Preface to the <i>Computing Handbook Set</i>	xiii
Preface to Volume I: Computer Science and Software Engineering.....	xv
Acknowledgments	xxvii
Editors.....	xxix
Contributors	xxx

PART I Overview of Computer Science

1 Structure and Organization of Computing.....	1-1
<i>Peter J. Denning</i>	
2 Computational Thinking.....	2-1
<i>Valerie Barr</i>	

PART II Algorithms and Complexity

3 Data Structures.....	3-1
<i>Mark Allen Weiss</i>	
4 Basic Techniques for Design and Analysis of Algorithms.....	4-1
<i>Edward M. Reingold</i>	
5 Graph and Network Algorithms.....	5-1
<i>Samir Khuller and Balaji Raghavachari</i>	
6 Computational Geometry	6-1
<i>Marc van Kreveld</i>	
7 Complexity Theory	7-1
<i>Eric W. Allender, Michael C. Loui, and Kenneth W. Regan</i>	
8 Formal Models and Computability.....	8-1
<i>Tao Jiang, Ming Li, and Bala Ravikumar</i>	

9	Cryptography	9-1
	<i>Jonathan Katz</i>	
10	Algebraic Algorithms.....	10-1
	<i>Ioannis Z. Emiris, Victor Y. Pan, and Elias P. Tsigaridas</i>	
11	Some Practical Randomized Algorithms and Data Structures	11-1
	<i>Michael Mitzenmacher and Eli Upfal</i>	
12	Approximation Algorithms and Metaheuristics.....	12-1
	<i>Teofilo F. Gonzalez</i>	
13	Combinatorial Optimization	13-1
	<i>Vijay Chandru and M.R. Rao</i>	
14	Graph Drawing.....	14-1
	<i>Ioannis G. Tollis and Konstantinos G. Kakoulis</i>	
15	Pattern Matching and Text Compression Algorithms.....	15-1
	<i>Maxime Crochemore and Thierry Lecroq</i>	
16	Distributed Algorithms.....	16-1
	<i>Dan Alistarh and Rachid Guerraoui</i>	

PART III Architecture and Organization

17	Digital Logic.....	17-1
	<i>Miriam Leeser and James Brock</i>	
18	Memory Systems.....	18-1
	<i>Yoongu Kim and Onur Mutlu</i>	
19	Storage Systems	19-1
	<i>Alexander Thomasian</i>	
20	High-Speed Computer Arithmetic	20-1
	<i>Earl E. Swartzlander, Jr.</i>	
21	Input/Output Devices and Interaction Techniques	21-1
	<i>Ken Hinckley, Robert J.K. Jacob, Colin Ware, Jacob O. Wobbrock, and Daniel Wigdor</i>	
22	Performance Enhancements	22-1
	<i>Joseph Dumas</i>	
23	Parallel Architectures	23-1
	<i>Michael J. Flynn and Kevin W. Rudd</i>	
24	Multicore Architectures and Their Software Landscape.....	24-1
	<i>Raphael Poss</i>	
25	DNA Computing	25-1
	<i>Hieu Bui, Harish Chandranm, Sudhanshu Garg, Nikhil Gopalkrishnan, Reem Mokhtar, John Reif, and Tianqi Song</i>	

PART IV Computational Science and Graphics

26	Computational Electromagnetics	26-1
	<i>J.S. Shang</i>	
27	Computational Fluid Dynamics	27-1
	<i>David A. Caughey</i>	
28	Computational Astrophysics.....	28-1
	<i>Jon Hakkila, Derek Buzasi, and Robert J. Thacker</i>	
29	Computational Chemistry	29-1
	<i>J. Phillip Bowen, Frederick J. Heldrich, Clyde R. Metz, Shawn C. Sendlinger, Neal E. Tonks, and Robert M. Panoff</i>	
30	Computational Biology: The Fundamentals of Sequence-Based Techniques.....	30-1
	<i>Steven M. Thompson</i>	
31	Terrain Modeling for the Geosciences	31-1
	<i>Herman Haverkort and Laura Toma</i>	
32	Geometric Primitives	32-1
	<i>Lee Staff, Gustavo Chávez, and Alyn Rockwood</i>	
33	Computer Animation	33-1
	<i>Nadia Magnenat Thalmann and Daniel Thalmann</i>	

PART V Intelligent Systems

34	Paraconsistent Logic-Based Reasoning for Intelligent Systems.....	34-1
	<i>Kazumi Nakamatsu</i>	
35	Qualitative Reasoning.....	35-1
	<i>Kenneth Forbus</i>	
36	Machine Learning	36-1
	<i>Stephen Marsland</i>	
37	Explanation-Based Learning.....	37-1
	<i>Gerald DeJong</i>	
38	Search	38-1
	<i>Danny Kopec, James L. Cox, and Stephen Lucci</i>	
39	Planning and Scheduling	39-1
	<i>Roman Barták</i>	
40	Natural Language Processing	40-1
	<i>Nitin Indurkha</i>	
41	Understanding Spoken Language	41-1
	<i>Gokhan Tur, Ye-Yi Wang, and Dilek Hakkani-Tür</i>	

42	Neural Networks	42-1
	<i>Michael I. Jordan and Christopher M. Bishop</i>	
43	Cognitive Modeling.....	43-1
	<i>Eric Chown</i>	
44	Graphical Models for Probabilistic and Causal Reasoning	44-1
	<i>Judea Pearl</i>	

PART VI Networking and Communication

45	Network Organization and Topologies	45-1
	<i>William Stallings</i>	
46	Routing Protocols.....	46-1
	<i>Radia Perlman</i>	
47	Access Control.....	47-1
	<i>Sabrina De Capitani di Vimercati, Pierangela Samarati, and Ravi Sandhu</i>	
48	Data Compression	48-1
	<i>Ö. Ufuk Nalbantoğlu and K. Sayood</i>	
49	Localization in Underwater Acoustic Sensor Networks	49-1
	<i>Baozhi Chen and Dario Pompili</i>	
50	Semantic Web.....	50-1
	<i>Pascal Hitzler and Krzysztof Janowicz</i>	
51	Web Search Engines: Practice and Experience	51-1
	<i>Tao Yang and Apostolos Gerasoulis</i>	

PART VII Operating Systems

52	Process Synchronization and Interprocess Communication.....	52-1
	<i>Craig E. Wills</i>	
53	Thread Management for Shared-Memory Multiprocessors.....	53-1
	<i>Thomas E. Anderson, Brian N. Bershad, Edward D. Lazowska, and Henry M. Levy</i>	
54	Virtual Memory	54-1
	<i>Peter J. Denning</i>	
55	Secondary Storage and Filesystems	55-1
	<i>Marshall Kirk McKusick</i>	
56	Performance Evaluation of Computer Systems	56-1
	<i>Alexander Thomasian</i>	
57	Taxonomy of Contention Management in Interconnected Distributed Systems	57-1
	<i>Mohsen Amini Salehi, Jemal Abawajy, and Rajkumar Buyya</i>	

58	Real-Time Computing.....	58-1
	<i>Sanjoy Baruah</i>	
59	Scheduling for Large-Scale Systems.....	59-1
	<i>Anne Benoit, Loris Marchal, Yves Robert, Bora Uçar, and Frédéric Vivien</i>	
60	Distributed File Systems.....	60-1
	<i>Thomas W. Doepfner</i>	
61	Mobile Operating Systems.....	61-1
	<i>Ralph Morelli and Trishan de Lanerolle</i>	
62	Service-Oriented Operating Systems.....	62-1
	<i>Stefan Wesner, Lutz Schubert, and Daniel Rubio Bonilla</i>	

PART VIII Programming Languages

63	Imperative Language Paradigm.....	63-1
	<i>Michael J. Jipping and Kim Bruce</i>	
64	Object-Oriented Language Paradigm.....	64-1
	<i>Raimund K. Ege</i>	
65	Logic Programming and Constraint Logic Programming.....	65-1
	<i>Jacques Cohen</i>	
66	Multiparadigm Languages.....	66-1
	<i>Michael Hanus</i>	
67	Scripting Languages.....	67-1
	<i>Robert E. Noonan</i>	
68	Compilers and Interpreters.....	68-1
	<i>Kenneth C. Loudon and Ronald Mak</i>	
69	Programming Language Semantics.....	69-1
	<i>David A. Schmidt</i>	
70	Type Systems.....	70-1
	<i>Stephanie Weirich</i>	
71	Formal Methods.....	71-1
	<i>Jonathan P. Bowen and Michael G. Hinchey</i>	

PART IX Discipline of Software Engineering

72	Discipline of Software Engineering: An Overview.....	72-1
	<i>Jorge L. Díaz-Herrera and Peter A. Freeman</i>	
73	Professionalism and Certification.....	73-1
	<i>Stephen B. Seidman</i>	
74	Software Engineering Code of Ethics and Professional Practice.....	74-1
	<i>Don Gotterbarn</i>	

- 75 Software Business and Economics..... 75-1
Christof Ebert
- 76 Open Source and Governance: COTS..... 76-1
Brian M. Gaff, Gregory J. Ploussios, and Brian R. Landry

PART X Software Quality and Measurement

- 77 Evidence-Informed Software Engineering and the Systematic Literature Review.....77-1
David Budgen and Pearl Brereton
- 78 Empirical Software Engineering..... 78-1
David Budgen and Barbara Kitchenham
- 79 Software Quality and Model-Based Process Improvement 79-1
Bariş Özkan, Özlem Albayrak, and Onur Demirörs
- 80 Software Metrics and Measurements 80-1
David Zubrow

PART XI Software Development Management: Processes and Paradigms

- 81 Software Development: Management and Business Concepts81-1
Michael A. Cusumano
- 82 Project Personnel and Organization..... 82-1
Paul McMahon and Tom McBride
- 83 Project and Process Control 83-1
James McDonald
- 84 Agile..... 84-1
John Favaro
- 85 Service-Oriented Development..... 85-1
Andy Wang and Guangzhi Zheng
- 86 Software Product Lines..... 86-1
Jorge L. Díaz-Herrera and Melvin Pérez-Cedano

PART XII Software Modeling, Analysis, and Design

- 87 Requirements Elicitation.....87-1
Daniel M. Berry
- 88 Specification 88-1
Andrew McGettrick
- 89 Software Model Checking..... 89-1
Alastair Donaldson

90 Software Design Strategies 90-1
Len Bass

91 Software Architecture 91-1
Bedir Tekinerdogan

92 Human–Computer Interfaces for Speech Applications 92-1
Shelby S. Darnell, Naja Mack, France Jackson, Hanan Alnizami, Melva James, Josh Ekandem, Ignacio Alvarez, Marvin Andujar, Dekita Moon, and Juan E. Gilbert

93 Software Assurance 93-1
Nancy R. Mead, Dan Shoemaker, and Carol Woody

Preface to the *Computing Handbook Set*

The purpose of the *Computing Handbook Set* is to provide a single, comprehensive reference for specialists in computer science, information systems, information technology, software engineering, and other fields who wish to broaden or deepen their understanding in a particular subfield of the computing discipline. Our goal is to provide up-to-date information on a wide range of topics in a form that is accessible to students, faculty, and professionals.

The discipline of computing has developed rapidly since CRC Press published the second edition of the *Computer Science Handbook* in 2004 (Tucker, 2004). Indeed, it has developed so much that this third edition requires repartitioning and expanding the topic coverage into a two-volume set.

The need for two volumes recognizes not only the dramatic growth of computing as a discipline but also the relatively new delineation of computing as a family of five separate disciplines, as described by their professional societies—The Association for Computing Machinery (ACM), The IEEE Computer Society (IEEE-CS), and The Association for Information Systems (AIS) (Shackelford et al., 2005).

These separate disciplines are known today as computer engineering, computer science, information systems, information technology, and software engineering. These names more or less fully encompass the variety of undergraduate and graduate degree programs that have evolved around the world, with the exception of countries where the term *informatics* is used for a subset of these disciplines. The document “Computing curricula 2005: The overview report” describes computing this way (Shackelford et al., 2005, p. 9):

In a general way, we can define computing to mean any goal-oriented activity requiring, benefiting from, or creating computers. Thus, computing includes designing and building hardware and software systems for a wide range of purposes; processing, structuring, and managing various kinds of information; doing scientific studies using computers; making computer systems behave intelligently; creating and using communications and entertainment media; finding and gathering information relevant to any particular purpose, and so on.

To add much flesh to the bones of this very broad definition, this handbook set describes in some depth what goes on in research laboratories, educational institutions, and public and private organizations to advance the effective development and utilization of computers and computing in today’s world. The two volumes in this set cover four of the five disciplines in the following way:*

1. Volume I: Computer Science and Software Engineering
2. Volume II: Information Systems and Information Technology

* The fifth discipline, computer engineering, is the subject of a separate handbook published by CRC Press in 2008.

This set is not designed to be an easy read, as would be gained by browsing a collection of encyclopedia entries on computing and its various subtopics. On the contrary, it provides deep insights into the subject matter through research-level survey articles. Readers who will benefit most from these articles may be undergraduate or graduate students in computing or a related discipline, researchers in one area of computing aiming to expand their knowledge of another area, or other professionals interested in understanding the principles and practices that drive computing education, research, and development in the twenty-first century.

This set is designed as a professional reference that serves the interests of readers who wish to explore the subject matter by moving directly to a particular part and chapter of the appropriate volume. The chapters are organized with minimal interdependence, so that they can be read in any order. To facilitate rapid inquiry, each volume also contains a table of contents and a subject index, thus providing access to specific topics at various levels of detail.

The Preface to Volume I provides a more detailed overview of the organization and content of this volume. A similar overview of the coverage of information systems and information technology appears in the Preface to Volume II.

Preface to Volume I: Computer Science and Software Engineering

This volume is organized to mirror the modern taxonomy of computer science and software engineering as described by the ACM and IEEE-CS (Joint Task Force, 2012):

- Algorithms and Complexity
- Architecture and Organization
- Computational Science
- Discrete Structures
- Graphics and Visual Computing
- *Human–Computer Interaction
- *Security and Information Assurance
- *Information Management
- Intelligent Systems
- Networking and Communication
- Operating Systems
- Platform-Based Development
- Parallel and Distributed Computing
- Programming Languages
- Software Development Fundamentals
- Software Engineering
- Systems Fundamentals
- Social and Professional Issues

To avoid redundancy, the three starred (*) topics in this list (Human–Computer Interaction, Security and Information Assurance, and Information Management) are covered in Volume II, while the remaining topics are covered in this volume.

The first eight parts of this volume cover the discipline of computer science (edited by Teofilo Gonzalez), while the last four parts cover software engineering (edited by Jorge Díaz-Herrera). Allen Tucker is the editor in chief of the two volumes.

Computer Science

Implicit in the aforementioned taxonomy (and, indeed, in all current thinking about the nature of computer science) is the idea of a dynamic discipline with an increasingly broad reach. For example, the *computational science* area noted earlier emphasizes the necessity of interaction among computer scientists and natural scientists in the many research and educational areas where their work now overlaps.

A more elaborate description of this idea is expressed in the following definition of computer science, taken from the 2005 Joint Task Force Report (Shackelford, 2005, p. 13):

Computer science spans a wide range, from its theoretical and algorithmic foundations to cutting-edge developments in robotics, computer vision, intelligent systems, bioinformatics, and other exciting areas. We can think of the work of computer scientists as falling into three categories.

1. They design and implement software. Computer scientists take on challenging programming jobs. They also supervise other programmers, keeping them aware of new approaches.
2. They devise new ways to use computers. Progress in the CS areas of networking, database, and human-computer-interface enabled the development of the World Wide Web. Now CS researchers are working with scientists from other fields to make robots become practical and intelligent aides, to use databases to create new knowledge, and to use computers to help decipher the secrets of our DNA.
3. They develop effective ways to solve computing problems. For example, computer scientists develop the best possible ways to store information in databases, send data over networks, and display complex images. Their theoretical background allows them to determine the best performance possible, and their study of algorithms helps them to develop new approaches that provide better performance.

The computer science chapters are organized into eight parts: (I) Overview of Computer Science; (II) Algorithms and Complexity; (III) Architecture and Organization; (IV) Computational Science and Graphics; (V) Intelligent Systems; (VI) Networking and Communication; (VII) Operating Systems; and (VIII) Programming Languages. A brief summary of what you can expect to find in each part is provided in the following.

Overview of Computer Science

Part I consists of two very important chapters. In Chapter 1, Peter Denning discusses the 50-year evolution of computer science as a discipline distinct from the fields from which it emerged: mathematics, science, and engineering. In Chapter 2, Valerie Barr introduces the idea of “computational thinking,” a relatively new term that is helping to shape modern thinking about the expanding presence of computer science, especially in the K-12 and undergraduate college curricula.

Algorithms and Complexity

This part discusses the algorithmic and computational complexity issues that underlie all of computer science. Chapter 3 covers important ways of organizing data inside computers to facilitate their retrieval. It discusses the time and space trade-offs for implementing the most important algorithms used in almost every application. The different design paradigms behind these algorithms are discussed in Chapter 4. The chapter covers greedy methods, divide-and-conquer, and dynamic programming, as well as other techniques that have been applied successfully in the design of efficient algorithms. Graphs and networks have been used to model a wide range of computer science problems as well as problems in different disciplines. Chapter 5 discusses graph and network techniques that have been devised to efficiently solve these problems. In some applications, computational problems can be simplified by formulating them as problems in two-dimensional space. Computational geometry problems include those that have intrinsic geometric properties. Chapter 6 discusses the techniques that have been applied successfully in this domain.

Chapter 7 discusses computational complexity classes. This is a grouping of problems according to the time and space required to solve them. The major classes are called P and NP, and they help characterize most of the computational challenges that arise in practice. A fundamental problem in computer science is to prove or disprove whether $P = NP$. In fact, it is so important that a so-called “Millennium Prize”

consisting of \$1,000,000 has been offered by the Clay Institute to anyone who solves this problem. At a more abstract level, Chapter 8 reviews formal methods and computability. This chapter explores the limits of what is computable within the most basic computing models that are equivalent to current computer architectures. One of the most complex areas of research is cryptography. Chapter 9 provides a comprehensive overview of this very important area. Since millions of private transactions take place on the Internet every second, we need ways to keep them secure and guarantee their integrity. Solutions in this area require sophisticated mathematical analysis techniques. Chapter 10 addresses the area of algebraic algorithms. The basic applications in this area are in science and engineering.

As the input size of most computationally complex problems continues to grow (sometimes referred to as the phenomenon of *big data*), the study of randomized algorithms has grown considerably in recent years. Chapter 11 discusses techniques to design such algorithms by presenting algorithms to solve some specific problems. Another way of dealing with computational complexity is to aim for approximations rather than optimal solutions. Chapter 12 discusses approximation algorithms and metaheuristics. The different methodologies used in these two areas are surveyed and applied to problems from different disciplines. Algorithms that take advantage of the combinatorial structure of the feasible solution space are discussed in Chapter 13. Another important algorithmic challenge is how to visualize data and their structure. Chapter 14 covers the area of graph drawing, which tries to design algorithms that display information in a clear way according to given objective functions. In this era of big data, we also need to discover ways of storing, retrieving, and transmitting it efficiently. Chapter 15 covers strategies for data compression and finding patterns in data quickly. Chapter 16 studies computing in a landscape where the computations are distributed among many computers. In this scenario, we need to address the issue of fault-tolerant computing; as the number of independent devices grows, the likely failure of at least one of the components increases substantially.

Architecture and Organization

Part III takes us closer to computing machines themselves by examining their architecture and organization. Starting at the most basic organizational level, Chapter 17 covers digital logic, how it is implemented, and how logical components are designed to carry out basic computations. Chapter 18 covers the organization of memory and its implementation, including the different levels of memory, access speeds, and implementation costs. Chapter 19 extends this discussion to the treatment of secondary storage. A main issue here is how to store files in disks, solid state devices, and flash memories to ensure reliability. Chapter 20 covers computer arithmetic, including the efficient implementation of the basic arithmetic and logical operations that are fundamental to all computing activities. Modern input and output devices are discussed in Chapter 21. As the way we interact with computers has changed over the years, input and output design remains at the forefront of research and development.

Chapter 22 discusses performance enhancements for instruction processing, such as the use of overlap and low-level concurrency. Focusing on the theme of design for efficiency, Chapter 23 surveys the different ways of organizing parallel computers. It begins with the standard types introduced several decades ago and concludes with the highly successful GP-GPUs as well as cloud computing. To circumvent the memory access and sequential performance walls, modern architectures include multiple processors on a single chip. Chapter 24 discusses the hardware and software challenges for the design and use of multicore architectures. Chapter 25 explains how DNA can be used to compute some logical functions and perform biological tests. Currently, performing these tests takes some time because it requires several computational facilities and involves human intervention.

Computational Science and Graphics

Some aspects of computational science have been part of computing since its beginning. Computational electromagnetics (Chapter 26) basically studies the computational solution of Maxwell equations. Analytical solutions to Maxwell equations are usually unavailable, and the few closed-form results that exist have very

restrictive solutions. The use of computer-based methods for the prediction of fluid flows has seen tremendous growth in the past half century. Fluid dynamics (Chapter 27) has been one of the earliest, and most active, fields for the application of numerical techniques. Computational astrophysics (Chapter 28) covers astrophysics, a computationally intensive discipline. Physics and astronomy make heavy use of online access and data retrieval. Databases, data analysis, and theoretical modeling go hand in hand in this area. The gravitational n -body problem and its modeling form the basis for cosmology. Chapter 29 discusses the rich set of computational applications in chemistry. Computational biology/bioinformatics is an area that has grown tremendously over the last decade. Chapter 30 discusses the interplay between the genetic analysis provided by computational algorithms and the underlying biological processes. Chapter 31 on terrain modeling examines the computational problems and new insights arising from the analysis of GIS data.

Computer graphics provides the underlying tools for scientific visualization and animation of a wide variety of real and imaginary phenomena. Chapter 32 discusses the basic geometric primitives manipulated by typical graphics systems. These primitives allow for the efficient representation and manipulation of visual objects in a computer. Chapter 33 covers computer animation, which has become widely used in the production of movies and videos.

Intelligent Systems

Mathematical logic and declarative programming provide theoretical foundations for artificial intelligence applications, which are called intelligent systems. Chapter 34 explores the use of logic to allow a system to work in spite of contradictions, dilemmas, and conflicts. Chapter 35 discusses qualitative reasoning, which supports reasoning with very little information. This is the first approach that one uses to understand a problem before developing a more formal or quantitative strategy. Machine learning, discussed in Chapter 36, is concerned with identifying and exploiting patterns in data to simulate human learning. Applications of machine learning to real-world problems are widely used on the Internet, for example, in marketing. Chapter 37 introduces explanation-based learning, which adds inferential domain theory to expand the reach of statistical machine learning. This theory adds expressiveness to statistical methods such as Bayesian or Markov models.

Chapter 38 describes searching, which is a basic operation in most computing areas and is particularly important in intelligent systems where the search domain is often complex. This chapter explores both blind exhaustive search methods using informed heuristics and optimal heuristics. Chapter 39 covers planning (the process of creating an organized set of actions) and scheduling (the process of assigning a set of actions to resources over time). These are basic operations arising in all sorts of environments and have been studied over the years in several disciplines. Chapter 40 explores natural language processing, or developing systems to understand human languages. In 2011, IBM's Watson program convincingly won the popular Jeopardy game over the most highly skilled human competitors. This was a major accomplishment for natural language processing. Spoken language understanding, covered in Chapter 41, is an emerging field between the areas of speech processing and natural language processing. This area leverages technologies from machine learning to create systems that would facilitate communication with users. Chapter 42 covers neural networks, which have been used to solve a wide range of problems in modeling intelligent behavior. Chapter 43 deals with cognitive modeling and surveys the methods and models used to understand human cognition. The semantic basis and properties of graphic models (Bayesian Networks) are explored in Chapter 44. Applications to reasoning and planning are discussed in this chapter.

Networking and Communication

In the last 20 years, the use of computer networks for communication has become an integral part of our daily life. An incredible volume of information is transferred constantly worldwide through computer networks, and these must operate efficiently and reliably so that modern business and commerce can function

effectively. Chapter 45 examines the communications software needed to interconnect computers, servers, and all sort of devices across networks. The unique aspects of wireless networks are discussed in Chapter 61 in Part VII. Chapter 46 discusses the routing algorithms that manage information flow across networks, including the trade-offs that exist among different alternatives. Chapter 47 discusses access control, which is fundamental for protecting information against improper disclosure or modification.

Compression of images and videos needed for the efficient storage and transmission of these types of data is covered in Chapter 48. Chapter 49 introduces underwater sensor networks, whose challenges and techniques are very different from those in other types of networks. Chapter 50 surveys ideas for transforming the World Wide Web to facilitate interoperability and integration of multiauthored, multithematic, and multiperspective information services seamlessly. Chapter 51 deals with search engines, which have become indispensable in almost all aspects of our daily life. It discusses the fundamental issues involved in designing and constructing search engines that interact with enormous amounts of information and digest it for users.

Operating Systems

An operating system is the fundamental software that controls all aspects of a computer, its applications, and its user interface. Chapter 52 discusses processes, the basic software activities that an operating system manages, and the mechanisms needed for communication and synchronization. Chapter 53 covers thread management, where threads are basic sequences of code that comprise a program running in a system. Breaking programs and systems into threads is particularly useful in multicore machines, the modern organization of computers. Virtual memory, discussed in Chapter 54, explains the way in which computer memory is organized for efficient access in computers. This chapter also discusses how these techniques apply to other levels of storage and systems. The organization of file systems and secondary storage is discussed in Chapter 55. The main concern is the use of secondary storage space for its use as long storage media.

Chapter 56 covers performance modeling of computer systems. Different computer architectures have different performance limits. The chapter discusses different ways to analyze computer system performance. Chapter 57 deals with a similar topic but for interconnected distributed computer systems such as clusters, grids, and clouds. An important issue here is maintaining quality of service during contention management. The architecture and special applications of real-time systems are discussed in Chapter 58. In these systems, response must occur within specific deadlines; it is a challenge for the operating system to schedule processes so that these deadlines are met. The design of distributed operating systems faces two main challenges: scheduling, covered in Chapter 59, and file systems, covered in Chapter 60. Mobile devices pose new challenges for operating system design, and these are addressed in Chapter 61. The proliferation of smart phones and tablets has brought this area to the forefront of research and development. Chapter 62 provides an introduction to service-oriented operating systems and concludes this part.

Programming Languages

Programming language research has a rich history, and it has remained vibrant with the development of modern architectures, networks, and applications. Chapter 63 covers imperative programming languages, the oldest and probably the most prolific style of programming. These types of languages are in widespread use and are familiar to software developers in all areas of computing. The object-oriented programming paradigm discussed in Chapter 64 has become popular as it facilitates modeling real-world software systems using object decomposition. Another form of programming, logic programming discussed in Chapter 65, has major applications in artificial intelligence and natural language processing research. Recent developments have been especially active in the areas of multiparadigm programming languages and scripting languages described in Chapter 66 and Chapter 67, respectively.

Chapter 68 deals with compilers and interpreters, which provide the interface between programs written in higher-level programming languages and an equivalent encoding that a computer can understand and carry out. Many aspects of this process have been automated, and the techniques and limitations of these processes are also discussed. Every programming language has syntax and semantics. Syntax refers to the valid strings of characters that define valid programs in the language, and semantics refers to the meaning of such strings. Chapter 69 covers formal semantics for programming languages. Chapter 70 describes type systems, which are used in modern programming languages to guarantee that programs are free of type-related errors. This chapter discusses the formal underpinnings of type systems as well as their implementations. Chapter 71 covers formal methods, a set of notations and tools that provide a mathematical basis for proving the correctness of a program with regard to its formal specification.

Software Engineering

As an academic field of study, software engineering was introduced in the early 1970s as a specialization of computer science and engineering, first as master-level programs. In the 1990s, the field proliferated in North America, Europe, and Australia, first in the form of BS programs and, more recently, programs at the PhD level; that is, software engineering programs separate from computer science programs (Lethbridge et al., 2006). *What is the difference and why do we care?*

Software is of critical importance in today's world and of increasingly serious public significance in our daily lives for our safety and security. Although the voicing of concerns about the critical consequences of not considering software development as a more rigorous profession dates back to the late 1960s (Naur, 1969), today software engineering *is still not a fully formed, mature professional discipline*. This seems more of an elusive goal than a concrete reality or even a future possibility. Some wonder if trying to retrofit software engineering with the traditional *engineering* paradigm has hindered its acceptance as a professional discipline. Particularly lacking is a widespread recognition of software developers as professionals in the full sense of the word.*

Over the past decades, we have identified scientific and engineering body of knowledge needed to solve technical software problems that meet user requirements (functional and otherwise) and deliver software within budget, on time, as well as within its economic, legal, and social considerations. The study of engineering requires a strong background in mathematics and the physical sciences. Although this is not different for software engineers, the kind of mathematics and the specific science may be different from more traditional engineering disciplines. However, a legitimate research question remains on whether there could be a scientific basis for understanding the complexity of software such that it can be *engineered* to have predictable quality and behavior.

Ian Sommerville (1999) introduced the idea that software engineering is perhaps something else: “In essence, the type of systems which we are interested in are *socio-technical software-intensive systems*.... Systems, therefore, always include computer hardware, software which may be specially designed or bought-in as off-the-shelf packages, policies and procedures, and people who may be end-users and producers/consumers of information used by the system.” Furthermore, Sommerville and his colleagues claim that “there is no technical solution to software complexity” (Sommerville, 2012).

The fact that *computing* has become a distinct branch of knowledge, that is, a discipline in its own right different from science and engineering—an idea first formally introduced by Denning (1998) and further developed by Denning and Freeman (Denning, 2009)—fits this notion as has been demonstrated by the creation of a unifying and enclosing academic entity that embraces the science, engineering, and technology of computing: the computing college, “standing alone, headed by its own dean, with the

* It is a fact of life that many of the software industry professionals are graduates from computer science and related fields. This is of no surprise since in most advertisements for such positions, the educational requirements often listed are degrees in computer science. However, once hired, employers give them the title of software engineer.

same stature as traditional colleges” [op. cit.]. In this way, computer science is a different kind of science and software engineering a different kind of engineering.

The chapters in the last four parts consolidate our current understanding of the discipline of software engineering and its effect on the practice of software development and the education of software professionals. There are four main parts. (1) Discipline of Software Engineering; (2) Software Quality and Measurement; (3) Software Development Management: Processes and Paradigms; and (4) Software Modeling, Analysis, and Design (notice that programming topics were amply covered in Part VIII, programming languages).

Discipline of Software Engineering

This part includes five chapters. It starts with Chapter 72, which provides an overview of software engineering. The chapter delineates the historical development of the discipline and provides an analysis of accepted definitions and an outline of the elements of the field. It looks at generally accepted definitions of engineering and shows the relation of certain elements to software development. It also points out important differences and demonstrates through a detailed analysis how prominent features that cut across all engineering disciplines can reasonably be mapped to software development. In this regard, the two most fundamental aspects are problem solving and engineering design. Mastery of *problem solving* involves a combination of proper judgment, experience, common sense, and know-how that must be used to reduce a real-world problem to such a form that *science* can be applied to find its solution. *Engineering design*, on the other hand, is the process of devising a system, component, or process to meet desired needs by finding technical solutions to specific practical problems, while taking into account economic, legal, and ecological considerations. Among the fundamental elements of this process are the establishment of objectives and criteria, synthesis, analysis, construction, testing, and evaluation, all of which have a counterpart in software engineering.

