Area

Like software security and software assurance, resilience is a property of software and systems. Developing and acquiring resilient* software and systems requires a resilience-focused dedicated process that encompasses the software and system life cycle. As described in the CERT-RMM (CERT 2012) resilient technical solution engineering (RTSE) process area (Caralli et al. 2010), the process defines what is required to develop resilient software and systems and is as follows (Caralli et al. 2010):

- *Establish a plan for addressing resiliency as part of the organization's (or supplier's) regular development life cycle and integrate the plan into the organization's corresponding development process. Plan development and execution includes identifying and mitigating risks to the success of the project.*
- *Identify practice-based guidelines that apply to all phases such as threat analysis and modeling as well as those that apply to a specific life cycle phase.*
- *Elicit, identify, develop, and validate assurance and resiliency requirements (using methods for representing attacker and defender perspectives, for example). Such processes, methods, and tools are performed alongside similar processes for functional requirements.*
- *Use architectures as the basis for design that reflect a resiliency and assurance focus, including security, sustainability, and operations controls.*
- *Develop assured and resilient software and systems through processes that include secure coding of software, software defect detection and removal, and the development of resiliency and assurance controls based on design specifications.*
- *Test assurance and resiliency controls for software and systems and refer issues back to the design and development cycle for resolution.*
- *Conduct reviews throughout the development life cycle to ensure that resiliency (as one aspect of assurance) is kept in the forefront and given adequate attention and consideration.*
- *Perform system-specific continuity planning and integrate related service continuity plans to ensure that software, systems, hardware, networks, telecommunications, and other technical assets that depend on one another are sustainable.*
- *Perform a post-implementation review of deployed systems to ensure that resiliency (as well as assurance) requirements are being satisfied as intended.*

* There is substantial overlap in the definitions of assured software (or software assurance) and resilient software (or software resilience). Resilient software is software that continues to operate as intended (including recovering to a known operational state) in the face of a disruptive event (satisfying business continuity requirements) so as to satisfy its confidentiality, availability, and integrity requirements (reflecting operational and security requirements) (Caralli et al. 2010).

- *In operations, monitor software and systems to determine if there is variability that could indicate the effects of threats or vulnerabilities and to ensure that controls are functioning properly.*
- *Implement configuration management and change control processes to ensure software and systems are kept up to date to address newly discovered vulnerabilities and weaknesses (particularly in vendor-acquired products and components) and to prevent the intentional or inadvertent introduction of malicious code or other exploitable vulnerabilities.*

In addition to RTSE, the following are goals and practices in other CERT-RMM process areas that organizations should consider when developing and acquiring software and systems that need to meet assurance and resiliency requirements (Caralli et al. 2010):

- *Resiliency requirements for software and system technology assets in operation, including those that may influence quality attribute requirements in the development process, are developed and managed in the Resiliency Requirements Development (RRD) and Resiliency Requirements Management (RRM) process areas respectively.*
- *Identifying and adding newly developed and acquired software and system assets to the organization's asset inventory is addressed in the Asset Definition and Management (ADM) process area.*
- *The management of resiliency for technology assets as a whole, particularly for deployed, operational assets, is addressed in the Technology Management (TM) process area. This includes, for example, asset fail-over, backup, recovery, and restoration.*
- *Acquiring software and systems from external entities and ensuring that such assets meet their resiliency requirements throughout the asset life cycle is addressed in the External Dependencies Management process area. That said, RTSE specific goals and practices should be used to aid in evaluating and selecting external entities that are developing software and systems (EXD:SG3.SP3), formalizing relationships with such external entities (EXD:SG3.SP4), and managing an external entity's performance when developing software and systems (EXD:SG4).*
- *Monitoring for events, incidents, and vulnerabilities that may affect software and systems in operation is addressed in the Monitoring (MON) process area.*
- *Service continuity plans are identified and created in the Service Continuity (SC) process area. These plans may be inclusive of software and systems that support the services for which planning is performed.*

The RTSE process area assumes that the organization has one or more existing, defined processes for software and system development into which resiliency controls and activities can be integrated. If this is not the case, the organization should not attempt to implement the goals and practices identified in RTSE or other CERT-RMM process areas as previously described.