Chapters 73 and 74 deal with *professionalism and certification* issues and the *code of ethics and professional conduct*, respectively. Chapter 73 addresses software engineering as a profession from the point of view of the body of knowledge, accreditation of academic programs, and issues on licensure and certification of software engineering professionals. It provides a good account of the political realities of making software development a professional discipline and concludes that “it seems clear that the future of software engineering professionalism will be driven by industry and government,” although the uptake of credentials has been driven by practitioners’ interest (e.g., IEEE-CS CSDP).

Concomitant with the development of software engineering as a professional discipline is the introduction of a code of ethics, and in late 1999 the Association for Computing Machinery and the IEEE Computer Society approved the Software Engineering Code of Ethics and Professional Practice. In Chapter 74, Gotterbarn, a principal architect of the code, provides a rich historical account of its development and a thorough description of its purpose and principles, together with simple cases as examples and practical guidance for public accountability and educational purposes.

Chapters 75 and 76 address *software IT business and economics* and *open source and governance*. Chapter 75 provides an overview of the business of software from an IT and economics point of view, with a focus on the success rate of projects in terms of schedule predictability and quality, while emphasizing available solutions and best practices to practically implement this framework. It concludes with a look at business trends, naturally influenced and determined by external factors such as demand for value, fashion, individualism, ever-changing expectations, demand for ubiquitous services, global competition, economic and ecologic behaviors, and the need for security and stability, which in turn influence trends for software and IT business.

Chapter 76 on open source and governance is an authoritative manifesto in the subject, providing a comprehensive set of underlying principles regarding copyright law and license terms, including the peculiarities of COTS (commercial off-the-shelf). It also contains numerous examples of best practices covering a myriad of situations in which companies “desiring to supplement and expand the capabilities of their existing software” can find themselves.

Software Quality and Measurement

This part highlights an important aspect that makes software engineering a distinct computing discipline and that lends it much scientific credibility. The first two chapters focus on *evidence-informed software engineering* and *empirical software engineering*. Chapter 77 introduces the evidence-based paradigm, which originally emerged in medicine, together with a *systematic literature review* of its application in software engineering. The idea, first advocated by Kitchenham et al. in 2004, suggests that with some adaptation to fit the nature of software engineering studies, this could be a valuable way of consolidating our empirical knowledge about what works, when, and where. Chapter 78 provides an overview of how the ideas and practices associated with empirical software engineering have evolved. It represents an invaluable aid for identifying suitable forms of study for a particular need and to provide enough background for software engineers to appreciate the strengths and limitations of empirical knowledge and practice. This is particularly relevant if software engineering is to become a professional discipline; in this way, its practices, methods, and tools would need to be informed by evidence from well-conducted empirical studies.

Chapter 79 looks at quality in general and provides a comprehensive survey and analysis of quality under the umbrella of software process improvement. It differentiates software quality attributes from the point of view of the end user to IT operations, through marketing and projects and technical concerns. It also describes five perspective approaches to quality, that is, transcendental, product, user, manufacturing, and value based, with corresponding mappings to ISO quality standards. The chapter then juxtaposes process and quality and cost and quality. It provides an overview of best practices covering the various approaches to software process maturity such as CMM and SPICE together with practical implementation implications. It also identifies issues associated with small organizations and Agile development, as well as measurement and the use of statistical process control.

Chapter 80 focuses on *software metrics and measurements* and hence follows naturally here. This is an important component of software engineering as a professional discipline. The chapter demonstrates the value of software measurement and the role of international standards. These standards embody principles and best practices as defined and codified by experts in the field. Several approaches to implement measurement are discussed, including CMMI measurement and analysis (M&A), measurement and analysis infrastructure diagnostic (MAID), and goal-question-metric (GQM) among others. The chapter also covers predictive models and indicators, developing benchmarks and heuristics and improving data quality, concluding that “software measurement is required to quantify quality and performance and to provide an empirical and objective foundation for decision making—a foundation that is a necessary element if software engineering is truly to be a disciplined field of engineering.”

Software Development Management: Processes and Paradigms

The chapters in this part address the development of software from a higher-level managerial, rather than code development point of view. The first three chapters deal with management and organizational issues. Chapter 81 argues that there is no one best way to develop software and manage projects for all kinds of applications but that there are some basic principles that can be applied to a variety of projects within their contexts. It takes us through a series of high-level process concepts, innovation and design, and architecture strategies and how they are used in different situations. It concludes with a brief analysis of the results of a survey on global differences in practices and performance metrics in different regions of the world.

Chapter 82 covers issues related to *project personnel and organization* such as how to put together a team and how to decide on the types of personnel that you will need in your team based on the different types of roles and responsibilities. The chapter also explains the different ways you can organize

your personnel along with the advantages and disadvantages of each approach, as well as underlying principles and best practices.

Chapter 83 discusses *project and process control*. It makes a distinction between the project manager's control activities in executing a project, that is, *project control*, and the control of the underlying software development processes, or *process control*. Controlling a project and controlling the underlying processes are very different activities and, consequently, they require very different techniques to make them effective. The chapter describes the underlying mathematical and engineering foundations of two well-known control methods that can be applied to controlling software development projects and to their underlying software development processes. The first is closely related to traditional engineering methods for controlling manufacturing and communications systems using feedback. The second is known as statistical process control (SPC). The chapter concludes with a brief discussion of the extensive literature describing the application of SPC methods to software projects and the successes and failures that they have reported.

The last three chapters in this part address more recent development frameworks. Chapter 84 provides a thorough introduction to *Agile* methods, an umbrella term popularized with the publication of the Agile manifesto, reflecting an intention to differentiate Agile approaches from a trend in software development methodologies that had gained dominance in previous decades. It describes the set of 12 principles underlying the Agile approach as provided by the Agile manifesto. Specific implementations of the approach are described as best practices, including extreme programming, scrum, etc., together with an analysis of their specific incorporation, or not, of the 12 principles. The chapter concludes with a discussion of plan-driven approaches' compatibility, such as CMMIs, with Agile methods and thorough analyses of important research directions.

Chapter 85 presents a process for developing software based on service-oriented architectures. The fundamental building blocks of the approach are services, commonly viewed as self-contained software application modules exposed through interfaces over a distributed environment. The chapter introduces related elements such as component-based development, distributed components, and web services. The underlying principles of the approach are described together with the service infrastructure needed. In terms of best practices, the chapter outlines reference models and reference architectures and standards as well as the enterprise service bus idea and compares the specific implementations of the web services SOAP and REST.

Chapter 86 on *software product lines* (SPL) provides an introduction to the topic and a thorough analysis of its research challenges. SPL is one of the most active research areas of software engineering, and despite remarkable contributions, which are briefly highlighted, important technical problems remain. The chapter reports quantitative information, based on a secondary study and literature review, on these remaining problems, which slow down widespread adoption of SPL. The results provided are supported by a survey among longtime and active SPL researchers and practitioners. The top two reported research problems were variability management and evolution.

Software Modeling, Analysis, and Design

The last part of this section focuses on specific software development activities starting with requirements elicitation and specification, followed by model checking, design strategies, and software architecture and finally dealing with more overarching topics such human-computer interfaces and software assurance.

Chapter 87 covers *requirements elicitation*, a subprocess of requirements engineering concerned with gathering information about a computer-based system to be built. This is generally the first step in the software development life cycle regardless of the process model, whether it be waterfall, spiral, or even Agile. The chapter considers the different scenarios, reviews all available techniques with their pros and cons, and provides sound advice on what could go wrong during requirements elicitation.

Chapter 88 focuses on *specifications* for software systems and the *software requirements specification* document (SRS) document capturing them. Software requirement specifications are discussed at different stages from a very informal description to inform users, to descriptions in unambiguous terms, written in a rather formal (i.e., precise and unambiguous) manner. The chapter provides an overview of best practices for producing an SRS possessing all the desirable quality attributes and characteristics. It also provides a survey of the various specification languages and lists outstanding research issues such as completeness, nonfunctional requirements, cost, program construction and proof, and correctness-preserving program transformations.

Chapter 89 provides an overview of techniques and tools for analyzing the correctness of software systems using model checking. Two classes of techniques are covered, namely, counterexample-guided abstraction refinement (CEGAR) using predicate abstraction, and bounded model checking; other key model checking techniques that are geared toward software verification analysis are also covered. The chapter concludes with a brief survey of tools.

The next two chapters are about software design. Chapter 90 on *design strategies* leads us directly from requirements as “one assumption underlying any design is that the design will satisfy some set of requirements.” A set of underlying principles is discussed, including the notion of views, architectural patterns and tactics, decomposition and refinements, and code generation and testing. Design best practices are presented together with an analysis of important research concerns such as automatic/semiautomatic design, the accuracy of models, and the use and appropriate place for tools.

Chapter 91 on *software architecture* focuses exclusively on the main product of design: an architectural design of the software system to solve a specified problem. Various architectural frameworks are contrasted from their specific viewpoints, as well as a survey of design methods. A metaprocess is described, starting with concern analysis and domain analysis and concluding with architecture design, evaluation, and realization. Research topics in software architectures presented include modeling quality and issues related to model-driven design.

Chapter 92 on *human-computer interfaces* in software engineering uses speech applications (both input and synthesis) from requirements to design and implementation to illustrate principles and best practices and describe difficult research issues that lie ahead on the implication of human-computer interaction on software development. The latter discusses inherent current limits in speech applications design.

Chapter 93 deals with *software assurance*. It discusses the impact of the risks associated with software vulnerabilities and introduces basic definitions of software assurance. It also presents modern principles of software assurance and identifies a number of relevant process models, frameworks, and best practices. The chapter concludes with a research framework to support and identify gaps for future research and includes a description of the knowledge areas for a Master of Software Assurance as mapped to maturity levels for building assured systems.

Acknowledgments

This volume would not have been possible without the tireless and dedicated work of all the authors and reviewers. We appreciate the willingness of both established experts and influential younger researchers to join this effort and contribute to this work. Even though we have been working for decades in the computing field, our work on this volume has enriched substantially our knowledge and understanding of computing.

We would also like to thank the editorial staff at Chapman & Hall/CRC Press, particularly the persistent and gentle leadership of Randi Cohen, computer science acquisitions editor, whose role has extended beyond any reasonable call of duty. Bob Stern, as the original computer science editor who helped create this handbook in its original and second editions, also deserves recognition for his continued support over the years.

Teo acknowledges the support of the University of California, Santa Barbara (UCSB). Without his sabbatical leave, this project would not have been possible. He also wants to thank his wife, Dorothy, and children, Jeanmarie, Alexis, Julia, Teofilo, and Paolo, for their love, encouragement, understanding, patience, and support throughout the project and his tenure at UCSB.

Jorge acknowledges the support of Dr. Özlem Albayrak during the entire project. He is grateful to his team at Keuka College, particularly Lori Haines and Sandra Wilmott, for their moral support and encouragement as he took the helm of the College concomitant with the start of this project.

Allen acknowledges Bowdoin College for providing him the time and support needed to develop the first, second, and third editions of this handbook set over the last 15 years. He also thanks the many colleagues who have contributed to earlier editions of this handbook, without which the current edition would not have been possible. Finally, he thanks his wife, Meg, and children, Jenny and Brian, for their constant love and support over a lifetime of teaching and learning.

We hope that this volume will be actively and frequently used both by academics who want to explore the current status and new opportunities within specific research areas and by advanced practitioners who want to understand how they can benefit from the latest thinking within the disciplines of computer science and software engineering. We also warmly welcome your feedback.

Bowdoin College

Editors

Allen B. Tucker is the Anne T. and Robert M. Bass Professor Emeritus in the Department of Computer Science at Bowdoin College, Brunswick, Maine, where he served on the faculty from 1988 to 2008. Prior to that, he held similar positions at Colgate and Georgetown Universities. Overall, he served for 18 years as a department chair and two years as an associate dean of the faculty. While at Colgate, he held the John D. and Catherine T. MacArthur Chair in Computer Science.

Professor Tucker earned a BA in mathematics from Wesleyan University in 1963 and an MS and PhD in computer science from Northwestern University in 1970. He is the author or coauthor of several books and articles in the areas of programming languages, natural language processing, and software engineering. He has given many talks, panel discussions, and workshop presentations in these areas and has served as a reviewer for various journals, NSF programs, and curriculum projects. He has also served as a consultant to colleges, universities, and other institutions in the areas of computer science curriculum, software development, programming languages, and natural language processing applications. Since retiring from his full-time academic position, Professor Tucker continues to write, teach, and develop open source software for nonprofit organizations.

A fellow of the ACM, Professor Tucker coauthored the 1986 Liberal Arts Model Curriculum in Computer Science and cochaired the ACM/IEEE-CS Joint Curriculum Task Force that developed Computing Curricula 1991. For these and related efforts, he received the ACM's 1991 Outstanding Contribution Award, shared the IEEE's 1991 Meritorious Service Award, and received the ACM SIGCSE's 2001 Award for Outstanding Contributions to Computer Science Education. In 2001, he was a Fulbright Lecturer at the Ternopil Academy of National Economy in Ukraine, and in 2005, he was an Erskine Lecturer at the University of Canterbury in New Zealand. Professor Tucker has been a member of the ACM, the NSF CISE Advisory Committee, the IEEE Computer Society, Computer Professionals for Social Responsibility, the Liberal Arts Computer Science (LACS) Consortium, and the Humanitarian Free and Open Source Software (HFOSS) Project.

Dr. Jorge L. Díaz-Herrera became the 19th president of Keuka College on July 1, 2011. He was professor and founding dean of the B. Thomas Golisano College of Computing and Information Sciences at Rochester Institute of Technology in Rochester, New York, since July 2002. Prior to this appointment, he was professor of computer science and department head at SPSU in Atlanta and Yamacraw project coordinator with Georgia Tech. He became the chair of the first Software Engineering Department in the United States at Monmouth University in New Jersey. He has had other academic appointments with Carnegie Mellon's Software Engineering Institute, George Mason University in Virginia, and at SUNY Binghamton in New York.

Dr. Díaz-Herrera has conducted extensive consulting services with a number of firms and government agencies, including New York Stock Exchange (SIAC), MITRE Corp., the Institute for Defense Analysis, General Electric, Singer-Link, TRW, EG&G, and IBM among others. He has participated in technical meetings and provided professional expertise to international organizations, including the

European Software Institute, Australian Defense Science and Technology Office, Kyoto Computing Gaikum, Kuwait University, Cairo University, Instituto Politecnico Santo Domingo (INTEC), Bilkent University in Turkey, and Malaysia University of Technology among others. He has chaired several national and international conferences and has been a technical reviewer for the National Science Foundation, the American Society for Engineering Education, and several conferences and journals. He has more than 90 publications.

Dr. Díaz-Herrera is a senior member of the IEEE, and was a member of IEEE-CS Distinguished Visitor Program for nine consecutive years, a leading writer of the Software Engineering Professional Examination, and coeditor of the *Software Engineering* volume of the Computing Curricula project. He was an active member of the CRA-Deans Group of the Computer Research Association in Washington, DC and serves, and has served, on various technical advisory committees and governing boards, including the Technical Advisory Group, SEI, Carnegie Mellon University, Pittsburgh, Pennsylvania; Advisory Committee for CISE, National Science Foundation, Washington, DC; Advisory Committee for GPRA/PA, National Science Foundation, Washington, DC; Board of Trustees, Strong National Museum of Play, Rochester, New York; Board of Trustees, Gallaudet University, Washington, DC; NY State Universal Broadband Council, Action Team on Digital Literacy, Albany, New York; and Research Board, Instituto Tecnológico de las Américas (ITLA), Dominican Republic.

Dr. Díaz-Herrera completed his undergraduate education in Venezuela and holds both a master's degree and a PhD in computing studies from Lancaster University in the United Kingdom. He completed two graduate certificates in management leadership in education from Harvard University's Graduate School of Education. He recently received a doctor honoris causa from his alma mater, Universidad Centro Occidental Lisandro Alvarado, in Barquisimeto, Venezuela.

Professor Teofilo F. Gonzalez was one of the first ten students who received a computer science undergraduate degree in Mexico (ITESM 1972). He received his PhD from the University of Minnesota in 1975. He has been member of the faculty at OU, Penn State, and UT Dallas and has spent sabbatical leave at the ITESM (Monterrey, Mexico) and U. Utrecht (the Netherlands). Since 1984, he has served as professor of computer science at the University of California, Santa Barbara.

Professor Gonzalez's main research contributions include the development of exact and approximation algorithms as well as establishing complexity results for problems in several research areas, including message dissemination (multicasting), scheduling, VLSI placement and routing, computational geometry, graph problems, clustering, etc.

Professor Gonzalez edited the *Handbook on Approximation Algorithms and Metaheuristics* (Chapman & Hall/CRC, 2007). This handbook was the first one in the area and included contributions from top researchers worldwide. His work has been published in top journals in computer science, operations research and computer engineering, as well as in research books and conference proceedings. Professor Gonzalez has served as editor and guest editor of several publications. Currently, he serves as associate editor of *IEEE Transactions on Computers and ACM Computing Surveys*. He has been program committee chair and general chair for many conferences. He has received the Outstanding Computer Science Professor of the Year Award three times. He also received the Outstanding Performance as PC Chair for PDCS several times. Professor Gonzalez is a IASTED fellow. Since 2002, he has participated in the ABET accreditation process as a CAC program evaluator and commissioner.

Peter J. Denning
*Naval Postgraduate
School in Monterey*

Computing is integral to science—not just as a tool for analyzing data but also as an agent of thought and discovery.

It has not always been this way. Computing is a relatively young discipline. It started as an academic field of study in the 1930s with a cluster of remarkable papers by Kurt Gödel, Alonzo Church, Emil Post, and Alan Turing. The papers laid the mathematical foundations that would answer the question, “what is computation?” and discussed schemes for its implementation. These men saw the importance of automatic computation and sought its precise mathematical foundation. The various schemes they each proposed for implementing computation were quickly found to be equivalent, as a computation in any one could be realized in any other. It is all the more remarkable that their models all led to the same conclusion that certain functions of practical interest—such as whether a computational algorithm (a method of evaluating a function) will ever come to completion instead of being stuck in an infinite loop—cannot be answered computationally.

In the time that these men wrote, the terms “computation” and “computers” were already in common use but with different connotations from today. Computation was taken to be the mechanical steps followed to evaluate mathematical functions. Computers were people who did computations. In recognition of the social changes they were ushering in, the designers of the first digital computer projects

* An earlier version of this chapter, without the section on technology view of the field, was published in *American Scientist* 98 (September–October 2010), pp. 198–202. It was reprinted in *Best Writings on Mathematics 2011* (M. Pitici, ed.), Princeton University Press (2011). Copyright is held by the author.

all named their systems with acronyms ending in “-AC,” meaning automatic computer or something similar—resulting in names such as ENIAC, UNIVAC, and EDSAC.

At the start of World War II, the militaries of the United States and the United Kingdom became interested in applying computation to the calculation of ballistic and navigation tables and the cracking of ciphers. They commissioned projects to design and build electronic digital computers. Only one of the projects completed before the war was over. That was the top-secret project at Bletchley Park in England, which cracked the German Enigma cipher using methods designed by Alan Turing.

Many people involved in those projects went on to start computer companies in the early 1950s. The universities began offering programs of study in the new field in the late 1950s. The field and the industry have grown steadily into a modern behemoth whose Internet data centers are said to consume almost 3% of the world’s electricity.

During its youth, computing was an enigma to the established fields of science and engineering. At first, it looked like only the technology applications of math, electrical engineering, or science, depending on the observer. However, over the years, computing seemed to provide an unending stream of new insights, and it defied many early predictions by resisting absorption back into the fields of its roots. By 1980, computing had mastered algorithms, data structures, numerical methods, programming languages, operating systems, networks, databases, graphics, artificial intelligence, and software engineering. Its great technology achievements—the chip, the personal computer, and the Internet—brought it into many lives. These advances stimulated more new subfields, including network science, web science, mobile computing, enterprise computing, cooperative work, cyberspace protection, user-interface design, and information visualization. The resulting commercial applications have spawned new research challenges in social networks, endlessly evolving computation, music, video, digital photography, vision, massive multiplayer online games, user-generated content, and much more.

The name of the field changed several times to keep up with the flux. In the 1940s, it was called *automatic computation*, and in the 1950s, *information processing*. In the 1960s, as it moved into academia, it acquired the name *computer science* in the United States and *informatics* in Europe. By the 1980s, the computing field comprised a complex of related fields including computer science, informatics, computational science, computer engineering, software engineering, information systems, and information technology. By 1990, the term *computing* became the standard for referring to this core group.

1.1 Computing Paradigm

Traditional scientists frequently questioned the name *computer science*. They could easily see an engineering paradigm (design and implementation of systems) and a mathematics paradigm (proofs of theorems) but they could not see much of a science paradigm (experimental verification of hypotheses). Moreover, they understood science as a way of dealing with the natural world, and computers looked suspiciously artificial.

The word “paradigm” for our purposes means a belief system and its associated practices, defining how a field sees the world and approaches the solutions of problems. This is the sense that Thomas Kuhn used in his famous book, *The Structure of Scientific Revolutions* (1962). Paradigms can contain subparadigms: thus, engineering divides into electrical, mechanical, chemical, civil, etc., and science divides into physical, life, and social sciences, which further divide into separate fields of science. Table 1.1 outlines the three paradigms that combined to make the early computing field.

The founders of the field came from all three paradigms. Some thought computing was a branch of applied mathematics, some a branch of electrical engineering, and some a branch of computational-oriented science. During its first four decades, the field focused primarily on engineering: The challenges of building reliable computers, networks, and complex software were daunting and occupied almost everyone’s attention. By the 1980s, these challenges largely had been met and computing was

TABLE 1.1 Subparadigms Embedded in Computing

	Math	Science	Engineering
1. Initiation	Characterize objects of study (definition).	Observe a possible recurrence or pattern of phenomena (hypothesis).	Create statements about desired system actions and responses (requirements).
2. Conceptualization	Hypothesize possible relationships among objects (theorem).	Construct a model that explains the observation and enables predictions (model).	Create formal statements of system functions and interactions (specifications).
3. Realization	Deduce which relationships are true (proof).	Perform experiments and collect data (validate).	Design and implement prototypes (design).
4. Evaluation	Interpret results.	Interpret results.	Test the prototypes.
5. Action	Act on results (apply).	Act on results (predict).	Act on results (build).

spreading rapidly into all fields, with the help of networks, supercomputers, and personal computers. During the 1980s, computers had become powerful enough that science visionaries could see how to use them to tackle the hardest, “grand challenge” problems in science and engineering. The resulting “computational science” movement involved scientists from all countries and culminated in the US Congress’s adopting the High Performance Computing and Communications (HPCC) act of 1991 to support research on a host of large computational problems.

Today, there is agreement that computing *exemplifies* science and engineering and that neither science nor engineering *characterizes* computing. Then what does? What is computing’s paradigm?

The leaders of the field struggled with the paradigm question ever since the beginning. Along the way, there were three waves of attempts to unify views. Newell et al. (1967) led the first one. They argued that computing was unique among all the sciences in its study of information processes. Simon (1996), a Nobel laureate in Economics, went so far as to call computing a science of the artificial. Amarel (1971) endorsed this basic idea and added an emphasis on interactions with other fields. A catchphrase of this wave was that “computing is the study of phenomena surrounding computers.”

The second wave focused on programming, the art of designing algorithms that produced information processes. In the early 1970s, computing pioneers Edsger Dijkstra and Donald Knuth took strong stands favoring algorithm analysis as the unifying theme. A catchphrase of this wave was “computer science equals programming.” In recent times, this view has foundered because the field has expanded well beyond programming, whereas public understanding of a programmer has narrowed to just those who write code.

The third wave came as a result of the NSF-funded Computer Science and Engineering Research Study (COSERS), led by Bruce Arden in the late 1970s. Its catchphrase was “computing is the automation of information processes.” Although its final report successfully exposed the science of computing and explained many esoteric aspects to the layperson, its central view did not catch on.

An important aspect of all three definitions was the positioning of the computer as the object of attention. The computational science movement of the 1980s began to step away from that notion, adopting the view that computing is not only a tool for science but also a new method of thought and discovery in science. The process of dissociating from the computer as the focal center came to completion in the late 1990s when leaders of the field of biology—epitomized by Nobel laureate David Baltimore (2001) and echoing cognitive scientist Douglas Hofstadter (1985)—said that biology had become an information science and DNA translation is a natural information process. Many computer scientists have joined biologists in research to understand the nature of DNA information processes and to discover what algorithms might govern them.

Take a moment to savor this distinction that biology makes. First, some information processes are natural. Second, we do not know whether all natural information processes are produced by algorithms.

The second statement challenges the traditional view that algorithms (and programming) are at the heart of computing. Information processes may be more fundamental than algorithms.

Scientists in other fields have come to similar conclusions. They include physicists working with quantum computation and quantum cryptography, chemists working with materials, economists working with economic systems, cognitive scientists working with brain processes, and social scientists working with networks. All have said that they discovered information processes in their disciplines' deep structures. Stephen Wolfram (2002), a physicist and creator of the software program *Mathematica*, went further, arguing that information processes underlie every natural process in the universe.

All this leads us to the modern catchphrase: "Computing is the study of information processes, natural and artificial." The computer is a tool in these studies but is not the object of study. Dijkstra once said: "Computing is no more about computers than astronomy is about telescopes."

The term *computational thinking* has become popular to refer to the mode of thought that accompanies design and discovery done with computation (Wing 2006). This term was originally called *algorithmic thinking* in the Newell et al. (1960) and was widely used in the 1980s as part of the rationale for computational science. To think computationally is to interpret a problem as an information process and then seek to discover an algorithmic solution. It is a very powerful paradigm that has led to several Nobel Prizes.

All this suggests that computing has developed a paradigm all its own (Denning and Freeman 2009). Computing is no longer just about algorithms, data structures, numerical methods, programming languages, operating systems, networks, databases, graphics, artificial intelligence, and software engineering, as it was prior to 1990. It now also includes exciting new subjects including Internet, web science, mobile computing, cyberspace protection, user-interface design, and information visualization. The resulting commercial applications have spawned new research challenges in social networking, endlessly evolving computation, music, video, digital photography, vision, massive multiplayer online games, user-generated content, and much more.

The computing paradigm places a strong emphasis on the scientific (experimental) method to understand computations. Heuristic algorithms, distributed data, fused data, digital forensics, distributed networks, social networks, and automated robotic systems, to name a few, are often too complex for mathematical analysis but yield to the scientific method. These scientific approaches reveal that *discovery* is as important as *construction* or *design*. Discovery and design are closely linked: the behavior of many large designed systems (such as the web) is discovered by observation; we design simulations to imitate discovered information processes. Moreover, computing has developed search tools that are helping make scientific discoveries in many fields.

The central focus of the computing paradigm can be summarized as information processes—natural or constructed processes that transform information. They can be discrete or continuous.

Table 1.2 summarizes the computing paradigm with this focus. While it contains echoes of engineering, science, and mathematics, it is distinctively different because of its central focus on information processes (Denning and Freeman 2009). It allows engineering and science to be present together without having to choose.

There is an interesting distinction between computational expressions and the normal language of engineering, science, and mathematics. Engineers, scientists, and mathematicians endeavor to position themselves as outside observers of the objects or systems they build or study. Outside observers are purely representational. Thus, traditional blueprints, scientific models, and mathematical models are not executable. (However, when combined with computational systems, they give automatic fabricators, simulators of models, and mathematical software libraries.) Computational expressions are not constrained to be outside the systems they represent. The possibility of self-reference makes for very powerful computational schemes based on recursive designs and executions and also for very powerful limitations on computing, such as the noncomputability of halting problems. Self-reference is common in natural information processes; the cell, for example, contains its own blueprint.

TABLE 1.2 The Computing Paradigm

Computing	
1. Initiation	Determine if the system to be built (or observed) can be represented by information processes, either finite (terminating) or infinite (continuing interactive).
2. Conceptualization	Design (or discover) a computational model (e.g., an algorithm or a set of computational agents) that generates the system's behaviors.
3. Realization	Implement designed processes in a medium capable of executing its instructions. Design simulations and models of discovered processes. Observe behaviors of information processes.
4. Evaluation	Test the implementation for logical correctness, consistency with hypotheses, performance constraints, and meeting original goals. Evolve the realization as needed.
5. Action	Put the results to action in the world. Monitor for continued evaluation.

1.2 Two Views of Computing

Part of a scientific paradigm is a description of the knowledge of the field, often referred to as the “body of knowledge.” Within the computing paradigm, two descriptions of the computing body of knowledge have grown up. They might be called a technology interpretation and a principles interpretation.

Before 1990, most computing scientists would have given a technological interpretation, describing the field in terms of its component technologies. After 1990, the increasingly important science aspect began to emphasize the fundamental principles that empower and constrain the technologies.

In reality, these two interpretations are complementary. They both see the same body of knowledge, but in different ways. The technological view reflects the way the field has evolved around categories of technology; many of these categories reflect technical specialties and career paths. The science view reflects a deeper look at timeless principles and an experimental outlook on modeling and validation in computing.

These two views are discussed in Sections 1.3 and 1.4.

1.3 View 1: Technologies of Computing

Over the years, the ACM and Institute of Electrical and Electronics Engineers Computer Society (IEEECS) collaborated on a computing body of knowledge and curriculum recommendations for computer science departments. The milestones of this process give a nice picture of the technological development of the field.

1.3.1 First Milestone: Curriculum 68

In the mid-1960s, the ACM (with help from people in IEEECS) undertook the task to define curriculum recommendations for schools that wished to offer degrees in the new field of computer science (ACM 1968). Their report said that the field consisted of three main parts:

- Information structures and processes
- Information processing systems
- Methodologies

The methodologies included design approaches for software and applications. The core material was mostly the mathematical underpinnings for the parts listed earlier:

- Algorithms
- Programming
- Data structures
- Discrete math
- Logic circuits
- Sequential machines
- Parsing
- Numerical methods

Many computer science departments adopted these recommendations.

1.3.2 Second Milestone: Computing as a Discipline

The ACM and IEEECS formally joined forces in 1987 to defend computing curricula from a bastardized view that “CS = programming.” Around Donald Knuth and Edsger Dijkstra (1970) started making strong and eloquent cases for formal methods of software design, analysis, and construction. They said “we are all programmers” trying to employ powerful intellectual tools to tame complexity and enable correct and dependable software. Although computer scientists understood a programmer as highly skilled expert at these things, the public view of programmers was narrowing to low-level coders, who occasionally caused trouble by hacking into other people’s systems.

The committee laid out a model of the computing field that emphasized its breadth, showing that it is much richer than simply programming (Denning et al. 1989). Table 1.3 depicts the 9×3 matrix model of the computing field offered by the committee. Theory, abstraction, and design were used in the report for the mathematics, science, and engineering paradigms, respectively. The report gave details about what ideas and technologies fit into each of the 27 boxes in the matrix. It became the basis for a major ACM/IEEE curriculum revision in 1991.

Although this effort had a strong internal influence on the curriculum, it had little external influence on the perception that “CS=programming.” In fact, that perception was alive and well in the early 2000s when enrollments declined by over 50%.

1.3.3 Third Milestone: Information Technology Profession

In 1998, the ACM launched an “IT profession” initiative, based on a widely held perception that the field had evolved from a discipline to a profession (Denning 1998, Denning 2001, Holmes 2000). The initiative responded to three trends: the growing interest in the industry for professional standards (especially in safety-critical systems), organized professional bodies representing various specialties,

TABLE 1.3 Matrix Model of Computing Discipline, 1989

Topic Area	Theory	Abstraction	Design
1. Algorithms and data structures			
2. Programming languages			
3. Architecture			
4. Operating systems and networks			
5. Software engineering			
6. Databases and information retrieval			
7. Artificial intelligence and robotics			
8. Graphics			
9. Human-computer interaction			

TABLE 1.4 The Profession of Information Technology

IT-Core Disciplines	IT-Intensive Disciplines	IT-Supportive Occupations
Artificial intelligence	Aerospace engineering	Computer technician
Computer science	Bioinformatics	Help desk technician
Computer engineering	Cognitive science	Network engineer
Computational science	Cryptography	Professional IT trainer
Database engineering	Digital library science	Security specialist
Graphics	E-commerce	System administrator
Human-computer interaction	Economics	Web services designer
Network engineering	Genetic engineering	Web identity designer
Operating systems	Information science	Database administrator
Performance engineering	Information systems	
Robotics	Public policy and privacy	
Scientific computing	Quantum computing	
Software architecture	Instructional design	
Software engineering	Knowledge engineering	
System security	Management information systems	
	Material science	
	Multimedia design	
	Telecommunications	

and a university movement to establish degree programs in information technology. The ACM leadership concluded that the computing field met the basic criteria for a profession and that it was time for ACM to configure itself accordingly.

Table 1.4 is an inventory ACM made of the organized groups in the field. They saw IT professionals as a much larger and more diverse group than computer scientists and engineers, with at least 42 organized affinity groups in three categories. The first category comprises the major technical areas of IT and spans the intellectual core of the field. The second category comprises other well-established fields that are intensive users of IT; they draw heavily on IT and often make novel contributions to computing. The third category comprises areas of skill and practice necessary to keep and support the IT infrastructures that everyone uses. Allen Tucker and Peter Wegner (1996) also noted the dramatic growth and professionalization of the field and its growing influence on many other fields.

Unfortunately, the talk about “profession” led to a new round of terminological confusion. A profession is a social structure that includes many disciplines, but it is not a discipline in its own right. IT is not a field of research; the core disciplines (left column) and partner disciplines (middle column) attend to the research. To what does the term “computing field” refer in this context?

A decade later, it was clear that this interpretation of the field did not match what had actually evolved (Denning and Freeman 2009). The popular label IT did not reconcile the three parts of the computing field under a single umbrella unique to computing. IT now connotes technological infrastructure and its financial and commercial applications, but not the core technical aspects of computing.

1.3.4 Fourth Milestone: Computing Curriculum 2001

The ACM and IEEECS Education Boards were more cautious than ACM leadership in embracing an IT profession when they undertook a curriculum review and revision in 1999. They focused on the core specialties (first column in Table 1.2) and identified the computing discipline with these six academic specialties:

- EE—Electrical engineering
- CE—Computer engineering
- CS—Computer science

SWE—Software engineering
 IS—Information systems
 IT—Information technology

It was understood that students interested in hardware would enroll in an EE or CE program; students interested in software in a CE, CS, or SWE program; and students interested in organizational and enterprise aspects would enroll in IS or IT programs. Here, the term “IT” is far from what the IT profession initiative envisioned—it refers simply to a set of degree programs that focus on organizational applications of computing technology.

The CC2001 committee organized the body of knowledge into 14 main categories, as follows:

Algorithms and complexity
 Architecture and organization
 Computational science
 Discrete structures
 Graphics and visual computing
 Human–computer interaction
 Information management
 Intelligent systems
 Net-centric computing
 Operating systems
 Programming fundamentals
 Programming languages
 Social and professional issues
 Software engineering

There were a total of 130 subcategories. The body of knowledge had 50% more categories than a decade before!

1.3.5 Fifth Milestone: Computing Curriculum 2013

The ACM and IEEECS again collaborated on a ten-year review of the computing curriculum. They learned that the field had grown from 14 to 18 knowledge areas since the 2001 review:

Algorithms and complexity
 Architecture and organization
 Computational science
 Discrete structure
 Graphics and visual computing
 Human–computer interaction
 Information assurance and security
 Information management
 Intelligent systems
 Networking and communications
 Operating systems
 Platform-based development
 Parallel and distributed computing
 Programming languages
 Software development fundamentals
 Software engineering
 Systems fundamentals
 Social and professional issues

The committee was concerned about the pressure to increase the size of the computer science core. They calculated that the 2001 curriculum recommended 280 core hours and an update in 2008 increased that to 290. The core hours to cover the list earlier would be 305. They divided the core into two parts. Tier 1, the “must have” knowledge, and Tier 2, the “good to have” knowledge. They recommended that individual departments choose at least 80% of the Tier 2 courses, for a total of 276 hours, leaving plenty of time for electives in a student’s specialization area.

When ACM issued Curriculum 68, most of us believed that every computer scientist should know the entire core. Today, that is very difficult, even for seasoned computer scientists, since the field has grown so much since 1968.

1.4 View 2: Great Principles of Computing

The idea of organizing the computing body of knowledge around the field’s fundamental principles is not new. Many of the field’s pioneers were deeply concerned about why computing seemed like a new field, not a subset of other fields like mathematics, engineering, or science. They spent considerable effort to explain what they were doing in terms of the fundamental principles they worked with. Prominent examples are Turing’s paper (1937); the essays of Newell et al. (1967); Simon’s book (1996); and Arden’s COSERS report (1971, 1983). In subsets of the field, thinkers ferreted out the fundamental principles. Examples are Coffman and Denning (1973) on operating systems, Kleinrock (1975) on queueing systems, Hillis (1999) on the nature of computing machines, and Harel (2003) on algorithms and limits of computing.

This viewpoint, however, stayed in the background. I think the reason was simply that for many years, we were concerned with the engineering problems of constructing computers and networks that worked reliably. Most computer scientists were occupied solving engineering problems. The ones most interested in fundamental principles were the ones interested in theory. By 1990, we had succeeded beyond our wildest dreams with the engineering. However, our descriptions of the field looked like combinations of engineering and mathematics. Many outsiders wondered what the word “science” was doing in our title.

When the computational science movement began in the 1980s, many computer scientists felt like they were being excluded. Computational scientists, for their part, did not realize that computer scientists were interested in science. A growing number of us became interested in articulating the science side of computing. It was not easy, because many scientists agreed with Herb Simon (1996), that we are at best a science of the artificial, but not a real science. Real sciences, in their opinions, dealt with naturally occurring processes.

But by 1990, prominent scientists were claiming to have discovered natural information processes, such as in biology, quantum physics, economics, and chemistry. This gave new momentum to our efforts to articulate a science-oriented view of computing (Denning 2005, Denning 2007).

Inspired by the great principles work of James Trefil and Robert Hazen (1996) for science, my colleagues and I have developed the Great Principles of Computing framework to accomplish this goal (Denning 2003, Denning and Martell 2004). Computing principles fall into seven categories: computation, communication, coordination, recollection, automation, evaluation, and design (Table 1.5).

Each category is a perspective on computing: a window into the computing knowledge space. The categories are not mutually exclusive. For example, the Internet can be seen as a communication system, a coordination system, or a storage system. We have found that most computing technologies use principles from all seven categories. Each category has its own weight in the mixture, but they are all there.

In addition to the principles, which are relatively static, we need to take account of the dynamics of interactions between computing and other fields. Scientific phenomena can affect each other in one of two ways: implementation and influence. A combination of existing things implements a phenomenon by generating its behaviors. Thus, digital hardware physically implements computation, artificial intelligence implements aspects of human thought, a compiler implements a high-level language with machine code, hydrogen and oxygen implement water, and complex combinations of amino acids implement life.

TABLE 1.5 Great Principles of Computing

Category	Focus	Examples
Computation	What can and cannot be computed	Classifying complexity of problems in terms of the number of computational steps to achieve a solution. Is P=NP? Quantum computation.
Communication	Reliably moving information between locations	Information measured as entropy. Compression of files, error-correcting codes, cryptography.
Coordination	Achieving unity of operation from many autonomous computing agents	Protocols that eliminate conditions that cause indeterminate results. Choice uncertainty: cannot choose between two near simultaneous signals within a deadline. Protocols that lead the parties to common beliefs about each other's system.
Recollection	Representing, storing, and retrieving information from media	All storage systems are hierarchical, but no storage system can offer equal access time to all objects. Locality principle: all computations favor subsets of their data objects in any time interval. Because of locality, no storage system can offer equal access time to all objects.
Automation	Discovering algorithms for information processes	Most heuristic algorithms can be formulated as searches over enormous data spaces. Human memory and inference are statistical phenomena described by Bayes Rule. Many human cognitive processes can be modeled as information processes.
Evaluation	Predicting performance of complex systems	Most computational systems can be modeled as networks of servers whose fast solutions yield close approximations of real throughput and response time.
Design	Structuring software systems for reliability and dependability	Complex systems can be decomposed into interacting modules and virtual machines following the principles of information hiding and least privilege. Modules can be stratified by layers corresponding to time scales of events that manipulate objects.

Influence occurs when two phenomena interact with each other. Atoms arise from the interactions among the forces generated by protons, neutrons, and electrons. Galaxies interact via gravitational waves. Humans interact with speech, touch, and computers. Interactions exist across domains as well as within domains. For example, computation influences physical action (electronic controls), life processes (DNA translation), and social processes (games with outputs). Table 1.6 illustrates interactions between computing and each of the physical, life, and social sciences as well as within computing itself. There can be no question about the pervasiveness of computing in all fields of science.

1.5 Relation between the Views

The technology and the principles views discussed earlier are two different interpretations of the same knowledge space. They are alternatives for expressing the computing body of knowledge.

The same principle may appear in several technologies, and a particular technology likely relies on several principles. The set of active principles (those used in at least one technology) evolves much more slowly than the technologies.

TABLE 1.6 Examples of Computing Interacting with Other Domains

	Physical	Social	Life	Computing
Implemented by	Mechanical, optical, electronic, quantum, and chemical computing	Wizard of Oz, mechanical robots, human cognition, games with inputs and outputs	Genomic, neural, immunological, DNA transcription, evolutionary computing	Compilers, OS, emulation, reflection, abstractions, procedures, architectures, languages
Implements	Modeling, simulation, databases, data systems, quantum cryptography	Artificial intelligence, cognitive modeling, autonomic systems	Artificial life, biomimetics, systems biology	
Influenced by	Sensors, scanners, computer vision, optical character recognition, localization	Learning, programming, user modeling, authorization, speech understanding	Eye, gesture, expression, and movement tracking, biosensors	Networking, security, parallel computing, distributed systems, grids
Influences	Locomotion, fabrication, manipulation, open-loop control	Screens, printers, graphics, speech generation, network science	Bioeffectors, haptics, sensory immersion	
Bidirectional influence	Robots, closed-loop control	Human-computer interaction, games	Brain-computer interfaces	

While the two styles of framework are different, they are strongly connected. To see the connection, imagine a 2D matrix. The rows name technologies, and the columns name categories of principles. The interior of the matrix is the knowledge space of the field.

Imagine someone who wants to enumerate all the principles involved with a technology. If the matrix is already filled in, the answer is simply to read the principles from the row of the matrix. Otherwise, fill it in by analyzing the technology for principles in each of the seven categories. In the figure later, we see that the security topic draws principles from all seven categories.

	Computation	Communication	Coordination	Recollection	Automation	Evaluation	Design
Security	O(.) of encryption functions	Secrecy authentication covert channels	Key distr protocol zero knowl proof	Confinement partitioning for MLS reference monitor	Instrusion detection biometric id	Protocol perform under various loads	End-to-end layered functions virtual machines

Within the principles framework, someone can enumerate all the technologies that employ a particular principle. In the example later, we see that the coordination category contributes principles to all the technologies listed.

	Computation	Communication	Coordination	Recollection	Automation	Evaluation	Design
Architecture			Hardware handshake				
Internet			TCP and IP protocols				
Security			Key distr protocol zero knowl proof				
Virtual memory			Page fault interrupt				
Database			Locking protocol				
Programming language			Semaphores monitors				

1.6 What Are Information Processes?

There is a potential difficulty with defining computation in terms of information. Information seems to have no settled definition. Claude Shannon the father of information theory, in 1948 defined information as the expected number of yes–no questions one must ask to decide which message was sent by a source. This definition describes the inherent information of a source before any code is applied; all codes for the course contain the same information. Shannon purposely skirted the issue of the meaning of bit patterns, which seems to be important to defining information. In sifting through many published definitions, Paolo Rocchi (2010) concluded that definitions of information necessarily involve an objective component, signs and their referents or, in other words, symbols and what they stand for, and a subjective component, meanings. How can we base a scientific definition of information on something with such an essential subjective component?

Biologists have a similar problem with “life.” Life scientist Robert Hazen (2007) notes that biologists have no precise definition of life, but they do have a list of seven criteria for when an entity is living. The observable affects of life, such as chemistry, energy, and reproduction, are sufficient to ground the science of biology. In the same way, we can ground a science of information on the observable affects (signs and referents) without a precise definition of meaning.

A representation is a pattern of symbols that stands for something. The association between a representation and what it stands for can be recorded as a link in a table or database or as a memory in people’s brains. There are two important aspects of representations: *syntax* and *stuff*. Syntax is the rules for constructing patterns; it allows us to distinguish patterns that stand for something from patterns that do not. Stuff is measurable physical states of the world that hold representations, usually in media or signals. Put these two together and we can build machines that can detect when a valid pattern is present.

A representation that stands for a method of evaluating a function is called an algorithm. A representation that stands for values is called data. When implemented by a machine, an algorithm controls the transformation of an input data representation to an output data representation. The distinction between the algorithm and the data representations is pretty weak; the executable code output by a compiler looks like data to the compiler and algorithm to the person running the code.

Even this simple notion of representation has deep consequences. For example, as Gregory Chaitin (2006) has shown, there is no algorithm for finding the shortest possible representation of something.

Some scientists leave open the question of whether an observed information process is actually controlled by an algorithm. DNA translation can be called an information process; if someone discovers a controlling algorithm, it could be also called a computation.

Some mathematicians define computation separate from implementation. They do this by treating computations as logical orderings of strings in abstract languages and are able to determine the logical limits of computation. However, to answer questions about running time of observable computations, they have to introduce costs representing the time or energy of storing, retrieving, or converting representations. Many real-world problems require exponential-time computations as a consequence of these implementable representations. I still prefer to deal with implementable representations because they are the basis of a scientific approach to computation.

These notions of representation are sufficient to give us the definitions we need for computing. An information process is a sequence of representations. (In the physical world, it is a continuously evolving, changing representation.) A computation is an information process in which the transitions from one element of the sequence to the next are controlled by a representation. (In the continuous world, we would say that each infinitesimal time and space step is controlled by a representation.)

1.7 Where Computing Stands

Computing as a field has come to exemplify good science as well as engineering. The science is essential to the advancement of the field because many systems are so complex that experimental methods are the only way to make discoveries and understand limits. Computing is now seen as a broad field that studies information processes, natural and artificial.

This definition is broad enough to accommodate three issues that have nagged computing scientists for many years: Continuous information processes (such as signals in communication systems or analog computers), interactive processes (such as ongoing web services), and natural processes (such as DNA translation) all seemed like computation but did not fit the traditional algorithmic definitions.

The great principles framework reveals a rich set of rules on which all computation is based. These principles interact with the domains of the physical, life, and social sciences, as well as with computing technology itself.

Computing is not a subset of other sciences. None of those domains is fundamentally concerned with the nature of information processes and their transformations. Yet this knowledge is now essential in all the other domains of science. Computer scientist Paul Rosenbloom (2012) of the University of Southern California argued that computing is a new great domain of science. He is on to something.

2.1 Introduction

The early twenty-first century is a time of two trends in computing. One trend is that computing technology has become less expensive and more ubiquitous. The second trend is “big data,” both the existence of extremely large amounts of data and a push to be able to process large amounts of data. For example, in 2012 the Big Data R&D Initiative committed six US federal agencies and departments to “improve our ability to extract knowledge and insights” from large quantities of digital data [1].

Concurrent with these trends, the term “computational thinking” (CT) has come into use. This frequently refers to a set of computational concepts and skills that should be widely taught. These concepts and skills are generally seen as important and necessary additions to the mathematical, linguistic, and logical thinking skills already taught [2]. There have been several approaches to this in the past, including teaching students basic computer literacy (usually identified as being able to use the computer as a tool), teaching programming in specific languages, or teaching programming through specific application areas [2]. Many computer scientists, however, generally feel that these approaches do not lead to a clear understanding of the shifts in thinking and approach that are necessary and facilitated when computing technology is incorporated into problem solving. Yet with the increased use of the term “computational thinking,” there has arisen considerable debate about exactly what it means, who should be expected to do it, and in what contexts. The confusion about what CT means is even apparent in nontechnical discourse. An example of this is found in a March 2012 article in the *New York Times* [3] in which the author conflates “understanding of computational processes” and “the general concepts programming languages employ.”

In 2010, the National Research Council’s Committee for the Workshops on Computational Thinking identified an ongoing need in the field to “build consensus on the scope, nature, and structure of computational thinking.” To some extent, the lack of consensus stems from disagreement about the level of granularity used in the definition. This has led to a set of questions that are at the heart of discussions about CT. Does CT refer to the ways in which we change our thoughts about a problem and its possible

solution when we know we can incorporate computing? Is CT about managing layers of abstraction through use of computation, or should it explicitly involve detailed computing concepts such as state machines, formal correctness, recursion, and optimization [2]? Is there a set of analytical skills, unique to computing disciplines, that *all* people should develop? Is there a distinction between doing CT and effectively applying computation to solve problems? Is CT something other than simply saying “let’s apply computing to solve a problem in X (e.g., biology, economics, literary analysis, etc.)”? Finally, who is best equipped or best suited to teach CT to those outside of computer science? Should it be computer scientists, or should it be disciplinary specialists?

2.2 Definitions of Computational Thinking

The term “computational thinking” was first introduced by Seymour Papert [4] in a 1996 paper about math education. It was next brought into use by Jeanette Wing in 2006 [5] and subsequently clarified by her in later work (e.g., [6,7]). Since 2006, there have been various attempts to clarify and redefine the term, as well as efforts to articulate the ways in which CT should shape K-12 and college level education and pedagogy. There is not yet consensus about what is meant by the term, especially across educational levels, though a wide range of activities have evolved that are enriching educational practices in computer science and related fields.

In his paper, Papert [4] laid out several approaches to solving a geometric problem, all of which could be implemented using software packages or programming approaches: a probabilistic approach, a standard Euclidean solution, and a heuristic approach that was used to create a supporting visualization. This led Papert to identify two ways in which computers are typically used to contribute to problem solving. The first, evident in the probabilistic approach, is to use the computer as a high-speed data analysis tool, able to evaluate many values and generate an answer. The second, in the Euclidean approach, is to use the computer to provide an alternative to building geometric representations by hand. In both the cases, the computer quickly and effectively generates a solution, but does so using representations that have no clear connection to the original problem and do not bring clarity to the solution. Papert argued that a computationally thoughtful approach would allow one to address his fundamentally geometric problem with a combination of different kinds of computer approaches, making it possible to use the computer to solve problems in ways that “forge ideas,” that allow one to carry out heuristic approaches, and that actually help people better analyze and explain the problem, the solution, and the connection between them.

At her most basic, Wing defines CT as a problem-solving and system design approach that “draws on concepts fundamental to computing” [6] and as the “thought processes involved in formulating problems and their solutions so that the solutions are represented in a form that can be effectively carried out by an information-processing agent” [7]. Key to CT, in Wing’s view, are the layers of symbolic abstractions of data, processes, and equipment that are used when problems are encoded so that they can be solved using a computer. She argues that the underlying computing device forces a strictly computational problem-solving approach, yet she labels as computational various concepts and skills that predate the advent of computing and are used across numerous disciplines. By contrast, Papert argues that the use of computing devices, in combination with other fields of knowledge and *their* problem-solving approaches, enables rich, creative problem-solving methods that are new and not merely the computerization of an algorithm that already exists in another discipline.

The fundamental differences between Papert’s and Wing’s definitions lie in the relationship between computing and the problem domain, and in the genesis of the problem-solving strategy. Wing’s is a unidirectional view, basically asking the question “What would I have to do to get a computer to implement an existing solution to this problem?” [6]. In this view, the computer has a set of capabilities. Based on these capabilities, problems are expressed algorithmically, as a set of specific instructions that the computer can execute. Papert’s approach is bidirectional, using computing in concert with other problem-solving approaches to evolve new solution methods. He interprets “computation” broadly, not

just numerically, and sees the computer as an agent that can provide us with useful capabilities and encourage new ways of viewing a problem. It is this rich bidirectional perspective that allows us to address problems that lie at the intersection of disciplines, and is reflected in the development of new fields, such as bioinformatics, computational linguistics, and lexomics [8].

It is when Wing makes a distinction between shallow and deep CT [6] that she begins to approach Papert's view. While still rooted in a largely unidirectional view (choice of abstractions, modeling larger order-of-magnitude problems, hierarchical decomposition), she also considers that initial problem-solving steps can prompt new questions and new ways of viewing data. However, it is not clear that computing is necessarily the best means for teaching concepts such as abstraction, for example. In fact, abstraction is used quite differently in computing than in mathematics. In computing, abstraction is used as a way to express details so that they are manipulable by the computer, whereas in mathematics, underlying detail can be completely ignored or forgotten once the abstraction is created.

Much of the discussion about CT following Wing's 2006 article has followed a unidirectional approach, focusing on whether there is a set of experiences, knowledge, concepts, and skills that are necessary in order for people to be able to apply algorithmic solutions to problems in non-computer science fields. Is CT a definable set of concepts that can be taught? Are these concepts taught, by default, to computer science students, or is CT relevant only in the context of non-computer science disciplines? Should it be taught explicitly as a set of concepts and skills, or only implicitly through the combination of disciplinary knowledge and computational methods? These questions have arisen repeatedly in discussions of pedagogy and curriculum, particularly in K-12 where decisions ultimately depend on the age of the students as well as the context in which the teaching is being carried out. At the college level, we have to ask whether the goal is to expect a single person to have sufficient depth in both computing and another discipline, or whether the goal is to prepare people to bring their respective knowledge and skills to a conversation that can examine how computing and another discipline influence and serve each other. Overall, the discussion of CT has largely ignored the question of what level of exposure to computer science concepts and skills is necessary in order for people to achieve the bidirectional problem-solving insights that Papert presumed can take place.

Several writers have critiqued Wing's original definition of CT or tried to pose definitions that will lead more directly to curriculum and classroom practices. In many cases, a fundamental question raised is whether her definition is at all different than "algorithmic thinking" or "logical thinking." The critiques are summarized and expanded on by David Hemmendinger [9] who cautions against easy distortions of CT. Echoing Papert, he argues that computational metaphors may inspire new problem solutions (and the solving of new problems) in non-computer science disciplines. Hemmendinger points out that "thinking with computation" requires use of algorithms and a consideration of resources that would not be necessary if one were not planning on a computer implementation. Yet he cautions that a push for "computational thinking" is easily permuted into a call to make everyone think like computer scientists, when the goal should be to promote instances in which applications of computing facilitate explicative problem solutions.

At the 2012 ACM Turing Centenary [10], Turing Award recipient Dana Scott posed the question "Is computational thinking or algorithmic thinking something that one knows when he sees it, or can it be explained?" Interestingly, none of the responses delved into any distinction between computational and algorithmic thinking. Donald Knuth commented that algorithmic thinking has been present in works of past centuries, including thirteenth century Sanskrit writings about permutations in music. He discussed the importance of being able to fluently jump levels of abstraction, "seeing things in the small and the large simultaneously, and being able to go effortlessly to many levels in between." Christos Papadimitriou followed Knuth by saying that algorithmic thinking meant "being comfortable with detail, understanding that it is detail, being able to push it away and work without it, and then come back to it." Les Valiant added that we had to recognize the latent computational content of scientific objects and processes. This is an example of the implicit view of CT, not arguing that we should impose on a problem a computer science decision about the appropriate algorithmic solution, but rather suggesting

that we ask what data and algorithmic content is already present. This is particularly the case for biological applications in which nature has already provided considerable data encoding.

Papert introduced CT in an education-oriented context, based on the idea that “every time you learn something, you learn two things, the other being the model of learning you just used” [4]. The computer science community has understandably embraced CT, in part because we want people to learn *about* computing by learning via computing. Wing has also discussed CT in a context of core concepts and tools that should be taught to children in K-12, particularly taking advantage of children’s willingness to explore new technology devices. Subsequent to Wing’s call for “computational thinking for everyone,” many efforts were undertaken to incorporate CT into the K-12 educational landscape and into the college experience. In the following sections, we discuss a number of these efforts.

Despite the lack of consensus within the community about what CT is, there does seem to be consensus that students at all levels will benefit from exposure to and increased practice with computing-related concepts and skills. Depending on the degree and type of exposure, students will better understand the role that computing can play in the formulation and execution of problem solutions. This will ultimately help them engage in collaborative problem solving across a range of disciplines, either as a disciplinary specialist with an understanding of computation or as a computer scientist who can collaborate with disciplinary specialists. Certainly, there is no denying that the increasing use of computational methods in many disciplines, and the development of new interdisciplinary fields that include computing, requires that we educate students in a manner that prepares them to do that work.

This still leaves open, however, the question of whether there truly are core aspects of computing that everyone needs to understand. The National Science Foundation (NSF), in their 2009 CPATH solicitation (CISE Pathways to Revitalized Undergraduate Computing Education) [11], loosely defined CT as “competencies in computing concepts, methods, technologies, and tools” [12]. On their FAQ site, they said “NSF has described a broad CT framework, but does not attempt to define the computing constructs. You are invited to join in the definition and articulation of the computing constructs that have permeated and transformed our modern world and to use these to develop methods, curricula, and pedagogies to assure that all students are able to think computationally.” The CPATH program focused primarily on college and university interventions, but also considered K-12 interventions in situations where they were tied to transition into an undergraduate program that involved CT. By contrast, the subsequent NSF CE21 solicitation (Computing Education for the twenty-first century) gives no definition of CT at all, simply saying that “Efforts can focus on computational thinking as taught in computing courses or infused across the curriculum” and will “increase ... knowledge of computational thinking concepts and skills” [13].

2.3 College and University

There are numerous examples of the infusion of computing and computer science content into non-computer science courses and non-computer science disciplines. While many do not explicitly mention CT, these efforts generally have a goal of exposing students to interdisciplinary applications of computing. We present a few examples, both individual courses at different curricular levels and efforts at larger programmatic or institutional change.

2.3.1 Individual Courses

2.3.1.1 Computing for Poets

Professor Mark LeBlanc of Wheaton College (Norton, MA) developed the course *Computing for Poets* [14], which focuses on the use of computers to analyze written text. It involves a number of “computational thinking skills,” including problem decomposition, algorithmic thinking, and experimental design. A key focus is on developing programs that can address new questions about texts, rather

than relying solely on existing text analysis tools. This course has been developed in the context of the Lexomics project [15] in which various computational and statistical methods are combined with existing text analysis approaches, leading to methods for answering new questions about ancient texts. The course is connected to two English courses, one on Anglo-Saxon Literature and another on J.R.R. Tolkien. This connection of courses gives students firsthand experience devising problem-solving methods that combine traditional and computational approaches, allowing them to ask new questions, and then ask whether bringing the power of computing to literary analysis leads to the formulation of new answers.

2.3.1.2 Computational Microeconomics

Professor Vincent Conitzer of Duke University developed the course *Computational Microeconomics* [16], which was intended to introduce undergraduates to work at the intersection of economics and computer science. The course is usually taken by students from computer science, economics, math, and electrical and computer engineering. It has minimal prerequisites and starts with an introduction to linear and integer programming, along with the MathProg language and the GNU Linear Programming Kit. The remainder of the course focuses on economics topics such as expressive marketplaces, game theory, Bayesian games, and auction design. The students work on both written and programming assignments and do a small (possibly team) project that involves programming. This course provides students with firsthand experience in working at the intersection of two disciplines.

2.3.1.3 Advanced Algorithmic Techniques for GPUs

In the context of a course on Advanced Algorithmic Techniques for GPUs (graphical processing units), two researchers from the visual computing technology company NVIDIA, Wen-mei Hwu and David Kirk, present a lengthy list of areas in which GPU computing is being used. They include a range of computing, business, scientific, and engineering applications such as financial analysis, digital audio and video processing, scientific simulation, computer vision, and biomedical informatics. The inference is that people from a range of backgrounds and disciplines are increasingly in a position to try to use GPUs, or to coordinate with computer scientists who will use GPUs. This is underscored when they put forward a definition of CT skills: “The ability to translate/formulate domain problems into computational models that can be solved efficiently by available computing resources” [17]. The goal of their course is to make commonly used many-core GPU techniques accessible to scientists and engineers, claiming that “computational thinking is not as hard as you may think it is.” They further define CT skills as

- Understanding the relationship between the domain problem and the computational models
- Understanding the strengths and limitations of the computing devices
- Defining problems and models to enable efficient computational solutions

2.3.2 Institutional Change

2.3.2.1 Bowdoin College

Bowdoin College is beginning to take steps toward institution-wide change, with initial discussion of the importance of some form of CT across the curriculum. Bowdoin’s president, Dr. Barry Mills, addressed this in his 2012 baccalaureate address to graduates [18]. Speaking about the role of information and the ability to interpret information, Mills addressed CT as a “mode of inquiry” in the curriculum. While citing Wing’s 2006 definition, Mills put forth that it is possible to “engage computational thinking and analysis” across disciplines that span the sciences, social sciences, and humanities. Rather than arguing for the direct application of computing, he argues for the integration of disciplines with “a rapidly changing landscape of data, information, and knowledge,” seeing this as an important step for the continued development of liberal arts education.

The perspective put forward by Dr. Mills is an indication of the extent to which leaders of educational institutions are beginning to grapple with some definition of CT as an educational priority.

2.3.2.2 DePaul University: Computational Thinking across the Curriculum

Faculty at DePaul University, led by Professors Amber Settle and Ljubomir Perkovic, undertook a project [19] designed to incorporate CT into the DePaul curriculum at all levels, using their Liberal Studies (general education) courses as the vehicle to accomplish this. The DePaul project leaders recognized that Wing's original definition of CT was problematic, in part because she gave no examples from outside the sciences and quantitative social sciences. They began their project by defining CT as "the intellectual and reasoning skills that a professional needs to master in order to apply computational techniques or computer applications to the problems and projects in their field." This definition hews closely to Wing's approach, though they argue in their project documents that hers is not a new way of thinking, pointing to a number of examples that significantly predate her article. However, they make a distinction between the implicit use of CT within various fields and the explicit recognition of the use of computationally oriented reasoning skills. The underlying principle of the DePaul project was that it could only be successful if faculty across disciplines agreed on a useful framework for implementing CT in their courses.

In order to convince faculty from other fields to participate, the project leaders developed a set of examples from a range of disciplines, based on categories of CT that they defined using Peter Denning's "Great Principles of Computing" [20]. Denning, preceding Wing's article by several years, put forward a set of principles with the goal of showing people in other disciplines "how to map the principles into their own fields." The DePaul project offered definitions of each principle (computation, communication, coordination, recollection, automation, evaluation, and design) and gave examples of how CT has been used in a number of disciplines. Ultimately, the project included 18 faculty at DePaul who modified 19 Liberal Studies courses. The project leaders also collaborated with six teachers at the University of Chicago Lab Schools in order to also explore middle school and high school course modifications [21].

2.3.2.3 Union College: Creating a Campus-Wide Computation Initiative

Union College [22], with NSF funding, carried out a five-year project to create a campus-wide computation initiative. The goal of the project was to provide an appropriate foundation in computing for non-computer science students who are or should be using computing in the context of their discipline. There were two key elements:

1. Provide engaging introductory computer science courses, open to all students on campus. The department offers six theme-based courses: big data, robotics, game development, artificial intelligence, media computation, and programming for engineers.
2. Support infusion of a computing component into non-computer science courses.