93.6 Research Framework

93.6.1 Building Assured Systems Framework

In an earlier research project, a broad framework based on the Master of Software Assurance Reference Curriculum BoK (Mead et al. 2010) was developed and named the Building Assured Systems Framework (BASF).

We developed maturity levels to support our work in software security engineering (refer to *Software Security Engineering* [Allen et al. 2008]). We then applied them to the software assurance BoK in the Master of Software Assurance Reference Curriculum (Mead et al. 2010). The association of BoK elements and maturity levels was accomplished by evaluating the extent to which relevant sources, practices, curricula, and courseware exist for a particular BoK element and the extent to which the element was observed in practice in organizations.

The maturity levels can serve as a litmus test for whether research is needed in a specific area. Presumably we want to focus software assurance research on topic areas that are less mature. The mapping of the maturity levels to the Master of Software Assurance BoK knowledge areas is in the Appendix 93.A.

93.6.1.1 Promising Software Assurance Research Areas

Using the software assurance curriculum model BoK (Mead et al. 2010), we performed an analysis to identify some promising software assurance research areas. In some cases, there has been a fair amount of research work, but more is needed; Assured Software Development is an example. With this in mind, here is our initial list of candidate research areas:

- Baseline level of assurance; allowable tolerances, if quantitative
- Product and process measures by life-cycle phase
- Other performance indicators that test for the baseline, by life-cycle phase
- Making the Business Case for Assurance
- Assured Software Development
- Assured Software Analytics
- Assurance in Acquisition

93.7 Summary

In this chapter we introduced software assurance, discussing the impact of software on our lives, the risks associated with software vulnerabilities, and some basic definitions of software assurance. We then introduced modern principles of software assurance, along with historical principles of software assurance. With this background in hand, we were able to identify a number of process models, frameworks, and best practices that were relevant to software assurance. Finally, we identified a research framework that could be used to support current research and to identify gap areas for future research.

We then performed a gap analysis to identify areas where additional research would be needed. The benefit of this approach is that it establishes a desirable linkage between software assurance research and the associated educational curriculum research. We also wanted to address a more generic problem, one that we had seen in our own work and elsewhere, namely that various research projects in building assured systems appear unrelated to one another; we and other research entities consequently don't have a good way to prioritize and select new research.

From a research perspective, researchers could periodically consider rating the maturity levels of their methods. This would assist users in deciding which methods to use. It would also be helpful if researchers could collect and/or provide available cost/benefit data and encourage users to assist in such data collection. All too often users decide on a particular method but do not collect enough information to determine whether the benefit justified the cost. At the same time, the smaller projects that researchers conduct on their own do not usually result in enough cost/benefit data to be sufficiently compelling.

The gap analysis that we have done could be used to help select, and to some extent prioritize, new research. For example, if research is proposed for an area where there are a number of mature approaches, it would be helpful to understand why that research would be considered a good investment, compared to areas where there are no mature approaches. Since there is a lot of research aimed at building assured systems, we anticipate that this framework would need regular review and revision in order to stay current.

Maturity levels are defined as follows (Table 93.A.1):

- L1—The area provides guidance for how to think about a topic for which there is no proven or widely accepted approach. The intent of the area is to raise awareness and aid the reader in thinking about the problem and candidate solutions. The area may also describe promising research results that may have been demonstrated in a constrained setting.

- L2—The area describes practices that are in early pilot use and are demonstrating some successful results.
- L3—The area describes practices that have been successfully deployed (mature) but are in limited use in industry or government organizations. They may be more broadly deployed in a particular market sector.
- L4—The area describes practices that have been successfully deployed and are in widespread use. Readers can start using these practices today with confidence. Experience reports and case studies are typically available.

Glossary

Software Assurance Definitions

The following are software assurance definitions we reviewed while developing the BASF.

The following is the US Department of Defense's (DoD) definition of systems assurance taken from *A DoD-Oriented Introduction to the NDIA's System Assurance Guidebook* (Popick et al. 2010):

The justified measures of confidence that a system functions as intended and is free of exploitable vulnerabilities, either intentionally or unintentionally designed or inserted as part of the system at any time during the life cycle (NDIA 2008).