To date, 24 faculty from 15 disciplines, working with summer research students, have developed computational components for over two dozen courses. These efforts were also extended to three other undergraduate institutions, with faculty-student teams at Mount Holyoke College (Music), Denison College (Geology), and Bard College (Computer Science and Literature). The nature of the computational modules is quite varied, with no common set of key concepts or skills across all of the courses. The key result, however, is that a majority of students taking the infused courses have reported that the computational component helped them understand the disciplinary material. In addition, in line with Papert's definition of CT, faculty and students alike have been able to move forward with new research efforts and new class exercises because incorporating a computational element allows them to ask new questions and combine data in new ways. Very few of the infused courses, however, have an explicit programming component, or any explicit discussion of concepts such as abstraction, problem decomposition, etc., beyond what would normally take place in the context of that discipline.

2.4 K-12

Considerable effort has been made to address content and pedagogy issues regarding CT in K-12. Despite the lack of consensus about exactly what CT is, numerous attempts have been made to bring component elements into the K-12 classroom. Each K-12 effort reflects an inherent definition of CT, with a resulting view of what should be introduced and how it should be incorporated into the classroom setting (as separate content, or integrated with existing curricular content). Concepts often considered part of CT that have been introduced across the array of K-12 activities include iterative refinement, problem decomposition, connections between social systems and physical systems, modeling of abstraction, continuous versus discrete data, Boolean operations, causal relationships, searching for patterns, data mining, and complexity. These concepts are introduced either through general subject areas or through domain-specific content, including scientific models (simple models of physical phenomena for younger children; more complex models for older students), visualization and large data sets, computational media, game development, genetics, and environmental simulations. Throughout the K-12 work, an important issue is the role of age and grade level in determining what students can do, and the transition from prebuilt examples and models to independent building or programming. Of course, competing pedagogies lead to different approaches based on how accessible the pedagogy makes different concepts and skills.

K-12 projects that are focused on teaching computer science can effectively sidestep the issue of how to define CT. Such courses (e.g., see Section 2.4.4) will cover concepts frequently considered part of CT because those are part and parcel of computer science. The Computer Science Teachers Association (CSTA) addresses grade level and implementation issues through a comprehensive set of curricular standards for K-12 computer science education [23]. These standards, divided into three levels, cover the introduction of fundamental concepts of computing at all levels, as well as additional secondary-level computer science courses. The curriculum is built around five complementary strands, one of which is CT (the others are collaboration; computing practice; computers and communication devices; and community, global, and ethical impacts).

The focus of the CT strand is to promote problem solving, system design, knowledge creation, and improved understanding of the power and limitations of computing. The CSTA uses the definition developed during a joint project with the International Society for Technology in Education (ISTE) (Section 2.4.1). The interdisciplinary view that CT is important for combining computer science with all disciplines can actually facilitate teaching it in lower grades since it does not necessitate specific detailed knowledge of computing on the part of teachers. For example, in grades K-3, the standard for CT is met if students can use certain technology resources to solve age-appropriate problems, use various tools to illustrate stories, and understand how to sort information. In grades 3–6, the standards are met by students understanding and using the basic steps of algorithmic problem solving, developing a simple understanding of an algorithm, and making a list of subproblems that contribute to the solution of a larger problem. These abilities continue to scale up for grades 6–9 and 9–12 so that eventually students can describe the software development process, understand sequence, selection, iteration, and recursion, compare techniques for analyzing massive data collections, etc.

2.4.1 CSTA and ISTE

The CSTA and the ISTE, with support from the NSF, undertook development of an operational (rather than formal) definition of CT for K-12 [24]. This effort, involving K-12 teachers, college faculty, and educational administrators, focused on a set of questions relevant to the K-12 setting (from [24]):

- What would CT look like in the classroom?
- What are the skills that students would demonstrate?
- What would a teacher need in order to put CT into practice?
- What are teachers already doing that could be modified and extended?

The consensus reached was that CT, in the K-12 setting, involves solving problems such that the solution can be implemented with a computer. Students will use concepts such as abstraction, recursion, and iteration, applying these across many subjects. This led to the identification of key concepts and capabilities, with examples of how these could be embedded in activities across the K-12 curriculum. This effort addresses an issue raised by Lu and Fletcher [25]. While agreeing with Wing's basic definition of CT, they argue for the gradual introduction of CT concepts through consistent terminology. Lu and Fletcher propose a *computational thinking language* of vocabulary and symbols that can be used from grades 3–12 to refer to computation, abstraction, information, execution, etc. Many disciplines involve problem solving and promote logical and algorithmic thinking, so active engagement of these practices across the disciplines will reinforce students' developing capabilities (such as designing solutions to problems, implementing designs, testing and debugging, etc.). In this sense, linguistic analysis of sentences in a Language Arts class may not seem inherently computational, but it will reinforce patterns of thinking that can be applied to problem solving in other fields. The full set of concepts and capabilities identified in the CSTA-ISTE effort includes data collection, data analysis, data representation, problem decomposition, abstraction, algorithms and procedures, automation, parallelization, and simulation. Examples are provided from computer science, math, science, social studies, and language arts. Finally, a set of resources provide concrete examples for classroom teachers [26,27].

2.4.2 UK Computing: A Curriculum for Schools

In 2012, the British Computing at School Working Group published the report *Computer Science: A curriculum for schools* [28]. The purpose of the report was to address the question of what constitutes computer science as a school subject. The authors present the following definition of CT, very much based on Wing: “a mode of thought that goes well beyond software and hardware, and that provides a framework within which to reason about systems and problems.” As might be expected in a document focused on computer science learning requirements, they see CT in the unidirectional way, as “the process of *recognising* aspects of computation in the world that surrounds us, and *applying* tools and techniques from computing to understand and reason about ... systems and processes.” They further argue that students are empowered by the combination of CT, computing principles, and a computational approach to problem solving.

Like the CSTA-ISTE project, the Computing at School group presents a detailed breakdown of what students should know about computing and computer science, and what they should be able to do at each academic level (roughly equivalent to grades K-2, 2-5, 5-8, and 8-10). The set of concepts is roughly equivalent to the CSTA-ISTE set, focusing on algorithms, programs, data, computers, and communication. Whereas the CSTA-ISTE project identifies ways in which the key concepts and capabilities could be addressed in non-computing disciplines, the Computing at School group does not address how the material should be taught. They do, however, provide a very clear set of “attainment targets” for each level student, demonstrating increased mastery as students progress.

2.4.3 Computational Science and Computational Science Thinking

The slogan of the Shodor Foundation [29] is “Transforming Learning Through Computational Thinking.” Their focus is on computational science, combining quantitative reasoning, analogical thinking, algorithmic thinking, and multiscale modeling. They want students to develop the math and computing knowledge and skills necessary to generate and understand computational results across a number of disciplines. (Part IV of this volume describes advances in computational science, including computational biology, bioinformatics, astrophysics, chemistry, scientific visualization, and other areas.) The Shodor Foundation provides resources for both faculty and students, including free online workshop materials that focus on model building, simulation, and model-based reasoning in various math and science disciplines (such as astronomy and astrophysics, biomedical science, computational chemistry, environmental science, forensic science, and physics). Without an overt emphasis on CT, Shodor also

provides instructional materials for various levels of K-12 that support student facility with underlying math and technology (databases and spreadsheets, graphics and visualization, and scientific computing, for example). Given the nature of their materials, much can be used either inside the classroom in a formal setting or outside the classroom in an informal education setting.

For college and university faculty, Shodor provides discipline-specific workshops that focus on the use of computation (e.g., computational biology, computational chemistry) as well as workshops that focus more generally on the use of parallel and cluster computing in computational science. A related effort is found in the *INSTANCES* project, Incorporating Computational Scientific Thinking Advances into Education and Science Courses [30]. The focus of this project is to introduce K-12 teachers, through a series of modules, to computing in the context of scientific problems, viewing computational science as the solution of scientific and engineering problems using the “combination of techniques, tools, and knowledge from multiple disciplines,” combined with computer simulations. Like the Shodor Foundation (part of the *INSTANCES* project), they argue that the problems that are central to computational science form an important core for science, math, and computer science education. They define computational science thinking (CST) as “using simulation and data processing to augment the scientific method’s search for scientific truth for the realities hidden within data and revealed by abstractions.” Each module details the learning goal and objectives, activities, products that will be generated by students, and discussion of the embedded CST. The modules cover areas such as exponential spontaneous decay, exponential biological growth, bug population dynamics, and projectile drag.

2.4.4 Exploring Computer Science, CS Principles

A number of efforts are aimed at increasing high school-level interest in computer science, particularly in ways that will encourage students to continue with computer science study in college. These efforts address CT to the extent that a student just learning about computer science would be encouraged to consider applications of computing to other disciplines.

Exploring Computer Science (ECS) [31] is a one-year college-preparatory course that evolved out of efforts to involve in computer science a larger number of underrepresented students in the Los Angeles Unified School District. The course is focused on computer science concepts, with the following key instructional units:

- Human Computer Interaction
- Problem Solving
- Web Design
- Introduction to Programming
- Data Analysis
- Robotics

The course is designed to address “real world, socially relevant, interdisciplinary, and creative applications of computing” [31]. In that context, the developers identify three CT practices: algorithm development, problem solving, and programming (specifically related to real-life problems faced by students).

The goal of the CS Principles project [32] is the development of a new Advanced Placement Computer Science course. A set of six CT practices are listed as part of the Principles project, including analyzing problems and artifacts, communicating, and collaborating. The three practices that most directly involve computing are

1. Connecting computing, specifically identifying its impacts, describing connections between people and computing, and explaining connections between computing concepts
2. Developing computational artifacts, using appropriate techniques and appropriate algorithmic and information management principles
3. Abstracting, which involves representation, identification of and use of abstractions in computation or modeling

These are reasonable, and not unexpected, practices to incorporate into a computer science course, and will be taught to students who are already committed to studying at least introductory computer science.

2.5 Changes to Computer Science

As discussed earlier, a bidirectional view of CT has led to the development of new disciplines, and it has also led to changes in computer science as a field. Computer science has become a driving force of innovative practices and new knowledge. The combination of computing power, existing and new computing techniques, and disciplinary knowledge leads to the identification of new problems and the development of new solution methods. An early example (1988) of this is the Human Genome Project, when computer science was faced with a “big data” problem. This led to efforts to build parallel sequence analysis algorithms, better visualization tools, mechanisms to distribute databases, new pattern recognition algorithms, and gene modeling algorithms. Today, we may think of this work within the disciplines of genomics or computational biology, but its origins were in efforts to determine how best to combine computing with biological knowledge and methods to solve a new problem. Similarly, data mining and information retrieval methods were advanced in the context of the genome project, and today are employed to solve problems relevant to a host of disciplines.

Beyond the above connections, the relationship between biology and computer science is extremely bidirectional. Initially, there were two separate efforts, with computational methods to solve biological problems and the study of biological systems to derive new optimization methods for computing. Increasingly, however, computing and biology have supported each other in new ways, based on a view of biological processes as algorithms and information processing systems that solve real-world problems. In an extensive survey [33], Navlakha and Bar-Joseph focus on coordination, networks, tracking, and vision as examples of areas in which an information processing view has led to better understanding of biological properties *and* led to the improvement of computational systems. They report on research on problems that can be addressed both computationally and biologically. A model constructed for the biological problem can then be used to improve the solution to the computational problem. For example, they cite research in visual processing computational neuroscience that is leading to new models of human visual processing, which in turn is leading to better algorithms for computer vision. The bidirectional connections between biology and computer science demonstrate that commonalities between computational and biological processes allow solutions to problems in one area to apply to problems in the other.

Terrain analysis (see Chapter 46) is another domain in which new computer science methods had to be developed if computing was to be used effectively as part of new problem-solving approaches. Terrain analysis involves applying computational models to very large global positioning system (GPS) data sets (replacing surveyor data) in order to analyze terrain features, particularly important for environmental modeling and land use management. The use of digital, remotely acquired, data for terrain analysis allows for the analysis of very remote, relatively unexplored areas for which actual on-site surveying would be prohibitive. The use of digital data for terrain analysis, however, has necessitated evolution of interpolation methods, visualization of the relevant GPS data, animation, and other areas of computer graphics. In general, the sizable number of tools available ([34] gives examples) is a clear indication of the extent to which the analysis of geographic information system data has become a critical part of certain fields, and computer science has developed the techniques necessary to meet the analysis needs.

There are also humanities disciplines and humanities research that present opportunities for computing to support research and for the demands of research to push developments in computing. One such area, underscored by a NSF and National Endowment for the Humanities (NEH) grant program, is documenting endangered languages [35]. The goal is to “exploit advances in information technology to build computational infrastructure for endangered language research.” The solicitation is explicit that funding can support fieldwork efforts related to the recording, documenting, and archiving of languages, but also will support preparation of “lexicons, grammars, text samples, and databases,” with an interest in data management and archiving. This is clear recognition that the

necessary computing infrastructure to address the problem of endangered languages may not yet exist. Therefore, the aggregate of projects in this area have to address both the humanities side and the computing side of the problem, and that work on both sides will be informed by understanding and knowledge of the other.

2.6 Summary

The increasing ubiquity of computing and increased focus on “big data” make it possible for almost every discipline to consider new questions or address longstanding problems. In some instances, the methods for solving those problems are already clear, requiring straightforward applications of computing in order to implement existing algorithms. In other situations both disciplinary and computing knowledge, the bidirectional form of CT, must be utilized to develop new solutions. This will continue to lead to changes in existing fields, and to the formulation of new disciplines. There is not yet agreement on a single set of CT concepts and skills that all students should be taught. There is clearly increasing interest, however, in broadening student exposure to elements of computing, preparing those in computer science and those in other fields to better contribute to interdisciplinary applications.

Acknowledgments

The author thanks Chris Stephenson (Executive Director, CSTA), Amber Settle (Associate Professor, DePaul University), and David Hemmendinger (Professor Emeritus, Union College) for their thoughtful feedback. Allen Tucker (editor and Professor Emeritus, Bowdoin College) provided a number of useful examples of ways in which computer science has been pushed by other fields.

University*

A *data structure* is a method for organizing large amounts of data so that it can be accessed efficiently. Any piece of software will almost certainly make use of fundamental data structures, and proper choices of data structures can have a significant impact on the speed of an application, while poor choices can make the application impractical for even modest-sized inputs. Consequently, the study of data structures is one of the classic topics in computer science. Most data structures can be viewed as *containers* that store collections of items.

3.1 Types of Containers

All basic containers support retrieving, inserting, and removing an item, and the basic containers differ in which items can be efficiently accessed. Containers also often provide a mechanism for viewing every item; in languages such as C++, C#, and Java, this is implemented with an *iterator* and a language *for loop construct*.

A *sequence container* stores items in a linear order, and an item is inserted at a specified position. Examples of sequence containers include *fixed-sized arrays*, *variable-length arrays*, and *linked lists*. Typically, retrieval is based on finding an item given a position; testing whether some item present in the list is likely to devolve into a sequential search and be inefficient.

A *set* container stores items without linear order and thus can provide for more efficient retrieval. Some sets will guarantee that items can be viewed in sorted order; others provide no such guarantees. Examples of sets include *search trees*, *skip lists*, and *hash tables*. In some languages, sets can have duplicates.

A *map* container allows searching for key/value pairs by key. Although the interface is different from the set container, the underlying data structures used for efficient implementation are the same.

A *priority queue* container provides access only to the minimum item. An efficient implementation of a priority queue is the *binary heap*.

Some containers are designed specifically for searching of text. Examples include *suffix trees* and *radix search trees* [1–3].

3.2 Organization of the Chapter

The remainder of this chapter focuses primarily on the fundamental container types, namely, the sequence containers, ordered and unordered sets, and the priority queue. We also discuss one data structure that is not a container: the *union/find data structure*. After examining the fundamental data structures, we discuss the recurring themes and interesting research challenges seen in the design of data structures.

3.2.1 Sequence Containers

A *sequence container* stores items in a linear order, and an item is inserted at a specified position. Typically, retrieval is based on finding an item given a position; testing whether some item present in the list is likely to devolve into a sequential search and be inefficient. If items can be accessed, inserted, and removed from only one end, the container is a *stack*. If items can be inserted at one end (typically the back) and removed only from the other end (the front), then the container is a *queue*. If all operations are allowed at both ends, the container is a *double-ended queue* [4].

3.2.1.1 Fixed-Size Arrays

A fixed-sized array is usually a language primitive array, as in C++ or Java. Items are accessed by the array-indexing operator, and the fixed-size array is often used as a building block for resizable arrays. In many cases, particularly when insertions and deletions are rare, fixed-sized arrays are the fastest sequence container.

3.2.1.2 Resizable Arrays

Resizable arrays allow efficient access to an item by specifying its position (an array index) and also efficient adding and removal of an item, provided that the position is at or very close to the high index. Inserting new items near the low index is inefficient because it requires pushing all the subsequent items one index higher in the array; similar logic applies for removing items near the front. Resizable arrays are often implemented by using a primitive array and maintaining a current size; the primitive array is replaced with a larger array if capacity is reached. If the array size is increased by a multiplicative factor (e.g., it is doubled) then the amortized overhead incurred by the expansion is constant time. The C++ `vector` and Java `ArrayList` are examples of resizable arrays.

3.3 Linked Lists

In a linked list, items are not maintained in (logically) contiguous order; this potentially avoids the problem of having to move large numbers of items during an insertion or deletion. In a *singly linked list*, a *node* stores an item along with a link to the next node in the list. Additionally, the size of the list and a link to the first item are stored. This gives $O(1)$ access time for adding, removing, or accessing the first item. If a link to the last item is also stored, we obtain $O(1)$ access time for adding or accessing the last item. If each node contains both the next and previous item in the list, we obtain a *doubly linked list*. Although the doubly linked list uses more space than the singly linked list, it supports the removal of the last item in $O(1)$ time and allows bidirectional traversal of the list.

FIGURE 3.1 Insertion into a doubly linked list.

	Resizable Array	Singly-Linked List	Doubly-Linked List
addFront	$O(N)$	$O(1)$	$O(1)$
addBack	$O(1)$	$O(1)$	$O(1)$
addAtIndex	$O(N)$	$O(N)$	$O(N)$
addAfterIterator	$O(N)$	$O(1)$	$O(1)$
addBeforeIterator	$O(N)$	$O(N)$	$O(1)$
removeFront	$O(N)$	$O(1)$	$O(1)$
removeBack	$O(1)$	$O(N)$	$O(1)$
removeAtIndex	$O(N)$	$O(N)$	$O(N)$
removeIterator	$O(N)$	$O(1)^*$	$O(1)$
getByIndex	$O(1)$	$O(N)$	$O(N)$
advanceIterator	$O(1)$	$O(1)$	$O(1)$
retreatIterator	$O(1)$	$O(N)$	$O(1)$
contains	$O(N)$	$O(N)$	$O(N)$
remove	$O(N)$	$O(N)$	$O(N)$

FIGURE 3.2 Running times for operations on sequential containers. * represents constant time if we are presented with the node prior to the one actually being removed; $O(N)$ otherwise.

Figure 3.1 shows how a new node is spliced into a doubly linked list (the reverse process also shows the removal).

Accessing of an item by specifying its index position is inefficient if the index is not near one of the list ends because the item can only be reached by sequentially following links.

Items can be inserted into the middle of a linked list with only a constant amount of data movement by splicing in a new node. However, an insertion based on providing an index is inefficient; rather these kinds of insertions are usually done by providing a link to the node itself using some form of an iterator mechanism.

Figure 3.2 summarizes the cost of the basic operations on the sequential containers.

3.4 Ordered Sets and Maps (Search Trees)

An *ordered set* stores a collection of unique items and allows for their efficient insertion, removal, and access. Iteration over the set is expected to view the items in their sorted order. An implementation using a sorted array allows for access of an item by using *binary search*. In a binary search, we compare the target item x with the item in the middle of the array. This either locates x or reduces to a search in either the lower or upper half of the array that can be resolved recursively. Since the recursion reaches a base case after in approximately $\log N$ steps,* the cost of an access is in $O(\log N)$ time; however, adding or removing items will take $O(N)$ time, because all items larger than the item being manipulated will need to be shifted one position in the array. Using a sorted linked list appears problematic because binary search requires accessing the middle item, and that operation is not efficiently supported by linked lists. Most set implementation use a different linked structure based on trees; typically, these are binary trees.

* Throughout, $\log N$ means $\log_2 N$.

FIGURE 3.3 Binary search tree (a) before and (b) after insertion of 9.

3.4.1 Binary Search Trees

In a *binary search tree*, each node stores an item and also contains a link to a left subtree and a right subtree. All items in the left subtree are smaller than the value in the node; all items in the right subtree are larger than the item in the node. The size of the tree and a link to the root node are also stored.

Figure 3.3a shows a binary search tree (the root is the node with item 15). Searching in a binary search tree starts at the root and branches either left or right depending on whether the item in a node is smaller or larger than the target. Either the target is found or we eventually reach the bottom. Thus, the search for 9 in the binary search tree in Figure 3.3a reports that 9 is not present, after visiting nodes containing 15, 6, and 12 in that order. Insertion of item x into a binary search tree proceeds in the same manner, by searching for x . If the item is found, the insertion will fail because duplicates are not allowed. Otherwise, the new item can be inserted at the exact point at which the search terminated, as shown in the insertion of 9 in Figure 3.3b. Removal of an item is slightly more complicated. If the item to remove is at the bottom of the tree (i.e., it is a *leaf*, having no children), it can be removed from the tree. If the item to remove has only one child (e.g., node 12 in Figure 3.3a), then it can be bypassed, as would be the case in a singly linked list. If the item to remove has two children, we leave the node in place and replace its value with the smallest value in the right subtree. This preserves the binary search tree order but creates a duplicate. The removal can be completed by removing the smallest value from the right subtree recursively.

The cost of any of insertion, removal, or access is dependent on the depth of the tree. If the tree is created by random insertions, the depth is $O(\log N)$ on average. However, for nonrandom insertion sequences, such as $1, 2, 3, 4, \dots, N$ that typically arise, the depth is $O(N)$, and thus, binary search trees are not suitable for general-purpose library implementations. Instead, slightly more advanced techniques are required in order to assure $O(\log N)$ behavior, which can be either a worst-case bound (balanced binary search trees), an expected-time bound (skip lists), or an amortized bound (splay trees).

3.4.2 Balanced Binary Search Trees

A *balanced binary search tree* is a binary search tree with a *balance condition* that guarantees that the depth of the tree is $O(\log N)$. With this balance condition in force, searching of a balanced binary search tree is identical to searching of a binary search tree but has an $O(\log N)$ worst-case guarantee. Insertion and removal in a balanced binary search tree are also identical to operations on a binary search tree, except that all nodes on the path from the accessed node back to the root must have their balance maintained and possibly restored. Examples of balanced binary search trees include *AVL trees* and *red-black trees*.

3.4.2.1 AVL Trees

The first balanced search tree was the *AVL tree* [5], and it is also one of the simplest to describe and implement. In an AVL tree, each node stores balance information (for instance its height), and the balancing property is that for every node, its left and right subtrees must have heights that differ from each other by at most 1.

The balancing property implies that the height of an AVL tree is at most approximately $\log_{\phi} N$, where $\phi = 1.618$ is the golden ratio, though in practice it is much closer to the optimal $\log N$.

Insertion of a new value x proceeds in the usual fashion as a binary search tree. This step will be $O(\log N)$ worst case, since the depth of the tree is now guaranteed. However, it potentially changes the height information of all nodes on the path from x to the root, and it may also violate the balance requirement. Thus, we follow the path from x back to the root, updating height information. If at any point a balance violation is detected, we repair the node by using a local *rotation* of tree nodes. Let α be the first node on the return path to the root whose balance is violated. There are four possible cases:

1. x was inserted into the left subtree of the left child of α .
2. x was inserted into the right subtree of the right child of α .
3. x was inserted into the right subtree of the left child of α .
4. x was inserted into the left subtree of the right child of α .

Note that cases 1 and 2 are mirror-image symmetries, as are cases 3 and 4. Hence, we focus on cases 1 and 3 only.

Case 1 is repaired with a single rotation as shown in Figure 3.4

Here, k_2 's left subtree is two levels deeper than k_2 's right subtree. By changing two links (k_2 's left child and k_1 's right child), the subtree becomes balanced. Once this subtree is reattached to the parent, the heights for the parent and all other nodes on the path to the root are all guaranteed to be unchanged from prior to the insertion of x .

Case 3 is repaired with a double rotation as shown in Figure 3.5

In this case, x is inserted into either subtree B or C , and one of those trees is two levels deeper than D (possibly both subtrees are deeper in the special case that all of A , B , C , and D are empty). B and C are

FIGURE 3.4 Single rotation (case 1) to fix an AVL tree. (a) Generic case before rotation, (b) generic case after rotation, and (c) rotation applied after insertion of 5.

FIGURE 3.5 Double rotation (case 3) to fix an AVL tree. (a) Generic case before rotation, (b) generic case after rotation, and (c) rotation applied after insertion of 7.

drawn $1\frac{1}{2}$ levels deeper, to signify this uncertainty, but the rotation shows that regardless of which tree is the deeper tree, the balance is repaired. Deletion in an AVL tree uses the same types of rotations, with more cases. Unlike insertion, a deletion may require a logarithmic number of rotations.

3.4.2.2 Red-Black Trees

Red-black trees [6] are currently used in both the C++ and Java libraries to implement ordered sets. Like AVL trees, they are balanced binary search trees with logarithmic depth that must be rebalanced after insertions or deletions. In a red-black tree,

1. Every node is colored either red or black.
2. The root is black.
3. If a node is red, its children must be black.
4. Every path from a node to a null link must contain the same number of black nodes.

The balancing rules guarantee that the depth of a red-black tree is at most $2\log(N + 1)$, though in practice it is much closer to the optimal $\log N$. Rebalancing is done by rotations and color changes, and red-black trees have the advantage that they can be implemented nonrecursively, with one top-down pass that incorporates rebalancing. The number of rotations needed for red-black trees is bounded by a constant.

3.4.3 Multiway Search Trees

In a multiway tree, each node can have k children, with the branching based on $k - 1$ keys per node. Examples of multiway trees include structures such as radix search trees and suffix trees (see Chapter 15) and B -trees [7,8], which we discuss briefly.

In a B -tree of order m , each non-leaf node has between $\lceil m/2 \rceil$ and m children (except that the root can have between 2 and m children if it is not a leaf) and all leaves are at the same level. Special cases of $m = 3$

and $m = 4$ are 2-3 trees and 2-3-4 trees. Interestingly, 2-3-4 trees are equivalent to red-black trees: a four-node is replaced with a black node and two red children; a three-node is replaced with a black node and one red child, and a two-node is replaced with a black node. If insertion of a new node would create an $(m + 1)$ th child for the node's potential parent, that parent is split into two nodes containing $\lceil m/2 \rceil$ and $\lfloor m/2 \rfloor$ children. As this adds a new child to the grandparent, the splitting process can potentially repeat all the way up until the root, in the worst case resulting in the creation of a new root with only two children. Deletion works in a similar manner by combining nodes. B-trees are widely used in the implementation of databases because large values of m will yield very shallow trees and minimize disk accesses.

3.4.3.1 Skip Lists

A *skip list* [9] implements an ordered set using a randomization strategy. As we described earlier in the section, binary search on a singly linked list does not work because it is difficult to get to the middle of the list. In a skip list, each node potentially stores many links. A level k node has k links, each storing a link to the next level i node for $1 \leq i \leq k$. As shown in the top of Figure 3.6, nodes 3, 9, 15, and 21 are level 1 nodes; nodes 6 and 18 are level 2 nodes; node 12 is a level 3 node; and there are currently no level 4 nodes. A header node is also provided, large enough to store the largest level.

To search the skip list, we use the highest levels to advance quickly, dropping down to lower levels when it is apparent that we have advanced too far. If levels are randomly assigned, and the probability that a node's level k is 2^{-k} , then on average there will be $O(\log N)$ levels, and we will spend only a constant amount of time on any level, yielding $O(\log N)$ expected performance for a search (here, the expectation is based on the randomness of the creating a level, not the particular input; see Chapter 11 for a discussion of randomized algorithms). Insertion is straightforward; as shown in the bottom of Figure 3.6, we create a new node with a randomly chosen level (level k is selected with probability 2^{-k}) and then it is spliced in at the points where search switched levels.

The primary advantage of the skip list is that it can be efficiently implemented in a multithreaded environment [10] and it is used in the standard Java library.

3.4.3.2 Splay Trees

A *splay tree* [11] is a binary search tree that stores no balance information yet provides a guarantee of $O(\log N)$ amortized cost per basic operation of insertion, removal, or access. In a splay tree, after a node x is accessed, it is repeatedly rotated toward the root until it becomes the root, a process that is called *splaying*. If the node is a child of the root, this is accomplished with a single rotation, which we call a *zig rotation* and which terminates the splaying step. Otherwise, let the node's parent be p , and its grandparent be g . Then we have four cases that are similar to an AVL tree:

1. x is the left child of p and p is the left child of g .
2. x is the right child of p and p is the right child of g .
3. x is the right child of p and p is the left child of g .
4. x is the left child of p and p is the right child of g .

FIGURE 3.6 Insertion into a skip list.

In cases 1 and 2, which are symmetric, we rotate p with g and then x with p . This is a *zig-zig rotation*. In cases 3 and 4, which are also symmetric, we rotate x with p and then x with g (this is a basic double rotation, known as a *zig-zag rotation* for splay trees). If this makes x the root, we are done; otherwise, we continue the splaying step.

Figure 3.7 shows the three types of rotations that can be involved in splaying, and Figure 3.8 shows how node 1 is splayed to the root. Splaying has the effect of roughly halving the length of long access paths.

A search in a splay tree is performed by a usual binary search tree search followed by a splay of the last accessed node. An insertion is performed by a usual binary search tree insertion, and then the inserted node is splayed to the root. A deletion is performed by first performing a search. This brings

FIGURE 3.7 Rotations in a splay tree: zig (top, a basic single rotation), zig-zag (middle, a basic double rotation), and zig-zig (bottom, unique to the splay tree).

FIGURE 3.8 Splaying node 1 to the root (two zig-zigs and one zig).

the item to delete to the root, at which point it can be removed, leaving just a left subtree and a right subtree. If either is empty, the deletion is easy to complete. Otherwise, the largest item in the left subtree can be accessed, bringing it to the root by a splay, and the right subtree can be attached to the new root of the left subtree.

The proof that splay trees take $O(\log N)$ amortized cost per operation is one of the classic results in amortized analysis.

3.5 Unordered Sets and Maps (Hashing)

An *unordered set* stores a collection of unique items and allows for their efficient insertion, removal, and access. Unlike an ordered set, iteration over the set is not expected to view the items in their sorted order, and thus, the items do not require the ability to be comparison ordered. Because the operations required for an unordered set are a subset of the ordered set operations, it is reasonable to expect that it can be implemented more efficiently.

3.5.1 Separate Chaining

The most common implementation of an unordered set is a *separate chaining hash table* [12]. In a separate chaining hash table, we maintain a collection of M buckets and provide a *hash function* that maps any item into a bucket index. If the hash function is reasonably chosen, then each bucket will have only N/M items on average. If N is $O(M)$, then each bucket will have constant size on average, and can be searched sequentially, and then updated as needed, all in constant average time. The items in the bucket will typically be maintained in a singly linked list.

3.5.2 Linear Probing

An alternative to separate chaining is *linear probing* [13]; we maintain a larger table (typically of size roughly $2N$) but only allow one item per bucket, thus avoiding the need to maintain linked lists. Let p be the position computed by the hash function for item x . When inserting, if position p is already occupied, we sequentially probe positions $p + 1$, $p + 2$, etc., until a vacant position is found (wrapping around to the start of the bucket array if needed). The average number of probes is determined by the load factor $\lambda = N/M$ and is approximately $(1 + 1/(1 - \lambda))/2$ for a successful search and $(1 + 1/(1 - \lambda)^2)/2$ for an insertion (or unsuccessful search) [14]. This is higher than the naïve estimate of $1/(1 - \lambda)$ that one would obtain if each probe was an independent random event, and translates to an average of 2.5 rather than 2.0 probes for insertion of an item into a half-full hash table, but significantly worse performance at higher load factors. This phenomenon is known as *primary clustering*: items that probe to different array slots (e.g., slots 6, 7, and 8) nonetheless attempt to resolve collisions in the same manner, thus creating long chains of occupied slots. Primary clustering was long thought to make linear probing a poor choice for hash tables, but it has recently reemerged as a popular choice due to its excellent locality of reference.

3.5.3 Quadratic Probing

Quadratic probing avoids the primary clustering of linear probing by using positions $p + 1^2$, $p + 2^2$, etc., again wrapping around as needed. Since $p + i^2 = (p + (i - 1)^2) + (2i - 1)$, the i th position can be computed from the $(i - 1)$ th position with two additions and a bit shift and, possibly, a subtraction if a wraparound calculation is needed [15,16]. Although quadratic probing has not been fully analyzed, its observed performance is similar to what would be expected without primary clustering, it is easy to implement, and it has locality properties that are similar to linear probing.

3.5.4 Alternative Hashing Schemes

Perfect hash tables [17] provide guarantees of constant access time, assuming that the items are known in advance. Using a random hash function, a primary hash table is constructed with N buckets; however, for each bucket i , if the bucket contains b_i items, the items will be stored in a secondary hash table of size b_i^2 , using a randomly generated hash function (each secondary hash table will use its own random hash function). This two-level scheme is shown in Figure 3.9.

If the total size of all the secondary hash tables exceeds $4N$, then we have picked an unlucky (primary) random hash function, and we simply pick a different hash function until the total size is no larger than $4N$. This will require only a constant number of attempts on average. In each secondary hash table, since there are b_i items and b_i^2 buckets, a collision occurs with probability less than $\frac{1}{2}$. Hence, only a constant number of attempts are needed to choose each secondary hash function until we obtain a collision-free secondary hash table. Once all this is done, at total cost of $O(N)$ to build all the tables, an access can be done in two table lookups. The perfect hash table can be extended to support insertions and deletions [18].

Cuckoo hash tables [19] provide $O(1)$ worst-case access using a relatively simple algorithm. In cuckoo hashing, we maintain two tables, each more than half empty, and we have two independent hash functions that can assign each item to one position in each table. Cuckoo hashing maintains the invariant that an item is always stored in one of its two hash locations. Consequently, the cost of a search is guaranteed to be $O(1)$, and the remove operation is likewise very simple. There are several alternative algorithms to insert an item x , all use the same basic concepts. If either of x 's valid locations is empty, then we are done. Otherwise, place x in one of the occupied locations, displacing some other element a . Then place a in a 's other valid location; if that other valid location was empty we are done; otherwise, we have displaced another element b , and we continue the same process until either we are able to place the most recently displaced item or we detect a cycle (or reach a threshold of displacement that indicates a high probability of a cycle). In this case, we choose a different random hash function and rebuild the table. If the tables are less than half empty, it is unlikely that a new random hash function is needed; however, the hash functions must be carefully chosen.

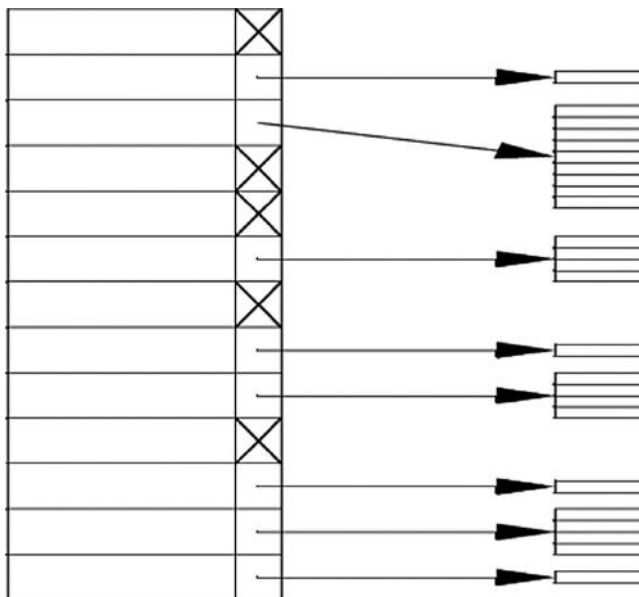

FIGURE 3.9 Perfect hash table.

3.5.5 Hash Functions

All implementations of hash tables presume the existence of a hash function that returns a suitable array index, which in modern languages will range from 0 to $M - 1$. Any hash function should satisfy basic properties:

1. If $x = y$, then $hash(x) = hash(y)$.
2. If $x \neq y$, then the collision probability that $hash(x) = hash(y)$ should be approximately $1/M$.

The hash function should be relatively easy to compute, since if it is a good function, the cost of computing the hash function will be a significant cost of any hash table operation.

Normally, the input values can be considered to be a long sequence of bits, so hash functions can be modeled as a mathematical operation on large integers. In such a case, $hash(x) = x \bmod M$ generates a hash code with the desired properties if the input values have a significantly larger range than 0 to $M - 1$ and if they are randomly distributed in that range. However, this hash function can be an unsuitable choice if, for example, M is a power of 2 and the low-order bits of all inputs are likely to be similar.

When random functions are needed, an alternative is to use a *universal hash function*, which provides the needed hash properties for all pairs x and y , where the collision probability for any pair (x, y) is taken over all choices of random functions [17]. One set of universal hash functions can be obtained by choosing a prime $p \geq M$ and then any random pair (a, b) such that $1 \leq a < p$ and $0 \leq b < p$, yielding

$$hash_{(a,b)}(x) = ((ax + b) \bmod p) \bmod M$$

An alternative scheme that is more efficient in practice is the multiply shift in [20].

An important use case for hash tables is storing strings. There have been many different hash functions proposed. The simplest that provides very good performance is the algorithm shown in Figure 3.10, implemented in C++. This function returns an unsigned integral type that can be brought into the proper range with a mod operation by the hash table implementation. Many choices of (a, h_0) have been used including $(31, 0)$ used in both the Java library and in [21]; other implementations replace addition with a bitwise-exclusive OR, some implementations perform the addition (or bitwise-exclusive OR) before the multiply, and implementations on 64-bit machines are likely to use large prime numbers for a .

Hash functions that are used in hash tables are generally reversible in the sense that it is possible to produce several inputs that map to the same output. *Cryptographic hash functions* are used to authenticate documents and store passwords; for these hash functions, it is infeasible to modify x without changing $hash(x)$, it is infeasible to produce an input y such that $hash(y)$ is some specified value, it is infeasible to recover x from $hash(x)$ even if a large number of x 's bits are known, and it is infeasible to produce a pair of inputs that compute the same output. Because cryptographic hash functions are expensive to compute, their use is primarily in computer security.

Chapter 11, which discusses randomized algorithms, has other material related to hashing (e.g., tabulation hashing, hashing with choices, and the analysis of cuckoo hashing).

```

1. size_t hash ( const string & key )
2. {
3.     size_t hashVal = h0;
4.
5.     for ( char ch : key )
6.         hashVal = a * hashVal + ch;
7.
8.     return hashVal;
9. }
```

FIGURE 3.10 Simple C++ hash function.

3.6 Priority Queues

A *priority queue* stores a collection of items and allows for their efficient insertion but allows removal (`deleteMin`) and access (`findMin`) of the minimum item only. Alternatively, sometimes priority queues are defined to allow removal and access of the maximum item only. Priority queues are used in diverse applications such as job scheduling, discrete-event simulation, sorting, and graph algorithms. As an example, suppose we want to merge k sorted lists containing a total of N items into one sorted list of N items. We can place the first item of each list in a priority queue and use `deleteMin` to select the smallest. We then insert the next item from the appropriate list in the priority queue, and repeat. After N insert and N `deleteMin` operations in a priority queue that never contains more than k items, we have successfully merged all sorted lists into one. This algorithm takes $O(N \log k)$ if priority queue operations are logarithmic.

In fact, priority queues can be implemented with a balanced binary search tree at logarithmic worst-case cost per operation. An alternative implementation that is likely to be faster and more space efficient is the binary heap.

3.6.1 Binary Heaps

A *binary heap* [22] stores items in a *complete binary tree*. In a complete binary tree, all levels are full except possibly the last level, which is filled in left to right with no missing nodes. A complete binary tree has at most $\lceil \log(N + 1) \rceil$ nodes on the path from the root to a bottom leaf and can be easily represented without using the normal links associated with a binary tree. Specifically, if we store the nodes in level order in an array whose index begins with 1, then the root is stored at index 1, and a node that is stored at index i will have its left child, right child, and parent stored at indices $2i$, $2i + 1$, and $\lfloor i/2 \rfloor$, respectively.

The items in the binary heap will also satisfy *heap order*: the value stored in any node is never smaller than the value stored in its parent. Figure 3.11 shows a binary heap and its representation in an array.

In a binary heap, the minimum item must be at the root. We can insert a new item x by creating an empty new node at the next available position and then placing x in the sorted position along the path from the newly created node to the root. Algorithmically, this involves moving the vacant node's parent into the vacant node until x can be placed into the vacant node without violating heap order and is easily seen to require at most $\log N$ comparisons. In this step, the vacant node moves up toward the root until x is finally placed in it. Figure 3.12 shows the insertion of 13 into a binary heap.

Figure 3.13 shows that removing the minimum item follows a similar process. The minimum item, which is at the root, is removed from the heap, thus vacating the root. The last node in the binary heap is removed, thus leaving one value, x , homeless. x is placed in the sorted position along the path from the root through smaller children. Algorithmically, this involves moving the vacant node's smaller child into the vacant node until x can be placed into the vacant node without violating heap order and requires at most $2\log N$ comparisons.

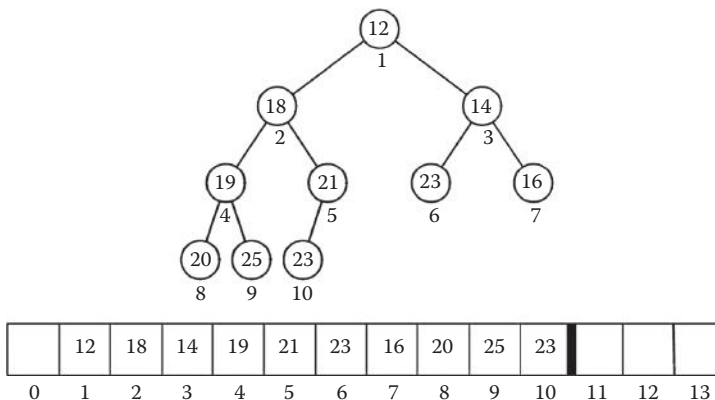

FIGURE 3.11 Binary heap and an array representation.

FIGURE 3.12 Initial binary heap; inserting 13 shows creation of new vacant node and the path to the root; 13 is inserted onto this path.

FIGURE 3.13 Initial binary heap; removing the minimum (12) vacates the root and displaces last item (23) path of minimum children is shown; 23 is placed by following path of minimum children.

A binary heap can also be constructed in linear time by placing the items in the binary tree without heap order and then repairing the heap order bottom-up [23].

If the position of an item is known, the item’s value can be either increased or decreased by generalizing the deletion or insertion algorithm; decreasing a value (decreaseKey) involves moving it up the tree toward the root, whereas increasing a value involves moving it down the tree through a path of minimum children; this operation takes $O(\log N)$ time. In some algorithms that use priority queues, such as computation of shortest paths, implementing the decreaseKey operation in $o(\log N)$ yields a faster running time. Thus, alternative priority queue schemes have been proposed, and most use linked heap-ordered tree structures that can be easily merged. Several examples include leftist heaps, Fibonacci heaps, and pairing heaps.

3.6.2 Mergeable Heaps

The first mergeable heap was the *leftist heap*, invented in 1972 [24]. A leftist heap is a heap-ordered tree with the “imbalance requirement” that for each node, the left subtree is at least as deep as the right subtree. The requirement forces the tree to lean left (hence its name); however, this property is easily seen to imply that the rightmost path has at most $\log(N + 1)$ nodes. Merging two leftist heaps simply involves merging right paths together and swapping left and right children of any node on the resulting right path that violates the leftist heap imbalance requirement and thus takes $O(\log N)$ time by virtue of the bound on the right path length. Insertion can be implemented as a merge with a one-node tree and is thus also $O(\log N)$. Removing the minimum is easily implemented in $O(\log N)$ by deleting the root node and merging its left and right subtrees.

Binomial queues [25] introduce the idea of using a heap-ordered tree that is not binary but of a restricted form known as a binomial tree and maintaining a priority queue as a collection of these heap-ordered binomial trees.

Fibonacci heaps [26] achieve $O(\log N)$ amortized cost for merge and deleteMin and $O(1)$ amortized cost for decreaseKey. This performance produces more efficient worst-case bounds for several graph algorithms, including Dijkstra’s shortest-path algorithm, but in general, Fibonacci heaps have overhead that limits its usefulness in practice. Fibonacci heaps introduce the idea of implementing decreaseKey by cutting a tree into two and also introduce the idea that there can be as many as $\Theta(N)$ trees while maintaining amortized efficiency.

Pairing heaps [27] were designed in the hope of matching Fibonacci heaps theoretical performance bounds while being simple to implement, and thus practical. A pairing heap is a single heap-ordered tree that is implemented by having each node store a link to its leftmost child and then having all siblings doubly linked. The leftmost child also stores a link back to its parent. Thus, in the bottom of Figure 3.14, each line between nodes represents one link in each direction.

To merge two pairing heaps, the larger root is made the new first child of the smaller root. We can treat an insertion as a merge of a one-node tree. To perform a decreaseKey of node p , we cut the subtree rooted at p from the tree and then merge the two resulting trees. Observe that all these operations take constant time.

Deleting the minimum, however, is more difficult. When the minimum is removed, what is left is a collection of subtrees (there could be N subtrees) that must all be combined back into one heap-ordered tree. There are several strategies, the best of which appears to be *two-pass merging* [28]. In the first pass,

FIGURE 3.14 (a) Pairing heap as a tree, and (b) pairing heap in left child, right sibling representation, using bidirectional links everywhere.

FIGURE 3.15 (a) Trees resulting from removal of root in Figure 3.14, (b) after first pass halves the number of trees, (c) first merge of the second pass, and (d) second merge of the second pass.

we merge each pair of heaps (see Figure 3.15b); then we work backward, merging the last two trees, then that result with the next tree, and so on (Figure 3.15c and d) until we obtain only one tree.

Although the performance of the pairing heap is excellent, the analysis of the pairing heap is still unresolved. It has been shown that if the amortized cost of merge and deleteMin are $O(\log N)$, decreaseKey is not $O(1)$. For a wide range of merging strategies, decrease Key's amortized cost will be $\Omega(\log \log N)$ and for two-pass merging, the cost has recently been bounded by $O(2^{2\sqrt{\log \log N}})$ [29,30].

3.7 Union/Find Data Structure

The *union/find data structure* is a classic solution to the problem of maintaining a partition of $\{1, 2, 3, \dots, N\}$ under the following operations:

- *initialize*: Creates N single element sets.
- *union*(s_1, s_2): Combines two sets s_1 and s_2 , destroying the original (thus maintaining the partition).
- *find*(x): Returns the set containing x (at the time of the query); most importantly, *find*(x) and *find*(y) return the same result if and only if x and y are in the same set.

```

1. class DisjointSets
2. {
3.     private:
4.         vector<int> p;
5.
6.     public:
7.         DisjointSets( int n ) : p( n, -1 ) // Size n, all -1s
8.         { }
9.
10.        void unionSets( int root1, int root2 )
11.        {
12.            if( p[ root2 ] < p[ root1 ] ) // More negative means larger root
13.                swap( root1, root2 ); // Make sure root1 is larger (or same)
14.
15.            p[ root1 ] += p[ root2 ]; // Update root1 size
16.            p[ root2 ] = root1; // Update root2 parent
17.        }
18.
19.        int find( int x )
20.        {
21.            if( p[ x ] < 0 )
22.                return x;
23.            else
24.                return p[ x ] = find( p[ x ] );
25.        }
26. };

```

FIGURE 3.16 Implementation of union by size with path compression.

The union/find operations can be used to maintain the connected components in an undirected graph and thus is a fundamental data structure in the implementation of spanning tree algorithms.

The most elegant approach to maintaining the partition represents each set as its own tree, with the root of the tree denoting the set name [31]. Each set also stores its size. Each node in the tree maintains a link to its parent only; thus, it is easy to provide an implicit implementation of this structure in a single array in which each entry that is not a root stores its parent and each entry that is a root stores its size information as a negative number.

To perform a union given two tree roots, we make the smaller tree a child of the larger tree and update the larger tree's size. This is clearly a constant-time operation. To perform a find, we simply follow parent links until we reach a root. The cost per operation is the number of nodes on the path to the root, which will be $O(\log N)$ if the union is done by size (because a node gets one level deeper only when its tree is combined into a larger tree, the size of the node's tree doubles every time it gets one level deeper). A simple optimization on the find known as *path compression* changes the parent of every node on the find search path to be the eventual root. With this optimization and union using the size rule (or a similar height rule), the amortized cost of a find operation is nearly constant and bounded by $O(\alpha(N))$, where $\alpha(N)$ is the exceptionally slow-growing inverse Ackermann function [32–34]. Figure 3.16 shows a complete C++ implementation (minus error checking) of the union/find data structure.

3.8 Recurring Themes and Ongoing Research

The study of data structures involves many recurring issues, most of which are still being actively researched, many of which lead into each other. We briefly discuss some of these, pointing especially to examples that we have already seen.

3.8.1 Static, Dynamic, and Persistent Structures

Static data structures restrict operations to access on the data and do not support updates. Examples in this chapter include the binary search and perfect hash table. *Dynamic data structures* support updates and are thus more complex; most of the data structures we have seen are of this type. Advanced data structures have been designed to maintain connected components and shortest paths in graphs even as the underlying structure of the graph can change. *Persistent data structures* support updates and allow operations on prior versions of the data structure. We have not examined any persistent data structures.

3.8.2 Implicit versus Explicit Structures

An *implicit data structure* stores the data using little extra memory, in such a way that the structure of the items can be implied without the need for extra storage for links between the items. Examples of implicit data structures include the binary heap and the union/find data structure. An explicit data structure is more typical and uses extra memory to link items together structurally.

3.8.3 Space versus Time Considerations

A recurring theme in data structures and algorithm design is the ability to trade space for time. The hash table is an example of a data structure in which the ability to use more space can save time; similarly, a doubly linked list will use more space than a singly linked list but has the advantage that some operations can be made faster because of the additional links.

3.8.4 Theory versus Practice

Although most data structures have theoretical asymptotic performance guarantees, usually expressed in Big-Oh notation, it is sometimes the case that the constants hidden in the Big-Oh notation can make it difficult to compare data structures with identical Big-Oh running times. Additionally, some bounds such as worst-case bounds can be overly pessimistic, leading to situations in which a theoretically inferior data structure performs better in practice than its counterpart with better run time guarantees. Examples include hash tables that are very difficult to compare based on the $O(1)$ run time per operation and also priority queues, in which the Fibonacci heap despite having the best time bound is generally outperformed by the pairing heap and binary heap (e.g., see [35]).

3.8.5 Modern Architecture Considerations

Because of many advances in computer hardware including multilevel memories and CPU design, experimental results for data structures can be very machine dependent, often requiring the designer to have several competitive alternatives to benchmark. For example, linear probing performs much better relative to other hash table algorithm on modern machines than on older computers. Multicore CPUs will require a reexamination of fundamental data structures that for the most part have been designed for single threaded efficiency (e.g., see [36]).

3.8.6 Data Structures for Specialized Types

Containers that work on types such as integers and strings have for many years been an active area of research. In particular, there has been much work designing priority queues for integers and containers for strings [37].

Key Terms

- AVL tree:** The first balanced binary search tree. Has a balance requirement that each node's left and right subtrees can have heights that differ by at most 1.
- Balanced binary search tree:** A binary search tree that adds a balance requirement to every node that guarantees the tree has $O(\log N)$ depth. Typically, this means that insertions and deletions must provide algorithms to maintain the balance requirement.
- Binary heap:** An implementation of a priority queue that uses only a simple array and supports insertion and deleteMin in logarithmic time.
- Binary search:** An algorithm to search a sorted array in $O(\log N)$ time by searching in the middle and recursing.
- Binary search tree:** An implementation of an ordered sequence collection that generally uses two links per node; without balancing, performance can be linear in the worst case but logarithmic on average.
- B-tree:** A multiway search tree often used for database systems.
- Complete binary tree:** A binary tree in which all levels are full, except possibly for the last level that is left-filled with no missing nodes. Used in the binary heap.
- Container:** Stores a collection of items.
- Cuckoo hash table:** A hash table implementation that uses two tables and two hash functions and supports constant worst-case access.
- Double-ended queue:** A sequence container in which operations are restricted to the front and back.
- Fibonacci heap:** An implementation of a priority queue that provides $O(1)$ amortized cost for decreaseKey.
- Hash function:** Maps items to array indices, with the property that if $x = y$, then $hash(x) = hash(y)$ and if $x \neq y$, then the collision probability that $hash(x) = hash(y)$ should be approximately $1/M$.
- Hash table:** An implementation of an unordered sequence collection that typically provides constant time search and update on average.
- Heap order:** In a priority queue that allows access to the minimum item, heap order means that every node's value is at least as large as its parent's value.
- Leftist heap:** The first efficient mergeable priority queue.
- Linear probing:** A hash table implementation that uses only a simple table and tries array slots sequentially starting from the hash value position until an empty slot is found.
- Linked list:** A sequence container in which the items are linked; can be singly linked, storing a link to the next item, or doubly linked, storing links to both the previous and next items.
- Map:** Stores key value pairs.
- Pairing heap:** An implementation of a priority queue that provides $o(\log N)$ amortized cost for decreaseKey, uses two links per node, does not require balance information, and performs very well in practice.
- Path compression:** In the union/find data structure, the process of changing the parent of every node on a find path to the root.
- Perfect hash table:** A hash table scheme that supports constant time access by using hash tables to resolve hash table collisions.
- Primary clustering:** A phenomena in linear probing in which keys with different hash values attempt to resolve to similar alternate locations, potentially resulting in poor performance.
- Priority queue:** A container in which only the minimum can be accessed and removed.
- Quadratic probing:** A hash table implementation that uses only a simple table and tries slots sequentially starting from the hash value position plus i^2 (starting with $i = 0$), until an empty slot is found.
- Queue:** A sequence container in which insertions are restricted to the back and access and removal is restricted to the front.
- Red-black tree:** A balanced search tree currently used in both the C++ and Java library.
- Rotation:** A process by which parent/child relations among a few nodes are changed, while retaining binary search tree order. Examples include single and double rotations for AVL trees and a zig-zig rotation for splay trees.

- Search tree:** An implementation of an ordered sequence collection that generally uses either binary trees or multiway trees.
- Separate chaining hash table:** A hash table scheme in which collisions are resolved by singly linked lists.
- Sequence container:** Stores items in a linear order, with items inserted at specified positions.
- Skip list:** An ordered container that uses linked lists with multiple forward pointers per node. A concurrent version is implemented as part of the Java library.
- Splay tree:** A binary search tree that maintains no balance information but that has $O(\log N)$ amortized cost per operation.
- Splaying:** The process in splay trees by which a node is rotated toward the root using zig, zig-zig, or zig-zag rotations.
- Stack:** A sequence container in which operations are restricted to one end.
- Union/find data structure:** Maintains a partition of $\{1, 2, \dots, N\}$ under a sequence of union and find operations at only slightly more than constant cost per find.
- Universal hash function:** A collection of hash functions such that for any specific $x \neq y$, only $O(1/M)$ of the hash functions in the collection yield $hash(x) = hash(y)$.

Further Information

Material in this chapter is based on the presentations in Weiss [15,16]. Other popular textbooks on data structures and algorithms include Cormen et al. [38], Sahni [39], and Sedgewick and Wayne [40].

We outline the basic methods of algorithm design and analysis that have found application in the manipulation of discrete objects such as lists, arrays, sets, and graphs, and geometric objects such as points, lines, and polygons. We begin by discussing recurrence relations and their use in the analysis of algorithms. Then we discuss some specific examples in algorithm analysis, sorting, and priority queues. In the final three sections, we explore three important techniques of algorithm design—divide-and-conquer, dynamic programming, and greedy heuristics.

4.1 Analyzing Algorithms

It is convenient to classify algorithms based on the relative amount of time they require: how fast does the time required grow as the size of the problem increases? For example, in the case of arrays, the “size of the problem” is ordinarily the number of elements in the array. If the size of the problem is measured by a variable n , we can express the time required as a function of n , $T(n)$. When this function $T(n)$ grows rapidly, the algorithm becomes unusable for large n ; conversely, when $T(n)$ grows slowly, the algorithm remains useful even when n becomes large.

We say an algorithm is $\Theta(n^2)$ if the time it takes quadruples when n doubles; an algorithm is $\Theta(n)$ if the time it takes doubles when n doubles; an algorithm is $\Theta(\log n)$ if the time it takes increases by a constant, independent of n , when n doubles; an algorithm is $\Theta(1)$ if its time does not increase at all when n increases. In general, an algorithm is $\Theta(T(n))$ if the time it requires on problems of size n grows proportionally to $T(n)$ as n increases. Table 4.1 summarizes the common growth rates encountered in the analysis of algorithms.

The analysis of an algorithm is often accomplished by finding and solving a recurrence relation that describes the time required by the algorithm. The most commonly occurring families of recurrences in the analysis of algorithms are linear recurrences and divide-and-conquer recurrences. In the following

TABLE 4.1 Common Growth Rates of Times of Algorithms

Rate of Growth	Comment	Examples
$\Theta(1)$	Time required is constant, independent of problem size	Expected time for hash searching
$\Theta(\log \log n)$	Very slow growth of time required	Expected time of interpolation search
$\Theta(\log n)$	Logarithmic growth of time required—doubling the problem size increases the time by only a constant amount	Computing x^n ; binary search of an array
$\Theta(n)$	Time grows linearly with problem size—doubling the problem size doubles the time required	Adding/subtracting n -digit numbers; linear search of an n -element array
$\Theta(n \log n)$	Time grows worse than linearly, but not much worse—doubling the problem size more than doubles the time required	Merge sort; heapsort; lower bound on comparison-based sorting
$\Theta(n^2)$	Time grows quadratically—doubling the problem size quadruples the time required	Simple-minded sorting algorithms
$\Theta(n^3)$	Time grows cubically—doubling the problem size results in an eight-fold increase in the time required	Ordinary matrix multiplication
$\Theta(c^n)$	Time grows exponentially—increasing the problem size by 1 results in a c -fold increase in the time required; doubling the problem size <i>squares</i> the time required	Traveling salesman problem

subsection, we describe the “method of operators” for solving linear recurrences; in the next subsection, we describe how to transform divide-and-conquer recurrences into linear recurrences by substitution to obtain an asymptotic solution.

4.1.1 Linear Recurrences

A linear recurrence with constant coefficients has the form

$$c_0 a_n + c_1 a_{n-1} + c_2 a_{n-2} + \cdots + c_k a_{n-k} = f(n), \quad (4.1)$$

for some constant k , where each c_i is constant. To solve such a recurrence for a broad class of functions f (i.e., to express a_n in closed form as a function of n) by the *method of operators*, we consider two basic operators on sequences: S , which shifts the sequence left,

$$S\langle a_0, a_1, a_2, \dots \rangle = \langle a_1, a_2, a_3, \dots \rangle,$$

and C , which, for any constant C , multiplies each term of the sequence by C :

$$C\langle a_0, a_1, a_2, \dots \rangle = \langle Ca_0, Ca_1, Ca_2, \dots \rangle.$$

Then, given operators A and B , we define the sum and product

$$(A + B)\langle a_0, a_1, a_2, \dots \rangle = A\langle a_0, a_1, a_2, \dots \rangle + B\langle a_0, a_1, a_2, \dots \rangle,$$

$$(AB)\langle a_0, a_1, a_2, \dots \rangle = A(B\langle a_0, a_1, a_2, \dots \rangle).$$

Thus, for example,

$$(S^2 - 4)\langle a_0, a_1, a_2, \dots \rangle = \langle a_2 - 4a_0, a_3 - 4a_1, a_4 - 4a_2, \dots \rangle,$$

which we write more briefly as

$$(S^2 - 4) \langle a_i \rangle = \langle a_{i+2} - 4a_i \rangle.$$

With the operator notation, we can rewrite Equation 4.1 as

$$P(S) \langle a_i \rangle = \langle f(i) \rangle,$$

where

$$P(S) = c_0 S^k + c_1 S^{k-1} + c_2 S^{k-2} + \dots + c_k$$

is a polynomial in S .

Given a sequence $\langle a_i \rangle$, we say that the operator $P(S)$ annihilates $\langle a_i \rangle$ if $P(S) \langle a_i \rangle = \langle 0 \rangle$. For example, $S^2 - 4$ annihilates any sequence of the form $\langle u2^i + v(-2)^i \rangle$, with constants u and v . In general,

The operator $S^{k+1} - c$ annihilates $\langle c^i \times \text{a polynomial in } i \text{ of degree } k \rangle$.

The *product* of two annihilators annihilates the *sum* of the sequences annihilated by each of the operators—that is, if A annihilates $\langle a_i \rangle$ and B annihilates $\langle b_i \rangle$, then AB annihilates $\langle a_i + b_i \rangle$. Thus, determining the annihilator of a sequence is tantamount to determining the sequence; moreover, it is straightforward to determine the annihilator from a recurrence relation.

For example, consider the Fibonacci recurrence

$$F_0 = 0,$$

$$F_1 = 1,$$

$$F_{i+2} = F_{i+1} + F_i.$$

The last line of this definition can be rewritten as $F_{i+2} - F_{i+1} - F_i = 0$, which tells us that $\langle F_i \rangle$ is annihilated by the operator

$$S^2 - S - 1 = (S - \phi) \left(\frac{S+1}{\phi} \right),$$

where $\phi = (1 + \sqrt{5})/2$. Thus we conclude that

$$F_i = u\phi^i + v(-\phi)^{-i},$$

for some constants u and v . We can now use the initial conditions $F_0 = 0$ and $F_1 = 1$ to determine u and v . These initial conditions mean that

$$u\phi^0 + v(-\phi)^{-0} = 0$$

$$u\phi^1 + v(-\phi)^{-1} = 1$$

and these linear equations have the solution

$$u = v = \frac{1}{\sqrt{5}},$$

and hence

$$F_i = \frac{\phi^i}{\sqrt{5}} + \frac{(-\phi)^{-i}}{\sqrt{5}}.$$

In the case of the similar recurrence,

$$\begin{aligned} G_0 &= 0, \\ G_1 &= 1, \\ G_{i+2} &= G_{i+1} + G_i + i, \end{aligned}$$

the last equation tells us that

$$(\mathcal{S}^2 - \mathcal{S} - 1) \langle G_i \rangle = \langle i \rangle,$$

so the annihilator for $\langle G_i \rangle$ is $(\mathcal{S}^2 - \mathcal{S} - 1)(\mathcal{S} - 1)^2$ since $(\mathcal{S} - 1)^2$ annihilates $\langle i \rangle$ (a polynomial of degree 1 in i) and hence the solution is

$$G_i = u\phi^i + v(-\phi)^{-i} + (\text{a polynomial of degree 1 in } i),$$

that is,

$$G_i = u\phi^i + v(-\phi)^{-i} + wi + z.$$

Again, we use the initial conditions to determine the constants u , v , w , and x .