The following definition is taken from the NDIA conference paper *Engineering Improvement in Software Assurance: A Landscape Framework* (Brownsword et al. 2009):

Environment of use:

Actual environment of use (not just the expected environment of use)

Means evaluating robustness against unexpected use, threats, and changes in the environment

The following is from the SEI webinar *Engineering Improvement in Software Assurance: A Landscape Framework* (Brownsword and Woody 2010):

Software assurance: a justified level of confidence that software-reliant systems function as intended within their operational environment

The following is the CNSS definition (CNSS 2010) used in the DHS SwA website (DHS 2010b) and *Software Security Engineering* book (Allen et al. 2008):

Software assurance (SwA) is the level of confidence that software is free from vulnerabilities, either intentionally designed into the software or accidentally inserted at any time during its life cycle, and that the software functions in the intended manner (from CNSS 4009 IA Glossary—see Wikipedia for definitions and descriptions).

The following is the SAFECODE software assurance definition (SAFECODE 2008):

Confidence that software, hardware and services are free from intentional and unintentional vulnerabilities and that the software functions as intended.

The following excerpt is from the software security assurance state-of-the-art report (SOAR) (Goertzel et al. 2007).

2.1 Definition 1: Software Assurance

Until recently, the term *software assurance* was most commonly relating two software properties: *quality* (i.e., “software assurance” as the short form of “software quality assurance”), and *reliability* (along with reliability’s most stringent quality—safety). Only in the past 5 years or so has the term software assurance been adopted to express the idea of the assured security of software (comparable to the assured security of information that is expressed by the term “information assurance”).

The discipline of software assurance can be defined in many ways. The most common definitions complement each other but differ slightly in terms of emphasis and approach to the problem of assuring the security of software.

In all cases, all definitions of software assurance convey the thought that software assurance must provide a reasonable level of *justifiable confidence* that the software will function correctly and predictably in a manner consistent with its documented requirements. Additionally, the function of software cannot be compromised either through direct attack or through sabotage by maliciously implanted code to be considered assured. Some definitions of software assurance characterize that assurance in terms of the software’s trustworthiness or “high confidence.”

Several leading definitions of software assurance are discussed below.

Instead of choosing a single definition of software assurance for this report, we synthesized them into a definition that most closely reflects software security assurance as we wanted it to be understood in the context of this report—*Software security assurance: The basis for gaining justifiable confidence that software will consistently exhibit all properties required to ensure that the software, in operation, will continue to operate dependably despite the presence of sponsored (intentional) faults. In practical terms, such software must be able to resist most attacks, tolerate as many as possible of those attacks it cannot resist, and contain the damage and recover to a normal level of operation as soon as possible after any attacks it is unable to resist or tolerate.*

2.1.1 CNSS Definition

The ability to establish confidence in the *security* as well as the predictability of software is the focus of the Committee on National Security Systems (CNSS) definitions of software assurance in its National Information Assurance Glossary [8]. The glossary defines software assurance as—

The level of confidence that software is free from vulnerabilities, regardless of whether they are intentionally designed into the software or accidentally inserted later in its life cycle, and that the software functions in the intended manner.

This understanding of software assurance is consistent with the use of the term in connection with information, i.e., information assurance (IA). By adding the term software assurance to its IA glossary, CNSS has acknowledged that software is directly relevant to the ability to achieve information assurance.

The CNSS definition is purely descriptive: it describes what software must *be* to achieve the level of confidence at which its desired characteristics—lack of vulnerabilities and predictable execution—can be said to be assured. The definition does not attempt to prescribe the means by which that assurance can, should, or must be achieved.

2.1.2 DoD Definition

The Department of Defense’s (DoD) Software Assurance Initiative’s definition is identical in meaning to that of the CNSS, although more succinct—

The level of confidence that software functions as intended and is free of vulnerabilities, either intentionally or unintentionally designed or inserted as part of the software [9].

2.1.3 NASA Definition

The National Aeronautics and Space Administration (NASA) defines software assurance as—

The planned and systematic set of activities that ensure that software processes and products conform to requirements, standards, and procedures.

The “planned and systematic set of activities” envisioned by NASA include—

Requirements specification

Testing

Validation

Reporting

The application of these functions “during a software development life cycle is called software assurance” [10].