In general, then, to solve the recurrence (4.1), we factor the annihilator

$$P(\mathcal{S}) = c_0\mathcal{S}^k + c_1\mathcal{S}^{k-1} + c_2\mathcal{S}^{k-2} + \cdots + c_k,$$

multiply it by the annihilator for $\langle f(i) \rangle$, write down the form of the solution from this product (which is the annihilator for the sequence $\langle a_i \rangle$), and use the initial conditions for the recurrence to determine the coefficients in the solution.

4.1.2 Divide-and-Conquer Recurrences

The divide-and-conquer paradigm of algorithm construction that we discuss in Section 4.3 leads naturally to divide-and-conquer recurrences of the type

$$T(n) = g(n) + uT(n/v),$$

for constants u and v , $v > 1$, and sufficient initial values to define the sequence $\langle T(0), T(1), T(2), \dots \rangle$. The growth rates of $T(n)$ for various values of u and v are given in Table 4.2. The growth rates in this table are derived by transforming the divide-and-conquer recurrence into a linear recurrence for a subsequence of $\langle T(0), T(1), T(2), \dots \rangle$.

To illustrate this method, we derive the penultimate line in Table 4.2. We want to solve

$$T(n) = n^2 + v^2T(n/v),$$

TABLE 4.2 Rate of Growth of the Solution to the Recurrence $T(n) = g(n) + uT(n/v)$, the Divide-and-Conquer Recurrence Relations

$g(n)$	u, v	Growth Rate of $T(n)$
$\Theta(1)$	$u = 1$	$\Theta(\log n)$
	$u \neq 1$	$\Theta(n^{\log_v u})$
$\Theta(\log n)$	$u = 1$	$\Theta[(\log n)^2]$
	$u \neq 1$	$\Theta(n^{\log_v u})$
$\Theta(n)$	$u < v$	$\Theta(n)$
	$u = v$	$\Theta(n \log n)$
	$u > v$	$\Theta(n^{\log_v u})$
$\Theta(n^2)$	$u < v^2$	$\Theta(n^2)$
	$u = v^2$	$\Theta(n^2 \log n)$
	$u > v^2$	$\Theta(n^{\log_v u})$

Note: u and v are positive constants, independent of n , and $v > 1$.

so we want to find a subsequence of $\langle T(0), T(1), T(2), \dots \rangle$ that will be easy to handle. Let $n_k = v^k$; then,

$$T(n_k) = n_k^2 + v^2 T\left(\frac{n_k}{v}\right),$$

or

$$T(v^k) = v^{2k} + v^2 T(v^{k-1}).$$

Defining $t_k = T(v^k)$,

$$t_k = v^{2k} + v^2 t_{k-1}.$$

The annihilator for t_k is then $(S - v^2)^2$ and thus

$$t_k = v^{2k}(ak + b),$$

for constants a and b . Expressing this in terms of $T(n)$,

$$T(n) \approx t_{\log_v n} = v^{2 \log_v n} (a \log_v n + b) = an^2 \log_v n + bn^2,$$

or

$$T(n) = \Theta(n^2 \log n).$$

4.2 Some Examples of the Analysis of Algorithms

In this section, we introduce the basic ideas of analyzing algorithms by looking at some data structure problems that occur commonly in practice, problems relating to maintaining a collection of n objects and retrieving objects based on their relative size. For example, how can we determine the smallest of the elements? Or, more generally, how can we determine the k th largest of the elements? What is the running time of such algorithms in the worst case? Or, on the average, if all $n!$ permutations of the input are equally likely? What if the set of items is dynamic—that is, the set changes through insertions and deletions—how efficiently can we keep track of, say, the largest element?

4.2.1 Sorting

The most demanding request that we can make of an array of n values $x[1], x[2], \dots, x[n]$ is that they be kept in perfect order so that $x[1] \leq x[2] \leq \dots \leq x[n]$. The simplest way to put the values in order is to mimic what we might do by hand: take item after item and insert each one into the proper place among those items already inserted:

```

1 void insert (float x[], int i, float a) {
2     // Insert a into x[1] ... x[i]
3     // x[1] ... x[i-1] are sorted; x[i] is unoccupied
4     if (i == 1 || x[i-1] <= a)
5         x[i] = a;
6     else {
7         x[i] = x[i-1];
8         insert(x, i-1, a);
9     }
10 }
11
12 void insertionSort (int n, float x[]) {
13     // Sort x[1] ... x[n]
14     if (n > 1) {
15         insertionSort(n-1, x);
16         insert(x, n, x[n]);
17     }
18 }
```

To determine the time required in the worst case to sort n elements with `insertionSort`, we let t_n be the time to sort n elements and derive and solve a recurrence relation for t_n . We have,

$$t_n \begin{cases} \Theta(1) & \text{if } n = 1, \\ t_{n-1} + s_{n-1} + \Theta(1) & \text{otherwise,} \end{cases}$$

where s_m is the time required to insert an element in place among m elements using `insert`. The value of s_m is also given by a recurrence relation:

$$s_m \begin{cases} \Theta(1) & \text{if } m = 1, \\ s_{m-1} + \Theta(1) & \text{otherwise.} \end{cases}$$

The annihilator for $\langle s_i \rangle$ is $(S - 1)^2$, so $s_m = \Theta(m)$. Thus the annihilator for $\langle t_i \rangle$ is $(S - 1)^3$, so $t_n = \Theta(n^2)$. The analysis of the average behavior is nearly identical; only the constants hidden in the Θ -notation change.

We can design better sorting methods using the divide-and-conquer idea of the next section. These algorithms avoid $\Theta(n^2)$ worst-case behavior, working in time $\Theta(n \log n)$. We can also achieve time $\Theta(n \log n)$ by using a clever way of viewing the array of elements to be sorted as a tree: consider $x[1]$ is the root of the tree and, in general, $x[2*i]$ is the root of the left subtree of $x[i]$ and $x[2*i + 1]$ is the root of the right subtree of $x[i]$. If we further insist that parents be greater than or equal to children, we have a *heap*; Figure 4.1 shows a small example.

A heap can be used for sorting by observing that the largest element is at the root, that is, $x[1]$; thus to put the largest element in place, we swap $x[1]$ and $x[n]$. To continue, we must restore the heap property which may now be violated at the root. Such restoration is accomplished by swapping $x[1]$ with its larger child, if that child is larger than $x[1]$, and the continuing to swap it downward until either it reaches the bottom or a spot where it is greater or equal to its children. Since the tree-cum-array has height $\Theta(\log n)$, this restoration process takes time $\Theta(\log n)$. Now, with the heap in $x[1]$ to $x[n-1]$ and

FIGURE 4.1 A heap—that is, an array, interpreted as a binary tree.

$x[n]$ the largest value in the array, we can put the second largest element in place by swapping $x[1]$ and $x[n-1]$; then we restore the heap property in $x[1]$ to $x[n-2]$ by propagating $x[1]$ downward—this takes time $\Theta(\log(n-1))$. Continuing in this fashion, we find we can sort the entire array in time

$$\Theta(\log n + \log(n-1) + \dots + \log 1) = \Theta(n \log n).$$

The initial creation of the heap from an unordered array is done by applying the restoration process successively to $x[n/2]$, $x[n/2-1]$, ..., $x[1]$ which takes time $\Theta(n)$.

Hence we have the following $\Theta(n \log n)$ sorting algorithm:

```

1 void heapify (int n, float x[], int i) {
2     // Repair heap property below x[i] in x[1] ... x[n]
3     int largest = i; // largest of x[i], x[2*i], x[2*i+1]
4     if (2*i <= n && x[2*i] > x[i])
5         largest = 2*i;
6     if (2*i+1 <= n && x[2*i+1] > x[largest])
7         largest = 2*i+1;
8     if (largest != i) {
9         // swap x[i] with larger child and repair heap below
10        float t = x[largest]; x[largest] = x[i]; x[i] = t;
11        heapify(n, x, largest);
12    }
13 }
14
15 void makeheap (int n, float x[]) {
16     // Make x[1] ... x[n] into a heap
17     for (int i=n/2; i>0; i--)
18         heapify(n, x, i);
19 }
20
21 void heapsort (int n, float x[]) {
22     // Sort x[1] ... x[n]
23     float t;
24     makeheap(n, x);
25     for (int i=n; i>1; i--) {
26         // put x[1] in place and repair heap
27         t = x[1]; x[1] = x[i]; x[i] = t;
28         heapify(i-1, x, 1);
29     }
30 }
  
```

Can we find sorting algorithms that take time less than $\Theta(n \log n)$? The answer is no if we are restricted to sorting algorithms that derive their information from comparisons between the values of elements.

The flow of control in such sorting algorithms can be viewed as binary trees in which there are $n!$ leaves, one for every possible sorted output arrangement. Because a binary tree with height h can have at most 2^h leaves, it follows that the height of a tree with $n!$ leaves must be at least $\log_2 n! = \Theta(n \log n)$. Since the height of this tree corresponds to the longest sequence of element comparisons possible in the flow of control, any such sorting algorithm must, in its worst case, use time proportional to $n \log n$.

4.2.2 Priority Queues

Aside from its application to sorting, the heap is an interesting data structure in its own right. In particular, heaps provide a simple way to implement a *priority queue*—a priority queue is an abstract data structure that keeps track of a dynamically changing set of values allowing the operations

`create`: Create an empty priority queue.
`insert`: Insert a new element into a priority queue.
`decrease`: Decrease an element in a priority queue.
`minimum`: Report the minimum element in a priority queue.
`deleteMinimum`: Delete the minimum element in a priority queue.
`delete`: Delete an element in a priority queue.
`merge`: Merge two priority queues.

A heap can implement a priority queue by altering the heap property to insist that parents are less than or equal to their children, so that the smallest value in the heap is at the root, that is, in the first array position. Creation of an empty heap requires just the allocation of an array, an $\Theta(1)$ operation; we assume that once created, the array containing the heap can be extended arbitrarily at the right end. Inserting a new element means putting that element in the $(n + 1)$ st location and “bubbling it up” by swapping it with its parent until it reaches either the root or a parent with a smaller value. Since a heap has logarithmic height, insertion to a heap of n elements thus requires worst-case time $O(\log n)$. Decreasing a value in a heap requires only a similar $O(\log n)$ “bubbling up.” The minimum element of such a heap is always at the root, so reporting it takes $\Theta(1)$ time. Deleting the minimum is done by swapping the first and last array positions, bubbling the new root value downward until it reaches its proper location, and truncating the array to eliminate the last position. Delete is handled by decreasing the value so that it is the least in the heap and then applying the `deleteMinimum` operation; this takes a total of $O(\log n)$ time.

The merge operation, unfortunately, is not so economically accomplished—there is little choice but to create a new heap out of the two heaps in a manner similar to the `makeheap` function in heap sort. If there are a total of n elements in the two heaps to be merged, this recreation will require time $O(n)$.

There are better data structures than a heap for implementing priority queues, however. In particular, the *Fibonacci heap* provides an implementation of priority queues in which the `delete` and `deleteMinimum` operations take $O(\log n)$ time and the remaining operations take $\Theta(1)$ time, *provided we consider the times required for a sequence of priority queue operations, rather than individual times*. That is, we must consider the cost of the individual operations *amortized over the sequence of operations*: Given a sequence of n priority queue operations, we will compute the total time $T(n)$ for all n operations. In doing this computation, however, we do not simply add the costs of the individual operations; rather, we subdivide the cost of each operation into two parts, the *immediate cost* of doing the operation and the *long-term savings* that result from doing the operation—the long-term savings represent costs *not* incurred by later operations as a result of the present operation. The immediate cost minus the long-term savings give the amortized cost of the operation.

It is easy to calculate the immediate cost (time required) of an operation, but how can we measure the long-term savings that result? We imagine that the data structure has associated with it a bank account; at any given moment, the bank account must have a nonnegative balance. When we do an operation that will save future effort, we are making a deposit to the savings account and when, later on, we derive the benefits of that earlier operation, we are making a withdrawal from the savings account.

Let $\mathcal{B}(i)$ denote the balance in the account after the i th operation, $\mathcal{B}(0) = 0$. We define the amortized cost of the i th operation to be

$$\begin{aligned} \text{amortized cost of } i\text{th operation} &= (\text{immediate cost of } i\text{th operation}) + (\text{change in bank account}) \\ &= (\text{immediate cost of } i\text{th operation}) + (\mathcal{B}(i) - \mathcal{B}(i-1)). \end{aligned}$$

Since the bank account \mathcal{B} can go up or down as a result of the i th operation, the amortized cost may be less than or more than the immediate cost. By summing the previous equation, we get

$$\begin{aligned} \sum_{i=1}^n (\text{amortized cost of } i\text{th operation}) &= \sum_{i=1}^n (\text{immediate cost of } i\text{th operation}) + (\mathcal{B}(n) - \mathcal{B}(0)) \\ &= (\text{total cost of all } n \text{ operations}) + \mathcal{B}(n) \\ &\geq \text{total cost of all } n \text{ operations} \\ &= T(n), \end{aligned}$$

because $\mathcal{B}(i)$ is nonnegative. Thus defined, the sum of the amortized costs of the operations gives us an upper bound on the total time $T(n)$ for all n operations.

It is important to note that the function $\mathcal{B}(i)$ is not part of the data structure, but is just our way to measure how much time is used by the sequence of operations. As such, we can choose *any rules* for \mathcal{B} , provided $\mathcal{B}(0) = 0$ and $\mathcal{B}(i) \geq 0$ for $i \geq 1$. Then the sum of the amortized costs defined by

$$\text{amortized cost of } i\text{th operation} = (\text{immediate cost of } i\text{th operation}) + (\mathcal{B}(i) - \mathcal{B}(i-1))$$

bounds the overall cost of the operation of the data structure.

Now, we apply this method to priority queues. A *Fibonacci heap* is a list of heap-ordered trees (not necessarily binary); since the trees are heap ordered, the minimum element must be one of the roots and we keep track of which root is the overall minimum. Some of the tree nodes are *marked*. We define

$$\begin{aligned} \mathcal{B}(i) &= (\text{number of trees after the } i\text{th operation}) \\ &\quad + 2 \times (\text{number of marked nodes after the } i\text{th operation}). \end{aligned}$$

The clever rules by which nodes are marked and unmarked, and the intricate algorithms that manipulate the set of trees, are too complex to present here in their complete form, so we just briefly describe the simpler operations and show the calculation of their amortized costs:

create: To create an empty Fibonacci heap, we create an empty list of heap-ordered trees. The immediate cost is $\Theta(1)$; since the numbers of trees and marked nodes are zero before and after this operation, $\mathcal{B}(i) - \mathcal{B}(i-1)$ is zero, and the amortized time is $\Theta(1)$.

insert: To insert a new element into a Fibonacci heap, we add a new one-element tree to the list of trees constituting the heap and update the record of what root is the overall minimum. The immediate cost is $\Theta(1)$. $\mathcal{B}(i) - \mathcal{B}(i-1)$ is also 1 since the number of trees has increased by 1, while the number of marked nodes is unchanged. The amortized time is thus $\Theta(1)$.

decrease: Decreasing an element in a Fibonacci heap is done by cutting the link to its parent, if any, adding the item as a root in the list of trees, and decreasing its value. Furthermore, the marked parent of a cut element is itself cut, propagating upward in the tree. Cut nodes become unmarked, and the unmarked parent of a cut element becomes marked. The immediate cost of

this operation is $\Theta(c)$, where c is the number of cut nodes. If there were t trees and m marked elements before this operation, the value of \mathcal{B} before the operation was $t + 2m$. After the operation, the value of \mathcal{B} is $(t + c) + 2(m - c + 2)$ so $\mathcal{B}(i) - \mathcal{B}(i - 1) = 4 - c$. The amortized time is thus $\Theta(c) + 4 - c = \Theta(1)$ by changing the definition of \mathcal{B} by a multiplicative constant large enough to dominate the constant hidden in $\Theta(c)$.

minimum: Reporting the minimum element in a Fibonacci heap takes time $\Theta(1)$ and does not change the numbers of trees and marked nodes; the amortized time is thus $\Theta(1)$.

deleteMinimum: Deleting the minimum element in a Fibonacci heap is done by deleting that tree root, making its children roots in the list of trees. Then, the list of tree roots is “consolidated” in a complicated $O(\log n)$ operation that we do not describe. The result takes amortized time $O(\log n)$.

delete: Deleting an element in a Fibonacci heap is done by decreasing its value to $-\infty$ and then doing a `deleteMinimum`. The amortized cost is the sum of the amortized cost of the two operations, $O(\log n)$.

merge: Merging two Fibonacci heaps is done by concatenating their lists of trees and updating the record of which root is the minimum. The amortized time is thus $\Theta(1)$.

Notice that the amortized cost of each operation is $\Theta(1)$ except `deleteMinimum` and `delete`, both of which are $O(\log n)$.

4.3 Divide-and-Conquer Algorithms

One approach to the design of algorithms is to decompose a problem into subproblems that resemble the original problem, but on a reduced scale. Suppose, for example, that we want to compute x^n . We reason that the value we want can be computed from $x^{\lfloor n/2 \rfloor}$ because

$$x^n = \begin{cases} 1 & \text{if } n = 0, \\ (x^{\lfloor n/2 \rfloor})^2 & \text{if } n \text{ is even,} \\ x \times (x^{\lfloor n/2 \rfloor})^2 & \text{if } n \text{ is odd.} \end{cases}$$

This recursive definition can be translated directly into

```

1  int power (float x, int n) {
2    // Compute the n-th power of x
3    if (n == 0)
4      return 1;
5    else {
6      int t = power(x, floor(n/2));
7      if ((n % 2) == 0)
8        return t*t;
9      else
10     return x*t*t;
11   }
12 }
```

To analyze the time required by this algorithm, we notice that the time will be proportional to the number of multiplication operations performed in lines 8 and 10, so the divide-and-conquer recurrence

$$T(n) = 2 + T(\lfloor n/2 \rfloor),$$

with $T(0) = 0$, describes the rate of growth of the time required by this algorithm. By considering the subsequence $n_k = 2^k$, we find, using the methods of the previous section, that $T(n) = \Theta(\log n)$. Thus above algorithm is considerably more efficient than the more obvious

```

1  int power (int k, int n) {
2    // Compute the n-th power of k
3    int product = 1;
4    for (int i = 1; i <= n; i++)
5      // at this point power is k*k*k*...*k (i times)
6      product = product * k;
7    return product;
8  }
```

which requires time $\Theta(n)$.

An extremely well-known instance of the divide-and-conquer algorithm is *binary search* of an ordered array of n elements for a given element—we “probe” the middle element of the array, continuing in either the lower or upper segment of the array, depending on the outcome of the probe:

```

1  int binarySearch (int x, int w[], int low, int high) {
2    // Search for x among sorted array w[low..high]. The integer returned
3    // is either the location of x in w, or the location where x belongs.
4    if (low > high) // Not found
5      return low;
6    else {
7      int middle := (low+high)/2;
8      if (w[middle] < x)
9        return binarySearch(x, w, middle+1, high);
10     else if (w[middle] == x)
11       return middle;
12     else
13       return binarySearch(x, w, low, middle-1);
14   }
15 }
```

The analysis of binary search in an array of n elements is based on counting the number of probes used in the search, since all remaining work is proportional to the number of probes. But, the number of probes needed is described by the divide-and-conquer recurrence

$$T(n) = 1 + T\left(\frac{n}{2}\right),$$

with $T(0) = 0$, $T(1) = 1$. We find from Table 4.2 (the top line) that $T(n) = \Theta(\log n)$. Hence binary search is much more efficient than a simple linear scan of the array.

To multiply two very large integers x and y , assume that x has exactly $l \geq 2$ digits and y has at most l digits. Let $x_0, x_1, x_2, \dots, x_{l-1}$ be the digits of x and y_0, y_1, \dots, y_{l-1} be the digits of y (some of the significant digits at the end of y may be zeros, if y is shorter than x), so that

$$x = x_0 + 10x_1 + 10^2x_2 + \dots + 10^{l-1}x_{l-1},$$

and

$$y = y_0 + 10y_1 + 10^2y_2 + \dots + 10^{l-1}y_{l-1}.$$

We apply the divide-and-conquer idea to multiplication by chopping x into two pieces, the leftmost n digits and the remaining digits:

$$x = x_{\text{left}} + 10^n x_{\text{right}},$$

where $n = l/2$. Similarly, chop y into two corresponding pieces:

$$y = y_{\text{left}} + 10^n y_{\text{right}},$$

because y has at most the number of digits that x does, y_{right} might be 0. The product $x \times y$ can be now written

$$\begin{aligned} x \times y &= (x_{\text{left}} + 10^n x_{\text{right}}) \times (y_{\text{left}} + 10^n y_{\text{right}}), \\ &= x_{\text{left}} \times y_{\text{left}} + 10^n (x_{\text{right}} \times y_{\text{left}} + x_{\text{left}} \times y_{\text{right}}) + 10^{2n} x_{\text{right}} \times y_{\text{right}}. \end{aligned}$$

If $T(n)$ is the time to multiply two n -digit numbers with this method, then

$$T(n) = kn + 4T\left(\frac{n}{2}\right);$$

the kn part is the time to chop up x and y and to do the needed additions and shifts; each of these tasks involves n -digit numbers and hence $\Theta(n)$ time. The $4T(n/2)$ part is the time to form the four needed subproducts, each of which is a product of about $n/2$ digits.

The line for $g(n) = \Theta(n)$, $u = 4 > v = 2$ in Table 4.2 tells us that $T(n) = \Theta(n^{\log_2 4}) = \Theta(n^2)$, so the divide-and-conquer algorithm is no more efficient than the elementary-school method of multiplication. However, we can be more economical in our formation of subproducts:

$$\begin{aligned} x \times y &= (x_{\text{left}} + 10^n x_{\text{right}}) \times (y_{\text{left}} + 10^n y_{\text{right}}), \\ &= B + 10^n C + 10^{2n} A, \end{aligned}$$

where

$$\begin{aligned} A &= x_{\text{right}} \times y_{\text{right}}, \\ B &= x_{\text{left}} \times y_{\text{left}}, \\ C &= (x_{\text{left}} + x_{\text{right}}) \times (y_{\text{left}} + y_{\text{right}}) - A - B. \end{aligned}$$

The recurrence for the time required changes to

$$T(n) = kn + 3T\left(\frac{n}{2}\right).$$

The kn part is the time to do the two additions that form $x \times y$ from A , B , and C and the two additions and the two subtractions in the formula for C ; each of these six additions/subtractions involves

n -digit numbers. The $3T(n/2)$ part is the time to (recursively) form the three needed products, each of which is a product of about $n/2$ digits. The line for $g(n) = \Theta(n)$, $u = 3 > v = 2$ in Table 4.2 now tells us that

$$T(n) = \Theta(n^{\log_2 3}).$$

Now,

$$\log_2 3 = \frac{\log_{10} 3}{\log_{10} 2} \approx 1.5849625 \dots,$$

which means that this divide-and-conquer multiplication technique will be faster than the straightforward $\Theta(n^2)$ method for large numbers of digits.

Sorting a sequence of n values efficiently can be done using the divide-and-conquer idea. Split the n values arbitrarily into two piles of $n/2$ values each, sort each of the piles separately, and then merge the two piles into a single sorted pile. This sorting technique, pictured in Figure 4.2, is called *merge sort*. Let $T(n)$ be the time required by merge sort for sorting n values. The time needed to do the merging is proportional to the number of elements being merged, so that

$$T(n) = cn + 2T(n/2),$$

because we must sort the two halves (time $T(n/2)$ each) and then merge (time proportional to n). We see by Table 4.2 that the growth rate of $T(n)$ is $\Theta(n \log n)$, since $u = v = 2$ and $g(n) = \Theta(n)$.

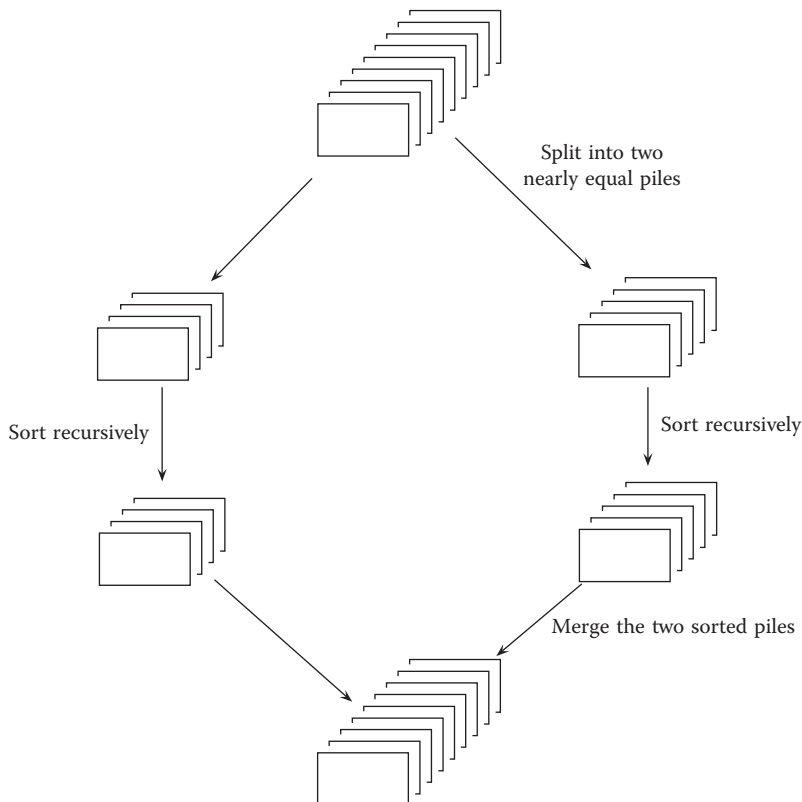

FIGURE 4.2 Schematic description of merge sort.

4.4 Dynamic Programming

In the design of algorithms to solve optimization problems, we need to make the optimal (lowest cost, highest value, shortest distance, and so on) choice from among a large number of alternative solutions; *dynamic programming* is an organized way to find an optimal solution by systematically exploring all possibilities without unnecessary repetition. Often, dynamic programming leads to efficient, polynomial-time algorithms for problems that appear to require searching through exponentially many possibilities.

Like the divide-and-conquer method, dynamic programming is based on the observation that many optimization problems can be solved by solving similar subproblems and composing the solutions of those subproblems into a solution for the original problem. In addition, the problem is viewed as a sequence of decisions, each decision leading to different subproblems; if a wrong decision is made, a suboptimal solution results, so all possible decisions need to be accounted for.

As an example of dynamic programming, consider the problem of constructing an optimal search pattern for probing an ordered sequence of elements. The problem is similar to searching an array—in the previous section, we described binary search in which an interval in an array is repeatedly bisected until the search ends. Now, however, suppose we know the frequencies with which the search will seek various elements (both in the sequence and missing from it). For example, if we know that the last few elements in the sequence are frequently sought—binary search does not make use of this information—it might be more efficient to begin the search at the right end of the array, not in the middle. Specifically, we are given an ordered sequence $x_1 < x_2 < \dots < x_n$ and associated frequencies of access $\beta_1, \beta_2, \dots, \beta_n$, respectively; furthermore, we are given $\alpha_0, \alpha_1, \dots, \alpha_n$ where α_i is the frequency with which the search will fail because the object sought, z , was missing from the sequence, $x_i < z < x_{i+1}$ (with the obvious meaning when $i = 0$ or $i = n$). What is the optimal order to search for an unknown element z ? In fact, how should we describe the optimal search order?

We express a search order as a *binary search tree*, a diagram showing the sequence of probes made in every possible search. We place at the root of the tree the sequence element at which the first probe is made, say x_i ; the left subtree of x_i is constructed recursively for the probes made when $z < x_i$, and the right subtree of x_i is constructed recursively for the probes made when $z > x_i$. We label each item in the tree with the frequency that the search ends at that item. Figure 4.3 shows a simple example. The search of sequence $x_1 < x_2 < x_3 < x_4 < x_5$ according to the tree of Figure 4.3 is done by comparing the unknown element z with x_4 (the root); if $z = x_4$, the search ends. If $z < x_2$, z is compared with x_2

FIGURE 4.3 A binary search tree.

(the root of the left subtree); if $z = x_2$, the search ends. Otherwise, if $z < x_2$, z is compared with x_1 (the root of the left subtree of x_2); if $z = x_1$, the search ends. Otherwise, if $z < x_1$, the search ends unsuccessfully at the leaf labeled α_0 . Other results of comparisons lead along other paths in the tree from the root downward. By its nature, a binary search tree is *lexicographic* in that for all nodes in the tree, the elements in the left subtree of the node are smaller and the elements in the right subtree of the node are larger than the node.

Because we are to find an optimal search pattern (tree), we want the cost of searching to be minimized. The cost of searching is measured by the *weighted path length* of the tree:

$$\sum_{i=1}^n \beta_i \times [1 + \text{level}(\beta_i)] + \sum_{i=0}^n \alpha_i \times \text{level}(\alpha_i),$$

defined formally as

$$W(T = \bigwedge_{T_l T_r}) = W(T_l) + W(T_r) + \sum \alpha_i + \sum \beta_i,$$

where the summations $\sum \alpha_i$ and $\sum \beta_i$ are over all α_i and β_i in T . Since there are exponentially many possible binary trees, finding the one with minimum weighted path length could, if done naively, take exponentially long.

The key observation we make is that a *principle of optimality* holds for the cost of binary search trees: subtrees of an optimal search tree must themselves be optimal. This observation means, for example, if the tree shown in Figure 4.3 is optimal, then its left subtree must be the optimal tree for the problem of searching the sequence $x_1 < x_2 < x_3$ with frequencies $\beta_1, \beta_2, \beta_3$ and $\alpha_0, \alpha_1, \alpha_2, \alpha_3$. (If a subtree in Figure 4.3 were *not* optimal, we could replace it with a better one, reducing the weighted path length of the entire tree because of the recursive definition of weighted path length.) In general terms, the principle of optimality states that subsolutions of an optimal solution must themselves be optimal.

The optimality principle, together with the recursive definition of weighted path length, means that we can express the construction of an optimal tree recursively. Let $C_{i,j}$, $0 \leq i \leq j \leq n$, be the cost of an optimal tree over $x_{i+1} < x_{i+2} < \dots < x_j$ with the associated frequencies $\beta_{i+1}, \beta_{i+2}, \dots, \beta_j$ and $\alpha_i, \alpha_{i+1}, \dots, \alpha_j$. Then,

$$C_{i,i} = 0,$$

$$C_{i,j} = \min_{i < k \leq j} (C_{i,k-1} + C_{k,j}) + W_{i,j},$$

where

$$W_{i,i} = \alpha_i,$$

$$W_{i,j} = W_{i,j-1} + \beta_j + \alpha_j.$$

These two recurrence relations can be implemented directly as recursive functions to compute $C_{0,n}$, the cost of the optimal tree, leading to the following two functions:

```

1  int W (int i, int j) {
2      if (i == j)
3          return alpha[j];
4      else
5          return W(i,j-1) + beta[j] + alpha[j];
6  }
7
8  int C (int i, int j) {
9      if (i == j)
10         return 0;
11     else {
12         int minCost = MAXINT;
13         int cost;
14         for (int k = i+1; k <= j; k++) {
15             cost = C(i,k-1) + C(k,j) + W(i,j);
16             if (cost < minCost)
17                 minCost = cost;
18         }
19         return minCost;
20     }
21 }
```

These two functions correctly compute the cost of an optimal tree; the tree itself can be obtained by storing the values of k when $\text{cost} < \text{minCost}$ in line 16.

However, the above functions are unnecessarily time-consuming (requiring exponential time) because the same subproblems are solved repeatedly. For example, each call $W(i, j)$ uses time $\Theta(j - i)$ and such calls are made repeatedly for the same values of i and j . We can make the process more efficient by caching the values of $W(i, j)$ in an array as they are computed and using the cached values when possible:

```

1  int W[n][n];
2  for (int i = 0; i < n; i++)
3      for (int j = 0; j < n; j++)
4          W[i][j] = MAXINT;
5
6  int W (int i, int j) {
7      if (W[i][j] = MAXINT)
8          if (i == j)
9              W[i][j] = alpha[j];
10         else
11             W[i][j] = W(i,j-1) + beta[j] + alpha[j];
12         return W[i][j];
13 }
```

In the same way, we should cache the values of $C(i, j)$ in an array as they are computed:

```

1  int C[n][n];
2  for (int i = 0; i < n; i++)
3      for (int j = 0; j < n; j++)
4          C[i][j] = MAXINT;
5
6  int C (int i, int j) {
```

```

7     if (C[i][j] == MAXINT)
8         if (i == j)
9             C[i][j] = 0;
10        else {
11            int minCost = MAXINT;
12            int cost;
13            for (int k = i+1; k <= j; k++) {
14                cost = C(i,k-1) + C(k,j) + W(i,j);
15                if (cost < minCost)
16                    minCost = cost;
17            }
18            C[i][j] = minCost;
19        }
20    return C[i][j];
21 }

```

The idea of caching the solutions to subproblems is crucial to making the algorithm efficient. In this case, the resulting computation requires time $\Theta(n^3)$; this is surprisingly efficient, considering that an optimal tree is being found from among exponentially many possible trees.

By studying the pattern in which the arrays C and W are filled in, we see that the main diagonal $C[i][i]$ is filled in first, then the first upper super-diagonal $C[i][i+1]$, then the second upper super-diagonal $C[i][i+2]$, and so on until the upper right corner of the array is reached. Rewriting the code to do this directly, and adding an array $R[i][j]$ to keep track of the roots of subtrees, we obtain

```

1     int W[n][n];
2     int R[n][n];
3     int C[n][n];
4
5     // Fill in main diagonal
6     for (int i = 0; i < n; i++) {
7         W[i][i] = alpha[i];
8         R[i][i] = 0;
9         C[i][i] = 0;
10    }
11
12    int minCost, cost;
13    for (int d = 1; d < n; d++)
14        // Fill in d-th upper super-diagonal
15        for (i = 0; i < n-d; i++) {
16            W[i][i+d] = W[i][i+d-1] + beta[i+d] + alpha[i+d];
17            R[i][i+d] = i+1;
18            C[i][i+d] = C[i][i] + C[i+1][i+d] + W[i][i+d];
19            for (int k = i+2; k <= i+d; k++) {
20                cost = C[i][k-1] + C[k][i+d] + W[i][i+d];
21                if (cost < C[i][i+d]) {
22                    R[i][i+d] = k;
23                    C[i][i+d] = cost;
24                }
25            }
26        }

```

which more clearly shows the $\Theta(n^3)$ behavior.

As a second example of dynamic programming, consider the *traveling salesman problem* in which a salesman must visit n cities, returning to his starting point, and is required to minimize

the cost of the trip. The cost of going from city i to city j is $C_{i,j}$. To use dynamic programming, we must specify an optimal tour in a recursive framework, with subproblems resembling the overall problem. Thus we define

$$T(i; j_1, j_2, \dots, j_k) = \begin{cases} \text{cost of an optimal tour from city } i \text{ to city} \\ \text{1 that goes through each of the cities } j_1, \\ j_2, \dots, j_k \text{ exactly once, in any order, and} \\ \text{through no other cities.} \end{cases}$$

The principle of optimality tells us that

$$T(i; j_1, j_2, \dots, j_k) = \min_{1 \leq m \leq k} \{C_{i, j_m} + T(j_m; j_1, j_2, \dots, j_{m-1}, j_{m+1}, \dots, j_k)\},$$

where, by definition,

$$T(i; j) = C_{i,j} + C_{j,1}.$$

We can write a function T that directly implements the above recursive definition, but as in the optimal search tree problem, many subproblems would be solved repeatedly, leading to an algorithm requiring time $\Theta(n!)$. By caching the values $T(i; j_1, j_2, \dots, j_k)$, we reduce the time required to $\Theta(n^{2^2^n})$, still exponential, but considerably less than without caching.

4.5 Greedy Heuristics

Optimization problems always have an objective function to be minimized or maximized, but it is not often clear what steps to take to reach the optimum value. For example, in the optimum binary search tree problem of the previous section, we used dynamic programming to examine systematically all possible trees; but perhaps there is a simple rule that leads directly to the best tree—say by choosing the largest β_i to be the root and then continuing recursively. Such an approach would be less time-consuming than the $\Theta(n^3)$ algorithm we gave, but it does not necessarily give an optimum tree (if we follow the rule of choosing the largest β_i to be the root, we get trees that are no better, on the average, than a randomly chosen trees). The problem with such an approach is that it makes decisions that are *locally optimum*, though perhaps not *globally optimum*. But, such a “greedy” sequence of locally optimum choices does lead to a globally optimum solution in some circumstances.

Suppose, for example, $\beta_i = 0$ for $1 \leq i \leq n$, and we remove the lexicographic requirement of the tree; the resulting problem is the determination of an optimal prefix code for $n + 1$ letters with frequencies $\alpha_0, \alpha_1, \dots, \alpha_n$. Because we have removed the lexicographic restriction, the dynamic programming solution of the previous section no longer works, but the following simple greedy strategy yields an optimum tree: Repeatedly combine the two lowest-frequency items as the left and right subtrees of a

newly created item whose frequency is the sum of the two frequencies combined. Here is an example of this construction; we start with five leaves with weights

First, combine leaves $\alpha_0 = 25$ and $\alpha_5 = 21$ into a subtree of frequency $25 + 21 = 45$:

Then combine leaves $\alpha_1 = 34$ and $\alpha_2 = 38$ into a subtree of frequency $34 + 38 = 72$:

Next, combine the subtree of frequency $\alpha_0 + \alpha_5 = 45$ with $\alpha_3 = 58$:

Then, combine the subtree of frequency $\alpha_1 + \alpha_2 = 72$ with $\alpha_4 = 95$:

Finally, combine the only two remaining subtrees:

How do we know that the above-outlined process leads to an optimum tree? The key to proving that the tree is optimum is to assume, by way of contradiction, that it is not optimum. In this case, the greedy strategy must have erred in one of its choices, so let's look at the *first* error this strategy made. Since all previous greedy choices were not errors, and hence lead to an optimum tree, we can assume that we have a sequence of frequencies $\alpha_0, \alpha_1, \dots, \alpha_n$ such that the first greedy choice is erroneous—without loss of generality assume that α_0 and α_1 are two smallest frequencies, those combined erroneously by the greedy strategy. For this combination to be erroneous, there must be no optimum tree in which these two leaves are siblings, so consider an optimum tree, the locations of α_0 and α_1 , and the location of the two deepest leaves in the tree, α_i and α_j ;

By interchanging the positions of α_0 and α_i and α_1 and α_j (as shown), we obtain a tree in which α_0 and α_1 are siblings. Because α_0 and α_1 are the two lowest frequencies (because they were the greedy algorithm's choice) $\alpha_0 \leq \alpha_i$ and $\alpha_1 \leq \alpha_j$, thus the weighted path length of the modified tree is no larger than before the modification since $\text{level}(\alpha_0) \geq \text{level}(\alpha_i)$, $\text{level}(\alpha_1) \geq \text{level}(\alpha_j)$ and hence

$$\text{level}(\alpha_i) \times \alpha_0 + \text{level}(\alpha_j) \times \alpha_1 \leq \text{level}(\alpha_0) \times \alpha_0 + \text{level}(\alpha_1) \times \alpha_1.$$

In other words, the first so-called mistake of the greedy algorithm was in fact not a mistake since there is an optimum tree in which α_0 and α_1 are siblings. Thus we conclude that the greedy algorithm never makes a first mistake—that is, it never makes a mistake at all!

The greedy algorithm above is called *Huffman's algorithm*. If the subtrees are kept on a priority queue by cumulative frequency, the algorithm needs to insert the $n + 1$ leaf frequencies onto the queue, and repeatedly remove the two least elements on the queue, unite those to elements into a single subtree, and put that subtree back on the queue. This process continues until the queue contains a single item, the optimum tree. Reasonable implementations of priority queues will yield $O(n \log n)$ implementations of Huffman's greedy algorithm.

The idea of making greedy choices, facilitated with a priority queue, works to find optimum solutions to other problems too. For example, a spanning tree of a weighted, connected, undirected graph $G = (V, E)$ is a subset of $|V| - 1$ edges from E connecting all the vertices in G ; a spanning tree is minimum if the

sum of the weights of its edges is as small as possible. *Prim’s algorithm* uses a sequence of greedy choices to determine a minimum spanning tree: Start with an arbitrary vertex $v \in V$ as the spanning-tree-to-be. Then, repeatedly add the cheapest edge connecting the spanning-tree-to-be to a vertex not yet in it. If the vertices not yet in the tree are stored in a priority queue implemented by a Fibonacci heap, the total time required by Prim’s algorithm will be $O(|E| + |V|\log |V|)$. But why does the sequence of greedy choices lead to a minimum spanning tree?

Suppose Prim’s algorithm does *not* result in a minimum spanning tree. As we did with Huffman’s algorithm, we ask what the state of affairs must be when Prim’s algorithm makes its first mistake; we will see that the assumption of a first mistake leads to a contradiction, proving the correctness of Prim’s algorithm. Let the edges added to the spanning tree be, in the order added, e_1, e_2, e_3, \dots , and let e_i be the first mistake. In other words, there is a minimum spanning tree T_{\min} containing e_1, e_2, \dots, e_{i-1} , but no minimum spanning tree contains e_1, e_2, \dots, e_i . Imagine what happens if we add the edge e_i to T_{\min} : since T_{\min} is a spanning tree, the addition of e_i causes a cycle containing e_i . Let e_{\max} be the highest-cost edge on that cycle. Because Prim’s algorithm makes a greedy choice—that is, chooses the lowest-cost available edge—the cost of e_{\max} is at least that of e_i , so the cost of the spanning $T_{\min} - \{e_{\max}\} \cup \{e_i\}$ is at most that of T_{\min} ; in other words, $T_{\min} - \{e_{\max}\} \cup \{e_i\}$ is also a minimum spanning tree, contradicting our assumption that the choice of e_i is the first mistake. Therefore, the spanning tree constructed by Prim’s algorithm must be a minimum spanning tree.

We can apply the greedy heuristic to many optimization problems, and even if the results are not optimal, they are often quite good. For example, in the n -city traveling salesman problem, we can get near-optimal tours in time $O(n^2)$ when the intercity costs are symmetric ($C_{ij} = C_{ji}$ for all i and j) and satisfy the triangle inequality ($C_{ij} \leq C_{i,k} + C_{k,j}$ for all i, j , and k). The *closest insertion algorithm* starts with a “tour” consisting of a single, arbitrarily chosen city, and successively inserts the remaining cities to the tour, making a greedy choice about which city to insert next and where to insert it: the city chosen for insertion is the city not on the tour but closest to a city on the tour; the chosen city is inserted adjacent to the city on the tour to which it is closest.

Given an $n \times n$ symmetric distance matrix C that satisfies the triangle inequality, let I_n be the tour of length $|I_n|$ produced by the closest insertion heuristic and let O_n be an optimal tour of length $|O_n|$. Then,

$$\frac{|I_n|}{|O_n|} < 2.$$

This bound is proved by an incremental form of the optimality proofs for greedy heuristics we have seen above: we ask not where the first error is, but by how much we are in error at each greedy insertion to the tour—we establish a correspondence between edges of the optimal tour and cities inserted on the closest insertion tour. We show that at each insertion of a new city to the closest insertion tour, the cost of that insertion is at most twice the cost of corresponding edge of the optimal tour.

To establish the correspondence, imagine the closest insertion algorithm keeping track not only of the current tour, but also of a spiderlike configuration including the edges of the current tour (the body of the spider) and pieces of the optimal tour (the legs of the spider). We show the current tour in solid lines and the pieces of optimal tour as dotted lines:

Initially, the spider consists of the arbitrarily chosen city with which the closest insertion tour begins and the legs of the spider consist of all the edges of the optimal tour *except* for one edge eliminated arbitrarily. As each city is inserted into the closest insertion tour, the algorithm will delete from the spider-like configuration one of the dotted edges from the optimal tour. When city k is inserted between cities l and m , the edge deleted is the one attaching spider to the leg containing the city inserted (from city x to city y), shown here in bold:

Now,

$$C_{k,m} \leq C_{x,y},$$

because of the greedy choice to add city k to the tour and not city y . By the triangle inequality,

$$C_{l,k} \leq C_{l,m} + C_{m,k},$$

and by symmetry we can combine these two inequalities to get

$$C_{l,k} \leq C_{l,m} + C_{x,y}.$$

Adding this last inequality to the first one,

$$C_{l,k} + C_{k,m} \leq C_{l,m} + 2C_{x,y},$$

that is,

$$C_{l,k} + C_{k,m} - C_{l,m} \leq 2C_{x,y}.$$

Thus, adding city k between cities l and m adds no more to I_n than $2C_{x,y}$. Summing these incremental amounts over the cost of the entire algorithm tells us

$$I_n \leq 2O_n,$$

as we claimed.

5.1 Introduction

Graphs are useful in modeling many problems from different scientific disciplines because they capture the basic concept of objects (vertices) and relationships between objects (edges). Indeed, many optimization problems can be formulated in graph-theoretic terms. Hence, algorithms on graphs have been widely studied. In this chapter, a few fundamental graph algorithms are described. For a more detailed treatment of graph algorithms, the reader is referred to textbooks on graph algorithms (Cormen et al. 2001, Even 1979, Gibbons 1985, Tarjan 1983).

An undirected *graph* $G = (V, E)$ is defined as a set V of *vertices* and a set E of *edges*. An edge $e = (u, v)$ is an unordered pair of vertices. A *directed graph* is defined similarly, except that its edges are ordered pairs of vertices; that is, for a directed graph, $E \subseteq V \times V$. The terms *nodes* and vertices are used interchangeably.

In this chapter, it is assumed that the graph has neither self-loops, edges of the form (v, v) , nor multiple edges connecting two given vertices. A graph is a *sparse graph* if $|E| \ll |V|^2$.

Bipartite graphs form a subclass of graphs and are defined as follows. A graph $G = (V, E)$ is bipartite if the vertex set V can be partitioned into two sets X and Y such that $E \subseteq X \times Y$. In other words, each edge of G connects a vertex in X with a vertex in Y . Such a graph is denoted by $G = (X, Y, E)$. Because bipartite graphs occur commonly in practice, algorithms are often specially designed for them.

A vertex w is *adjacent* to another vertex v if $(v, w) \in E$. An edge (v, w) is said to be *incident* on vertices v and w . The *neighbors* of a vertex v are all vertices $w \in V$ such that $(v, w) \in E$. The number of edges incident to a vertex v is called the *degree* of vertex v . For a directed graph, if (v, w) is an edge, then we say that the edge goes from v to w . The *out-degree* of a vertex v is the number of edges from v to other vertices. The *in-degree* of v is the number of edges from other vertices to v .

A *path* $p = [v_0, v_1, \dots, v_k]$ from v_0 to v_k is a sequence of vertices such that (v_i, v_{i+1}) is an edge in the graph for $0 \leq i < k$. Any edge may be used only once in a path. A *cycle* is a path whose end vertices are the same, that is, $v_0 = v_k$. A path is *simple* if all its internal vertices are distinct. A cycle is *simple* if every node has exactly two edges incident to it in the cycle. A *walk* $w = [v_0, v_1, \dots, v_k]$ from v_0 to v_k is a sequence of vertices such that (v_i, v_{i+1}) is an edge in the graph for $0 \leq i < k$, in which edges and vertices may be repeated. A walk is *closed* if $v_0 = v_k$. A graph is *connected* if there is a path between every pair of vertices. A directed graph is *strongly connected* if there is a path between every pair of vertices in each direction. An acyclic, undirected graph is a *forest*, and a *tree* is a connected forest. A directed graph without cycles is known as a *directed acyclic graph* (DAG). Consider a binary relation C between the vertices of an undirected graph G such that for any two vertices u and v , uCv if and only if there is a path in G between u and v . It can be shown that C is an equivalence relation, partitioning the vertices of G into equivalence classes, known as the connected components of G .

There are two convenient ways of representing graphs on computers. We first discuss the *adjacency list* representation. Each vertex has a linked list: there is one entry in the list for each of its adjacent vertices. The graph is thus represented as an array of linked lists, one list for each vertex. This representation uses $O(|V| + |E|)$ storage, which is good for sparse graphs. Such a storage scheme allows one to scan all vertices adjacent to a given vertex in time proportional to its degree. The second representation, the *adjacency matrix*, is as follows. In this scheme, an $n \times n$ array is used to represent the graph. The $[i, j]$ entry of this array is 1 if the graph has an edge between vertices i and j , and 0 otherwise. This representation permits one to test if there is an edge between any pair of vertices in constant time. Both these representation schemes can be used in a natural way to represent directed graphs. For all algorithms in this chapter, it is assumed that the given graph is represented by an adjacency list.

Section 5.2 discusses various types of tree traversal algorithms. Sections 5.3 and 5.4 discuss depth-first search (DFS) and breadth-first search (BFS) techniques. Section 5.5 discusses the single-source shortest path problem. Section 5.6 discusses minimum spanning trees (MSTs). Section 5.7 discusses the bipartite matching problem and the single commodity maximum-flow problem. Section 5.8 discusses some traversal problems in graphs, and the Further Information section concludes with some pointers to current research on graph algorithms.

5.2 Tree Traversals

A tree is *rooted* if one of its vertices is designated as the root vertex and all edges of the tree are oriented (directed) to point away from the root. In a rooted tree, there is a directed path from the root to any vertex in the tree. For any directed edge (u, v) in a rooted tree, u is v 's *parent* and v is u 's *child*. The *descendants* of a vertex w are all vertices in the tree (including w) that are reachable by directed paths starting at w . The *ancestors* of a vertex w are those vertices for which w is a descendant. Vertices that have no children are called *leaves*. A *binary tree* is a special case of a rooted tree in which each node has at most two children, namely, the left child and the right child. The trees rooted at the two children of a node are called the *left subtree* and *right subtree*.

In this section, we study techniques for processing the vertices of a given binary tree in various orders. We assume that each vertex of the binary tree is represented by a record that contains fields to hold attributes of that vertex and two special fields *left* and *right* that point to its left and right subtree, respectively.

The three major tree traversal techniques are *preorder*, *inorder*, and *postorder*. These techniques are used as procedures in many tree algorithms where the vertices of the tree have to be processed in a specific order. In a preorder traversal, the root of any subtree has to be processed *before* any of its descendants. In a postorder traversal, the root of any subtree has to be processed *after* all of its descendants. In an inorder traversal, the root of a subtree is processed after all vertices in its left subtree have been processed but before any of the vertices in its right subtree are processed. Preorder and postorder traversals generalize to arbitrary rooted trees. In the example to follow, we show how postorder can be used to count the number of descendants of each node and store the value in that node. The algorithm runs in linear time in the size of the tree:

Postorder Algorithm. *PostOrder* (T):

```

1  if  $T \neq \text{nil}$  then
2     $lc \leftarrow \text{PostOrder}(\text{left}[T])$ .
3     $rc \leftarrow \text{PostOrder}(\text{right}[T])$ .
4     $\text{desc}[T] \leftarrow lc + rc + 1$ .
5    return  $\text{desc}[T]$ .
6  else
7    return 0.
8  end-if
end-proc
```

5.3 Depth-First Search

DFS is a fundamental graph searching technique (Hopcroft and Tarjan 1973, Tarjan 1972). Similar graph searching techniques were given earlier by Tremaux (see Fraenkel 1970, Lucas 1882). The structure of DFS enables efficient algorithms for many other graph problems such as biconnectivity, triconnectivity, and planarity (Even 1979).

The algorithm first initializes all vertices of the graph as being unvisited. Processing of the graph starts from an arbitrary vertex, known as the root vertex. Each vertex is processed when it is first discovered (also referred to as *visiting* a vertex). It is first marked as visited, and its adjacency list is then scanned for unvisited vertices. Each time an unvisited vertex is discovered, it is processed recursively by DFS. After a node's entire adjacency list has been explored, that invocation of the DFS procedure returns. This procedure eventually visits all vertices that are in the same connected component of the root vertex. Once DFS terminates, if there are still any unvisited vertices left in the graph, one of them is chosen as the root and the same procedure is repeated.

The set of edges such that each one led to the discovery of a new vertex form a maximal forest of the graph, known as the *DFS forest*; a *maximal forest* of a graph G is an acyclic subgraph of G such that the addition of any other edge of G to the subgraph introduces a cycle. The algorithm keeps track of this forest using parent pointers. In each connected component, only the root vertex has a *nil* parent in the DFS tree.

5.3.1 Depth-First Search Algorithm

DFS is illustrated using an algorithm that labels vertices with numbers 1, 2, ... in such a way that vertices in the same component receive the same label. This labeling scheme is a useful

preprocessing step in many problems. Each time the algorithm processes a new component, it numbers its vertices with a new label.

Depth-First Search Algorithm. *DFS-Connected Component (G):*

```

1   $c \leftarrow 0$ .
2  for all vertices  $v$  in  $G$  do
3     $visited[v] \leftarrow false$ .
4     $finished[v] \leftarrow false$ .
5     $parent[v] \leftarrow nil$ .
6  end-for
7  for all vertices  $v$  in  $G$  do
8    if not  $visited[v]$  then
9       $c \leftarrow c + 1$ .
10      $DFS(v, c)$ .
11    end-if
12 end-for
end-proc

```

DFS (v, c):

```

1   $visited[v] \leftarrow true$ .
2   $component[v] \leftarrow c$ .
3  for all vertices  $w$  in  $adj[v]$  do
4    if not  $visited[w]$  then
5       $parent[w] \leftarrow v$ .
6       $DFS(w, c)$ .
7    end-if
8  end-for
9   $finished[v] \leftarrow true$ .
end-proc

```

5.3.2 Sample Execution

Figure 5.1 shows a graph having two connected components. DFS was started at vertex a , and the DFS forest is shown on the right. DFS visits the vertices b, d, c, e , and f , in that order. DFS then

FIGURE 5.1 Sample execution of DFS on a graph having two connected components: (a) graph and (b) DFS forest.

continues with vertices g , h , and i . In each case, the recursive call returns when the vertex has no more unvisited neighbors. Edges (d, a) , (c, a) , (f, d) , and (i, g) are called *back edges* (these do not belong to the DFS forest).

5.3.3 Analysis

A vertex v is processed as soon as it is encountered, and therefore at the start of DFS (v), $visited[v]$ is *false*. Since $visited[v]$ is set to true as soon as DFS starts execution, each vertex is visited exactly once. DFS processes each edge of the graph exactly twice, once from each of its incident vertices. Since the algorithm spends constant time processing each edge of G , it runs in $O(|V| + |E|)$ time.

Remark 5.1

In the following discussion, there is no loss of generality in assuming that the input graph is connected. For a rooted DFS tree, vertices u and v are said to be *related*, if either u is an ancestor of v , or vice versa.

DFS is useful due to the special way in which the edges of the graph may be classified with respect to a DFS tree. Notice that the DFS tree is not unique, and which edges are added to the tree depends on the order in which edges are explored while executing DFS. Edges of the DFS tree are known as *tree edges*. All other edges of the graph are known as *back edges*, and it can be shown that for any edge (u, v) , u and v must be related. The graph does not have any *cross edges*, edges that connect two vertices that are unrelated. This property is utilized by a DFS-based algorithm that classifies the edges of a graph into *biconnected* components, maximal subgraphs that cannot be disconnected by the removal of any single vertex (Even 1979).

5.3.4 Directed Depth-First Search

The DFS algorithm extends naturally to directed graphs. Each vertex stores an adjacency list of its outgoing edges. During the processing of a vertex, first mark it as visited, and then scan its adjacency list for unvisited neighbors. Each time an unvisited vertex is discovered, it is processed recursively. Apart from tree edges and back edges (from vertices to their ancestors in the tree), directed graphs may also have *forward edges* (from vertices to their descendants) and *cross edges* (between unrelated vertices). There may be a cross edge (u, v) in the graph only if u is visited after the procedure call DFS (v) has completed execution.

5.3.5 Sample Execution

A sample execution of the directed DFS algorithm is shown in Figure 5.2. DFS was started at vertex a , and the DFS forest is shown on the right. DFS visits vertices b , d , f , and c in that order. DFS then returns and continues with e and then g . From g , vertices h and i are visited in that order. Observe that (d, a) and (i, g) are back edges. Edges (c, d) , (e, d) , and (e, f) are cross edges. There is a single forward edge (g, i) .

5.3.6 Applications of Depth-First Search

Directed DFS can be used to design a linear-time algorithm that classifies the edges of a given directed graph into *strongly connected* components: maximal subgraphs that have directed paths connecting any pair of vertices in them, in each direction. The algorithm itself involves running DFS twice, once on the original graph and then a second time on G^R , which is the graph obtained by reversing the

FIGURE 5.2 Sample execution of DFS on a directed graph: (a) graph and (b) DFS forest.

direction of all edges in G . During the second DFS, we are able to obtain all of the strongly connected components. The proof of this algorithm is somewhat subtle, and the reader is referred to Cormen et al. (2001) for details.

Checking if a graph has a cycle can be done in linear time using DFS. A graph has a cycle if and only if there exists a back edge relative to any of its DFS trees. A directed graph that does not have any cycles is known as a DAG. DAGs are useful in modeling precedence constraints in scheduling problems, where nodes denote jobs/tasks, and a directed edge from u to v denotes the constraint that job u must be completed before job v can begin execution. Many problems on DAGs can be solved efficiently using dynamic programming.

A useful concept in DAGs is that of a *topological order*: a linear ordering of the vertices that is consistent with the partial order defined by the edges of the DAG. In other words, the vertices can be labeled with distinct integers in the range $[1 \dots |V|]$ such that if there is a directed edge from a vertex labeled i to a vertex labeled j , then $i < j$. The vertices of a given DAG can be ordered topologically in linear time by a suitable modification of the DFS algorithm. We keep a counter whose initial value is $|V|$. As each vertex is marked finished, we assign the counter value as its topological number and decrement the counter. Observe that there will be no back edges and that for all edges (u, v) , v will be marked finished before u . Thus, the topological number of v will be higher than that of u . Topological sort has applications in diverse areas such as project management, scheduling, and circuit evaluation.

5.4 Breadth-First Search

BFS is another natural way of searching a graph. The search starts at a root vertex r . Vertices are added to a queue as they are discovered and processed in first-in–first-out (FIFO) order.

Initially, all vertices are marked as unvisited, and the queue consists of only the root vertex. The algorithm repeatedly removes the vertex at the front of the queue and scans its neighbors in the graph. Any neighbor not visited is added to the end of the queue. This process is repeated until the queue is empty. All vertices in the same connected component as the root are scanned and the algorithm outputs a spanning tree of this component. This tree, known as a *breadth-first tree*, is made up of the edges that led to the discovery of new vertices. The algorithm labels each vertex v by $d[v]$, the distance (length of a shortest path) of v from the root vertex, and stores the BFS tree in the array p , using parent pointers. Vertices can be partitioned into levels based on their distance from the root. Observe that edges not in the BFS tree always go either between vertices in the same level or between vertices in adjacent levels. This property is often useful.

FIGURE 5.3 Sample execution of BFS on a graph: (a) graph and (b) BFS tree.

Breadth-First Search Algorithm. *BFS-Distance* (G, r):

```

1 MakeEmptyQueue (Q).
2 for all vertices  $v$  in  $G$  do
3    $visited[v] \leftarrow false$ .
4    $d[v] \leftarrow \infty$ .
5    $p[v] \leftarrow nil$ .
6 end-for
7  $visited[r] \leftarrow true$ .
8  $d[r] \leftarrow 0$ .
9 Enqueue (Q, r).
10 while not Empty (Q) do
11    $v \leftarrow$  Dequeue (Q).
12   for all vertices  $w$  in  $adj[v]$  do
13     if not  $visited[w]$  then
14        $visited[w] \leftarrow true$ .
15        $p[w] \leftarrow v$ .
16        $d[w] \leftarrow d[v] + 1$ .
17       Enqueue (Q, w).
18     end-if
19   end-for
20 end-while
end-proc

```

5.4.1 Sample Execution

Figure 5.3 shows a connected graph on which BFS was run with vertex a as the root. When a is processed, vertices b , d , and c are added to the queue. When b is processed, nothing is done since all its neighbors have been visited. When d is processed, e and f are added to the queue. Finally c , e , and f are processed.

5.4.2 Analysis

There is no loss of generality in assuming that the graph G is connected, since the algorithm can be repeated in each connected component, similar to the DFS algorithm. The algorithm processes each vertex exactly once and each edge exactly twice. It spends a constant amount of time in processing each edge. Hence, the algorithm runs in $O(|V| + |E|)$ time.

5.5 Single-Source Shortest Paths

A natural problem that often arises in practice is to compute the shortest paths from a specified node to all other nodes in an undirected graph. BFS solves this problem if all edges in the graph have the same length. Consider the more general case when each edge is given an arbitrary, nonnegative length,

and one needs to calculate a shortest-length path from the root vertex to all other nodes of the graph, where the length of a path is defined to be the sum of the lengths of its edges. The distance between two nodes is the length of a shortest path between them.

5.5.1 Dijkstra's Algorithm

Dijkstra's algorithm (Dijkstra 1959) provides an efficient solution to this problem. For each vertex v , the algorithm maintains an upper bound to the distance from the root to vertex v in $d[v]$; initially $d[v]$ is set to infinity for all vertices except the root. The algorithm maintains a set S of vertices with the property that for each vertex $v \in S$, $d[v]$ is the length of a shortest path from the root to v . For each vertex u in $V - S$, the algorithm maintains $d[u]$, the shortest known distance from the root to u that goes entirely within S , except for the last edge. It selects a vertex u in $V - S$ of minimum $d[u]$, adds it to S , and updates the distance estimates to the other vertices in $V - S$. In this update step, it checks to see if there is a shorter path to any vertex in $V - S$ from the root that goes through u . Only the distance estimates of vertices that are adjacent to u are updated in this step. Because the primary operation is the selection of a vertex with minimum distance estimate, a priority queue is used to maintain the d -values of vertices. The priority queue should be able to handle a `DecreaseKey` operation to update the d -value in each iteration. The next algorithm implements Dijkstra's algorithm.

Dijkstra's Algorithm. *Dijkstra-Shortest Paths* (G, r):

```

1  for all vertices  $v$  in  $G$  do
2     $visited[v] \leftarrow false$ .
3     $d[v] \leftarrow \infty$ .
4     $p[v] \leftarrow nil$ .
5  end-for
6   $d[r] \leftarrow 0$ .
7  BuildPQ ( $H, d$ ).
8  while not Empty ( $H$ ) do
9     $u \leftarrow DeleteMin (H)$ .
10    $visited[u] \leftarrow true$ .
11   for all vertices  $v$  in  $adj[u]$  do
12     Relax ( $u, v$ ).
13   end-for
14 end-while
end-proc

Relax ( $u, v$ )
1  if not  $visited[v]$  and  $d[v] > d[u] + w(u, v)$  then
2     $d[v] \leftarrow d[u] + w(u, v)$ .
3     $p[v] \leftarrow u$ .
4    DecreaseKey ( $H, v, d[v]$ ).
5  end-if
end-proc

```

5.5.1.1 Sample Execution

Figure 5.4 shows a sample execution of the algorithm. The column titled *Iter* specifies the number of iterations that the algorithm has executed through the *while* loop in step 8. In iteration 0, the initial values of the distance estimates are ∞ . In each subsequent line of the table, the column marked u shows the vertex that was chosen in step 9 of the algorithm and the change to the distance estimates at the end of that iteration of the *while* loop. In the first iteration, vertex r was chosen, after that a was chosen because

FIGURE 5.4 Dijkstra’s shortest path algorithm.

it had the minimum distance label among the unvisited vertices, and so on. The distance labels of the unvisited neighbors of the visited vertex are updated in each iteration.