The NASA software assurance definition predates the CNSS definition but similarly reflects the primary concern of its community—in this case, safety. Unlike the CNSS definition, NASA’s definition is both descriptive and prescriptive in its emphasis on the importance of a “planned and systematic set of activities.” Furthermore, NASA’s definition states that assurance must be achieved not only for the software itself but also the processes by which it is developed, operated, and maintained. To be assured, both software *and* processes must “conform to requirements, standards, and procedures.”

2.1.3 DHS Definition

Like CNSS, the Department of Homeland Security (DHS) definition of software assurance emphasizes the properties that must be present in the software for it to be considered “assured,” i.e.—

Trustworthiness, which DHS defines, like CNSS, in terms of the absence of exploitable vulnerabilities whether maliciously or unintentionally inserted

Predictable execution, which “provides justifiable confidence that the software, when executed, will function as intended [11].

Like NASA, DHS’s definition explicitly states that “a planned and systematic set of multidisciplinary activities” must be applied to ensure the conformance of both software and processes to “requirements, standards, and procedures” [12].

2.1.4 NIST Definition

The National Institute of Standards and Technology (NIST) defines software assurance in the same terms as NASA, whereas the required properties to be achieved are those included in the DHS

definition: trustworthiness and predictable execution. NIST essentially fuses the NASA and DHS definitions into a single definition, thereby clarifying the cause-and-effect relationship between “the planned and systematic set of activities” and the expectation that such activities will achieve software that is trustworthy and predictable in its execution [13].

2.2 Definition 2: Secure Software

DHS’s *Security in the Software Life Cycle* defines secure software in terms that have attempted to incorporate concepts from all of the software assurance definitions discussed in Section 93.1 as well as reflect both narrow-focused and holistic views of what constitutes secure software. The document attempts to provide a “consensus” definition that has, in fact, been vetted across the software security assurance community (or at least that part that participates in meetings of the DHS Software Assurance Working Groups [WG] and DoD/DHS Software Assurance Forums). According to *Security in the Software Life Cycle*—*Secure software cannot be intentionally subverted or forced to fail. It is, in short, software that remains correct and predictable in spite of intentional efforts to compromise that dependability. Security in the Software Life Cycle elaborates on this definition—*

Secure software is designed, implemented, configured, and supported in ways that enable it to:

Continue operating correctly in the presence of most attacks by either resisting the exploitation of faults or other weaknesses in the software by the attacker, or tolerating the errors and failures that result from such exploits

Isolate, contain, and limit the damage resulting from any failures caused by attack-triggered faults that the software was unable to resist or tolerate, and recover as quickly as possible from those failures

The document then enumerates the different security properties that characterize secure software and clearly associates the means by which software has been developed with its security:

Secure software has been developed such that—

Exploitable faults and other weaknesses are avoided by well-intentioned developers.

The likelihood is greatly reduced or eliminated that malicious developers can intentionally implant exploitable faults and weaknesses or malicious logic into the software.

The software will be attack-resistant or attack-tolerant, and attack-resilient.

The interactions among components within the software-intensive system, and between the system and external entities, do not contain exploitable weaknesses.

Computing Handbook, Third Edition: Computer Science and Software Engineering mirrors the modern taxonomy of computer science and software engineering as described by the Association for Computing Machinery (ACM) and the IEEE Computer Society (IEEE-CS). Written by established leading experts and influential young researchers, the first volume of this popular handbook examines the elements involved in designing and implementing software, new areas in which computers are being used, and ways to solve computing problems. The book also explores our current understanding of software engineering and its effect on the practice of software development and the education of software professionals.

Like the second volume, this first volume describes what occurs in research laboratories, educational institutions, and public and private organizations to advance the effective development and use of computers and computing in today's world. Research-level survey articles provide deep insights into the computing discipline, enabling readers to understand the principles and practices that drive computing education, research, and development in the twenty-first century.

Features

- Aligns with the undergraduate curriculum models developed by the ACM and IEEE-CS
- Describes the fundamental principles of computer science, such as algorithms and architecture
- Covers contemporary topics in computer science and software engineering, including graphics, intelligent systems, mobile computing, and agile development