5.5.1.2 Analysis

The running time of the algorithm depends on the data structure that is used to implement the priority queue H . The algorithm performs $|V|$ DeleteMin operations and, at most, $|E|$ DecreaseKey operations. If a binary heap is used to update the records of any given vertex, each of these operations runs in $O(\log |V|)$ time. There is no loss of generality in assuming that the graph is connected. Hence, the algorithm runs in $O(|E| \log |V|)$. If a Fibonacci heap is used to implement the priority queue, the running time of the algorithm is $O(|E| + |V| \log |V|)$. Although the Fibonacci heap gives the best asymptotic running time, the binary heap implementation is likely to give better running times for most practical instances.

5.5.2 Bellman–Ford Algorithm

The shortest path algorithm described earlier directly generalizes to directed graphs, but it does not work correctly if the graph has edges of negative length. For graphs that have edges of negative length, but no cycles of negative length, there is a different algorithm due to Bellman (1958) and Ford and Fulkerson (1962) that solves the single-source shortest paths problem in $O(|V||E|)$ time.

The key to understanding this algorithm is the RELAX operation applied to an edge. In a single scan of the edges, we execute the RELAX operation on each edge. We then repeat the step $|V| - 1$ times. No special data structures are required to implement this algorithm, and the proof relies on the fact that a shortest path is simple and contains at most $|V| - 1$ edges (see Cormen et al. 2001 for a proof).

This problem also finds applications in finding a feasible solution to a system of linear equations, where each equation specifies a bound on the difference of two variables. Each constraint is modeled by an edge in a suitably defined directed graph. Such systems of equations arise in real-time applications.

5.6 Minimum Spanning Trees

The following fundamental problem arises in network design. A set of sites needs to be connected by a network. This problem has a natural formulation in graph-theoretic terms. Each site is represented by a vertex. Edges between vertices represent a potential link connecting the corresponding nodes. Each edge is given a nonnegative cost corresponding to the cost of constructing that link. A tree is a minimal network that connects a set of nodes. The cost of a tree is the sum of the costs of its edges. A minimum-cost tree connecting the nodes of a given graph is called a minimum-cost spanning tree, or simply an **MST**. The problem of computing an MST arises in many areas and as a subproblem in combinatorial and geometric problems. MSTs can be computed efficiently using algorithms that are greedy in nature,

and there are several different algorithms for finding an MST. One of the first algorithms was due to Boruvka (1926). The two algorithms that are popularly known as Prim's algorithm and Kruskal's algorithm are described here. (Prim's algorithm was first discovered by Jarnik [1930].)

5.6.1 Prim's Algorithm

Prim's (1957) algorithm for finding an MST of a given graph is one of the oldest algorithms to solve the problem. The basic idea is to start from a single vertex and gradually grow a tree, which eventually spans the entire graph. At each step, the algorithm has a tree that covers a set S of vertices and looks for a *good* edge that may be used to extend the tree to include a vertex that is currently not in the tree. All edges that go from a vertex in S to a vertex in $V - S$ are candidate edges. The algorithm selects a minimum-cost edge from these candidate edges and adds it to the current tree, thereby adding another vertex to S .

As in the case of Dijkstra's algorithm, each vertex $u \in V - S$ can attach itself to only one vertex in the tree (so that cycles are not generated in the solution). Because the algorithm always chooses a minimum-cost edge, it needs to maintain a minimum-cost edge that connects u to some vertex in S as the candidate edge for including u in the tree. A priority queue of vertices is used to select a vertex in $V - S$ that is incident to a minimum-cost candidate edge.

Prim's Algorithm. *Prim-MST* (G, r):

```

1  for all vertices  $v$  in  $G$  do
2     $visited[v] \leftarrow false$ .
3     $d[v] \leftarrow \infty$ .
4     $p[v] \leftarrow nil$ .
5  end-for
6   $d[r] \leftarrow 0$ .
7  BuildPQ ( $H, d$ ).
8  while not Empty ( $H$ ) do
9     $u \leftarrow DeleteMin (H)$ .
10    $visited[u] \leftarrow true$ .
11   for all vertices  $v$  in  $adj[u]$  do
12     if not  $visited[v]$  and  $d[v] > w(u, v)$  then
13        $d[v] \leftarrow w(u, v)$ .
14        $p[v] \leftarrow u$ .
15       DecreaseKey ( $H, v, d[v]$ ).
16     end-if
17   end-for
18 end-while
end-proc
```

5.6.1.1 Analysis

First observe the similarity between Prim's and Dijkstra's algorithms. Both algorithms start building the tree from a single vertex and grow it by adding one vertex at a time. The only difference is the rule for deciding when the current label is updated for vertices outside the tree. Both algorithms have the same structure and therefore have similar running times. Prim's algorithm runs in $O(|E| \log |V|)$ time if the priority queue is implemented using binary heaps, and it runs in $O(|E| + |V| \log |V|)$ if the priority queue is implemented using Fibonacci heaps.

5.6.2 Kruskal's Algorithm

Kruskal's (1956) algorithm for finding an MST of a given graph is another classical algorithm for the problem and is also greedy in nature. Unlike Prim's algorithm, which grows a single tree, Kruskal's

algorithm grows a forest. First, the edges of the graph are sorted in nondecreasing order of their costs. The algorithm starts with the empty spanning forest (no edges). The edges of the graph are scanned in sorted order, and if the addition of the current edge does not generate a cycle in the current forest, it is added to the forest. The main test at each step is: does the current edge connect two vertices in the same connected component? Eventually, the algorithm adds $|V| - 1$ edges to make a spanning tree in the graph.

The main data structure needed to implement the algorithm is for the maintenance of connected components, to ensure that the algorithm does not add an edge between two nodes in the same connected component. An abstract version of this problem is known as the union–find problem for a collection of disjoint sets. Efficient algorithms are known for this problem, where an arbitrary sequence of UNION and FIND operations can be implemented to run in almost linear time (Cormen et al. 2001, Tarjan 1983).

Kruskal’s Algorithm. *Kruskal-MST* (G):

```

1  $T \leftarrow \phi$ .
2 for all vertices  $v$  in  $G$  do
3   Makeset( $v$ ).
4 Sort the edges of  $G$  by nondecreasing order of costs.
5 for all edges  $e = (u, v)$  in  $G$  in sorted order do
6   if Find ( $u$ )  $\neq$  Find ( $v$ ) then
7      $T \leftarrow T \cup (u, v)$ .
8   Union ( $u, v$ ).
9 end-proc
```

5.6.2.1 Analysis

The running time of the algorithm is dominated by step 4 of the algorithm in which the edges of the graph are sorted by nondecreasing order of their costs. This takes $O(|E| \log |E|)$ [which is also $O(|E| \log |V|)$] time using an efficient sorting algorithm such as heapsort. Kruskal’s algorithm runs faster in the following special cases: if the edges are presorted, if the edge costs are within a small range, or if the number of different edge costs is bounded by a constant. In all of these cases, the edges can be sorted in linear time, and the algorithm runs in near-linear time, $O(|E| \alpha(|E|, |V|))$, where $\alpha(m, n)$ is the inverse Ackermann function (Tarjan 1983).

Remark 5.2

The MST problem can be generalized to directed graphs. The equivalent of trees in directed graphs are called *arborescences* or *branchings*; and because edges have directions, they are rooted spanning trees. An incoming branching has the property that every vertex has a unique path to the root. An outgoing branching has the property that there is a unique path from the root to each vertex in the graph. The input is a directed graph with arbitrary costs on the edges and a root vertex r . The output is a minimum-cost branching rooted at r . The algorithms discussed in this section for finding MSTs do not directly extend to the problem of finding optimal branchings. There are efficient algorithms that run in $O(|E| + |V| \log |V|)$ time using Fibonacci heaps for finding minimum-cost branchings (Gabow et al. 1986, Gibbons 1985). These algorithms are based on techniques for weighted matroid intersection (Lawler 1976). Almost linear-time deterministic algorithms for the MST problem in undirected graphs are also known (Fredman and Tarjan 1987).

5.7 Matchings and Network Flows

Networks are important both for electronic communication and for transporting goods. The problem of efficiently moving entities (such as bits, people, or products) from one place to another in an underlying network is modeled by the *network flow* problem. The problem plays a central role in the fields of

operations research and computer science, and much emphasis has been placed on the design of efficient algorithms for solving it. Many of the basic algorithms studied earlier in this chapter play an important role in developing various implementations for network flow algorithms.

First, the *matching problem*, which is a special case of the flow problem, is introduced. Then, the *assignment problem*, which is a generalization of the matching problem to the weighted case, is studied. Finally, the network flow problem is introduced and algorithms for solving it are outlined.

The maximum matching problem is studied here in detail only for bipartite graphs. Although this restricts the class of graphs, the same principles are used to design polynomial time algorithms for graphs that are not necessarily bipartite. The algorithms for general graphs are complex due to the presence of structures called *blossoms*, and the reader is referred to Papadimitriou and Steiglitz (1982, Chapter 10) or Tarjan (1983, Chapter 9) for a detailed treatment of how blossoms are handled. Edmonds (see Even 1979) gave the first algorithm to solve the matching problem in polynomial time. Micali and Vazirani (1980) obtained an $O(\sqrt{|V||E|})$ algorithm for nonbipartite matching by extending the algorithm by Hopcroft and Karp (1973) for the bipartite case.

5.7.1 Matching Problem Definitions

Given a graph $G = (V, E)$, a matching M is a subset of the edges such that no two edges in M share a common vertex. In other words, the problem is that of finding a set of independent edges that have no incident vertices in common. The cardinality of M is usually referred to as its *size*.

The following terms are defined with respect to a matching M . The edges in M are called *matched edges* and edges not in M are called *free edges*. Likewise, a vertex is a *matched vertex* if it is incident to a matched edge. A *free vertex* is one that is not matched. The *mate* of a matched vertex v is its neighbor w that is at the other end of the matched edge incident to v . A matching is called *perfect* if all vertices of the graph are matched in it. The objective of the maximum matching problem is to maximize $|M|$ the size of the matching. If the edges of the graph have weights, then the *weight* of a matching is defined to be the sum of the weights of the edges in the matching. A path $p = [v_1, v_2, \dots, v_k]$ is called an *alternating path* if the edges (v_{2j-1}, v_{2j}) , $j = 1, 2, \dots$, are free and the edges (v_{2j}, v_{2j+1}) , $j = 1, 2, \dots$, are matched. An *augmenting path* $p = [v_1, v_2, \dots, v_k]$ is an alternating path in which both v_1 and v_k are free vertices.

Observe that an augmenting path is defined with respect to a specific matching. The symmetric difference of a matching M and an augmenting path P , $M \oplus P$, is defined to be $(M - P) \cup (P - M)$. The operation can be generalized to the case when P is any subset of the edges.

5.7.2 Applications of Matching

Matchings are the underlying basis for many optimization problems. Problems of assigning workers to jobs can be naturally modeled as a bipartite matching problem. Other applications include assigning a collection of jobs with precedence constraints to two processors, such that the total execution time is minimized (Lawler 1976). Other applications arise in chemistry, in determining structure of chemical bonds, matching moving objects based on a sequence of photographs, and localization of objects in space after obtaining information from multiple sensors (Ahuja et al. 1993).

5.7.3 Matchings and Augmenting Paths

The following theorem gives necessary and sufficient conditions for the existence of a perfect matching in a bipartite graph.

Theorem 5.1 (Hall's Theorem)

A bipartite graph $G = (X, Y, E)$ with $|X| = |Y|$ has a perfect matching if and only if $\forall S \subseteq X, |N(S)| \geq |S|$, where $N(S) \subseteq Y$ is the set of vertices that are neighbors of some vertex in S .

Although Theorem 5.1 captures exactly the conditions under which a given bipartite graph has a perfect matching, it does not lead directly to an algorithm for finding maximum matchings. The following lemma shows how an augmenting path with respect to a given matching can be used to increase the size of a matching. An efficient algorithm that uses augmenting paths to construct a maximum matching incrementally is described later.

Lemma 5.1

Let P be the edges on an augmenting path $p = [v_1, \dots, v_k]$ with respect to a matching M . Then, $M' = M \oplus P$ is a matching of cardinality $|M| + 1$.

Proof Since P is an augmenting path, both v_1 and v_k are free vertices in M . The number of free edges in P is one more than the number of matched edges. The symmetric difference operator replaces the matched edges of M in P by the free edges in P . Hence, the size of the resulting matching, $|M'|$, is one more than $|M|$.

The following theorem provides a necessary and sufficient condition for a given matching M to be a maximum matching.

Theorem 5.2

A matching M in a graph G is a maximum matching if and only if there is no augmenting path in G with respect to M .

Proof If there is an augmenting path with respect to M , then M cannot be a maximum matching, since by Lemma 5.1 there is a matching whose size is larger than that of M . To prove the converse, we show that if there is no augmenting path with respect to M , then M is a maximum matching. Suppose that there is a matching M' such that $|M'| > |M|$. Consider the set of edges $M \oplus M'$. These edges form a subgraph in G . Each vertex in this subgraph has degree at most two, since each node has at most one edge from each matching incident to it. Hence, each connected component of this subgraph is either a path or a simple cycle. For each cycle, the number of edges of M is the same as the number of edges of M' . Since $|M'| > |M|$, one of the paths must have more edges from M' than from M . This path is an augmenting path in G with respect to the matching M , contradicting the assumption that there were no augmenting paths with respect to M .

5.7.4 Bipartite Matching Algorithm**5.7.4.1 High-Level Description**

The algorithm starts with the empty matching $M = \emptyset$ and augments the matching in phases. In each phase, an augmenting path with respect to the current matching M is found, and it is used to increase the size of the matching. An augmenting path, if one exists, can be found in $O(|E|)$ time, using a procedure similar to BFS described in Section 5.4.

The search for an augmenting path proceeds from the free vertices. At each step when a vertex in X is processed, all its unvisited neighbors are also searched. When a matched vertex in Y is considered, only its matched neighbor is searched. This search proceeds along a subgraph referred to as the *Hungarian tree*.

Initially, all free vertices in X are placed in a queue that holds vertices that are yet to be processed. The vertices are removed one by one from the queue and processed as follows. In turn, when vertex v is removed from the queue, the edges incident to it are scanned. If it has a neighbor in the vertex set Y that is free, then the search for an augmenting path is successful; procedure AUGMENT is called to update the matching, and the algorithm proceeds to its next phase. Otherwise, add the mates of all of the matched neighbors of v to the queue if they have never been added to the queue, and continue the search for an augmenting path. If the algorithm empties the queue without finding an augmenting path, its current matching is a maximum matching and it terminates.

The main data structure that the algorithm uses consists of the arrays *mate* and *free*. The array *mate* is used to represent the current matching. For a matched vertex $v \in G$, $mate[v]$ denotes the matched neighbor of vertex v . For $v \in X$, $free[v]$ is a vertex in Y that is adjacent to v and is free. If no such vertex exists, then $free[v] = 0$.

Bipartite Matching Algorithm. *Bipartite Matching* ($G = (X, Y, E)$):

```

1  for all vertices  $v$  in  $G$  do
2     $mate[v] \leftarrow 0$ .
3  end-for
4  found  $\leftarrow false$ .
5  while not found do
6    Initialize.
7    MakeEmptyQueue ( $Q$ ).
8    for all vertices  $x \in X$  do
9      if  $mate[x] = 0$  then
10       Enqueue ( $Q, x$ ).
11        $label[x] \leftarrow 0$ .
12     endif
13   end-for
14   done  $\leftarrow false$ .
15   while not done and not Empty ( $Q$ ) do
16      $x \leftarrow$  Dequeue ( $Q$ ).
17     if  $free[x] \neq 0$  then
18       Augment ( $x$ ).
19       done  $\leftarrow true$ .
20     else
21       for all edges  $(x, x') \in A$  do
22         if  $label[x'] = 0$  then
23            $label[x'] \leftarrow x$ .
24           Enqueue ( $Q, x'$ ).
25         end-if
26       end-for
27     end-if
28     if Empty ( $Q$ ) then
29       found  $\leftarrow true$ .
30     end-if
31   end-while
32 end-while
end-proc

```

```

Initialize:
1  for all vertices  $x \in X$  do
2     $free[x] \leftarrow 0$ .
3  end-for
4   $A \leftarrow \emptyset$ .
5  for all edges  $(x, y) \in E$  do
6    if  $mate[y] = 0$  then  $free[x] \leftarrow y$ 
7    else if  $mate[y] \neq x$  then  $A \leftarrow A \cup (x, mate[y])$ .
8    end-if
9  end-for
end-proc

```

```

Augment( $x$ ):
1  if  $label[x] = 0$  then
2     $mate[x] \leftarrow free[x]$ .
3     $mate[free[x]] \leftarrow x$ 
4  else
5     $free[label[x]] \leftarrow mate[x]$ 
6     $mate[x] \leftarrow free[x]$ 
7     $mate[free[x]] \leftarrow x$ 
8    Augment ( $label[x]$ )
9  end-if
end-proc

```

5.7.4.2 Sample Execution

Figure 5.5 shows a sample execution of the matching algorithm. We start with a partial matching and show the structure of the resulting Hungarian tree. An augmenting path from vertex b to vertex u is found by the algorithm.

5.7.4.3 Analysis

If there are augmenting paths with respect to the current matching, the algorithm will find at least one of them. Hence, when the algorithm terminates, the graph has no augmenting paths with respect to the current matching and the current matching is optimal. Each iteration of the main *while* loop of the algorithm runs in $O(|E|)$ time. The construction of the auxiliary graph A and computation of the array $free$ also take $O(|E|)$ time. In each iteration, the size of the matching increases by one and thus there are, at most, $\min(|X|, |Y|)$ iterations of the *while* loop. Therefore, the algorithm solves the matching problem for bipartite graphs in time $O(\min(|X|, |Y|)|E|)$. Hopcroft and Karp (1973) showed how to improve the running time by finding a maximal set of shortest disjoint augmenting paths in a single phase in $O(|E|)$ time. They also proved that the algorithm runs in only $O(\sqrt{|V|})$ phases.

5.7.5 Assignment Problem

We now introduce the assignment problem, which is that of finding a maximum-weight matching in a given bipartite graph in which edges are given nonnegative weights. There is no loss of generality in assuming that the graph is complete, since zero-weight edges may be added between pairs of vertices that are nonadjacent in the original graph without affecting the weight of a maximum-weight matching. The minimum-weight perfect matching can be reduced to the maximum-weight matching problem as follows: choose a constant M that is larger than the weight of any edge. Assign each edge a new weight of $w'(e) = M - w(e)$. Observe that maximum-weight matchings with the new weight function are minimum-weight perfect

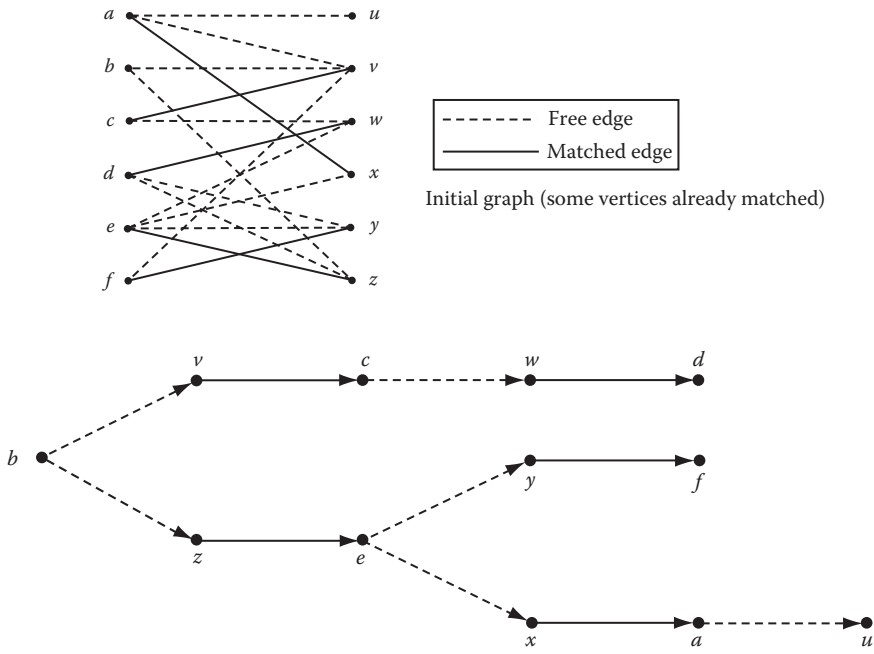

FIGURE 5.5 Sample execution of matching algorithm.

matchings with the original weights. We restrict our attention to the study of the maximum-weight matching problem for bipartite graphs. Similar techniques have been used to solve the maximum-weight matching problem in arbitrary graphs (see Lawler 1976, Papadimitriou and Steiglitz 1982).

The input is a complete bipartite graph $G = (X, Y, X \times Y)$ and each edge e has a nonnegative weight of $w(e)$. The following algorithm, known as the Hungarian method, was first given by Kuhn (1955). The method can be viewed as a primal-dual algorithm in the linear programming framework (Papadimitriou and Steiglitz 1982). No knowledge of linear programming is assumed here.

A *feasible vertex-labeling* ℓ is defined to be a mapping from the set of vertices in G to the real numbers such that for each edge (x_i, y_j) the following condition holds:

$$\ell(x_i) + \ell(y_j) \geq w(x_i, y_j)$$

The following can be verified to be a feasible vertex labeling. For each vertex $y_j \in Y$, set $\ell(y_j)$ to be 0; and for each vertex $x_i \in X$, set $\ell(x_i)$ to be the maximum weight of an edge incident to x_i :

$$\begin{aligned} \ell(y_j) &= 0, \\ \ell(x_i) &= \max_j w(x_i, y_j) \end{aligned}$$

The *equality subgraph*, G_e , is defined to be the subgraph of G , which includes all vertices of G but only those edges (x_i, y_j) that have weights such that

$$\ell(x_i) + \ell(y_j) = w(x_i, y_j)$$

The connection between equality subgraphs and maximum-weighted matchings is established by the following theorem.

Theorem 5.3

If the equality subgraph, G_e , has a perfect matching, M^* , then M^* is a maximum-weight matching in G .

Proof Let M^* be a perfect matching in G_e . By definition,

$$w(M^*) = \sum_{e \in M^*} w(e) = \sum_{v \in X \cup Y} \ell(v)$$

Let M be any perfect matching in G . Then,

$$w(M) = \sum_{e \in M} w(e) \leq \sum_{v \in X \cup Y} \ell(v) = w(M^*)$$

Hence, M^* is a maximum-weight perfect matching.

5.7.5.1 High-Level Description

Theorem 5.3 is the basis of the algorithm for finding a maximum-weight matching in a complete bipartite graph. The algorithm starts with a feasible labeling and then computes the equality subgraph and a maximum cardinality matching in this subgraph. If the matching found is perfect, by Theorem 5.3, the matching must be a maximum-weight matching and the algorithm returns it as its output. Otherwise, more edges need to be added to the equality subgraph by *revising* the vertex labels. The revision keeps edges from the current matching in the equality subgraph. After more edges are added to the equality subgraph, the algorithm grows the Hungarian trees further. Either the size of the matching increases because an augmenting path is found or a new vertex is added to the Hungarian tree. In the former case, the current phase terminates and the algorithm starts a new phase, because the matching size has increased. In the latter case, new nodes are added to the Hungarian tree. In n phases, the tree includes all of the nodes, and therefore there are at most n phases before the size of the matching increases.

It is now described in more detail how the labels are updated and which edges are added to the equality subgraph G_e . Suppose M is a maximum matching in G_e found by the algorithm. Hungarian trees are grown from all the free vertices in X . Vertices of X (including the free vertices) that are encountered in the search are added to a set S , and vertices of Y that are encountered in the search are added to a set T . Let $\bar{S} = X - S$ and $\bar{T} = Y - T$. Figure 5.6 illustrates the structure of the sets S and T . Matched edges are shown in bold; the other edges are the edges in G_e . Observe that there are no edges in the equality subgraph from S to \bar{T} , although there may be edges from T to \bar{S} . Let us choose δ to be the smallest value such that some edge of $G - G_e$ enters the equality subgraph. The algorithm now revises the labels as follows. Decrease all of the labels of vertices in S by δ and increase the labels of the vertices in T by δ . This ensures that edges in the matching continue to stay in the equality subgraph. Edges in G (not in G_e) that go from vertices in S to vertices in \bar{T} are candidate edges to enter the equality subgraph, since one label is decreasing and the other is unchanged. Suppose this edge goes from $x \in S$ to $y \in \bar{T}$. If y is free, then an augmenting path has been found. On the other hand, if y is matched, the Hungarian tree is grown by moving y to T and its matched neighbor to S , and the process of revising labels continues.

5.7.6 B-Matching Problem

The b-matching problem is a generalization of the matching problem. In its simplest form, given an integer $b \geq 1$, the problem is to find a subgraph H of a given graph G such that the degree of each vertex is

FIGURE 5.6 Sets S and T as maintained by the algorithm. Only edges in G_ϵ are shown.

exactly equal to b in H (such a subgraph is called a *b-regular subgraph*). The problem can also be formulated as an optimization problem by seeking a subgraph H with most edges, with the degree of each vertex to be at most b in H . Several generalizations are possible, including different degree bounds at each vertex, degrees of some vertices unspecified, and edges with weights. All variations of the b-matching problem can be solved using the techniques for solving the matching problem.

In this section, we show how the problem can be solved for the unweighted b-matching problem in which each vertex v is given a degree bound of $b[v]$, and the objective is to find a subgraph H in which the degree of each vertex v is exactly equal to $b[v]$. From the given graph G , construct a new graph G_b as follows. For each vertex $v \in G$, introduce $b[v]$ vertices in G_b , namely, $v_1, v_2, \dots, v_{b[v]}$. For each edge $e = (u, v)$ in G , add two new vertices e_u and e_v to G_b , along with the edge (e_u, e_v) . In addition, add edges between v_i and e_v , for $1 \leq i \leq b[v]$ (and between u_j and e_u , for $1 \leq j \leq b[u]$). We now show that there is a natural one-to-one correspondence between b-matchings in G and perfect matchings in G_b .

Given a b-matching H in G , we show how to construct a perfect matching in G_b . For each edge $(u, v) \in H$, match e_u to the next available u_j and e_v to the next available v_i . Since u is incident to exactly $b[u]$ edges in H , there are exactly enough nodes $u_1, u_2, \dots, u_{b[u]}$ in the previous step. For all edges $e = (u, v) \in G - H$, we match e_u and e_v . It can be verified that this yields a perfect matching in G_b .

We now show how to construct a b-matching in G , given a perfect matching in G_b . Let M be a perfect matching in G_b . For each edge $e = (u, v) \in G$, if $(e_u, e_v) \in M$, then do not include the edge e in the b-matching. Otherwise, e_u is matched to some u_j and e_v is matched to some v_i in M . In this case, we include e in our b-matching. Since there are exactly $b[u]$ vertices $u_1, u_2, \dots, u_{b[u]}$, each such vertex introduces an edge into the b-matching, and therefore the degree of u is exactly $b[u]$. Therefore, we get a b-matching in G .

5.7.7 Network Flows

A number of polynomial time flow algorithms have been developed over the past two decades. The reader is referred to Ahuja et al. (1993) for a detailed account of the historical development of the various flow methods. Cormen et al. (2001) review the preflow push method in detail; and to complement their coverage, an implementation of the blocking flow technique of Malhotra et al. (1978) is discussed here.

5.7.8 Network Flow Problem Definitions

First, the network flow problem and its basic terminology are defined.

Flow network: A flow network $G = (V, E)$ is a directed graph, with two specially marked nodes, namely, the source s and the sink t . There is a *capacity* function $c: E \mapsto R^+$ that maps edges to positive real numbers.

Max-flow problem: A flow function $f: E \mapsto R$ maps edges to real numbers. For an edge $e = (u, v)$, $f(e)$ refers to the flow on edge e , which is also called the net flow from vertex u to vertex v . This notation is extended to sets of vertices as follows: If X and Y are sets of vertices, then $f(X, Y)$ is defined to be $\sum_{x \in X} \sum_{y \in Y} f(x, y)$. A flow function is required to satisfy the following constraints:

- *Capacity constraint.* For all edges e , $f(e) \leq c(e)$.
- *Skew symmetry constraint.* For an edge $e = (u, v)$, $f(u, v) = -f(v, u)$.
- *Flow conservation.* For all vertices $u \in V - \{s, t\}$, $\sum_{v \in V} f(u, v) = 0$.

The capacity constraint says that the total flow on an edge does not exceed its capacity. The skew symmetry condition says that the flow on an edge is the negative of the flow in the reverse direction. The flow conservation constraint says that the total net flow out of any vertex other than the source and sink is zero.

The *value* of the flow is defined as

$$|f| = \sum_{v \in V} f(s, v)$$

In other words, it is the net flow out of the source. In the *maximum-flow problem*, the objective is to find a flow function that satisfies the three constraints and also maximizes the total flow value $|f|$.

Remark 5.3

This formulation of the network flow problem is powerful enough to capture generalizations where there are many sources and sinks (single commodity flow) and where both vertices and edges have capacity constraints.

First, the notion of cuts is defined, and the max-flow min-cut theorem is introduced. Then, residual networks, layered networks, and the concept of blocking flows are introduced. Finally, an efficient algorithm for finding a blocking flow is described.

An s - t *cut* of the graph is a partitioning of the vertex set V into two sets S and $T = V - S$ such that $s \in S$ and $t \in T$. If f is a flow, then the net flow across the cut is defined as $f(S, T)$. The capacity of the cut is similarly defined as $c(S, T) = \sum_{x \in X} \sum_{y \in Y} c(x, y)$. The net flow across a cut may include negative net flows between vertices, but the capacity of the cut includes only nonnegative values, that is, only the capacities of edges from S to T .

Using the flow conservation principle, it can be shown that the net flow across an s - t cut is exactly the flow value $|f|$. By the capacity constraint, the flow across the cut cannot exceed the capacity of the cut. Thus, the value of the maximum flow is no greater than the capacity of a minimum s - t cut. The well-known *max-flow min-cut theorem* (Elias et al. 1956, Ford and Fulkerson 1962) proves that the two numbers are actually equal. In other words, if f^* is a maximum flow, then there is some cut (X, \bar{X}) such that $|f^*| = c(X, \bar{X})$. The reader is referred to Cormen et al. (2001) and Tarjan (1983) for further details.

The *residual capacity* of a flow f is defined to be a function on vertex pairs given by $c'(v, w) = c(v, w) - f(v, w)$. The residual capacity of an edge (v, w) , $c'(v, w)$, is the number of additional units of flow that can be pushed from v to w without violating the capacity constraints. An edge e is *saturated* if $c(e) = f(e)$, that is, if its residual capacity, $c'(e)$, is zero. The residual graph $G_R(f)$ for a flow f is the graph with vertex set V , source and sink s and t , respectively, and those edges (v, w) for which $c'(v, w) > 0$.

An augmenting path for f is a path P from s to t in $G_R(f)$. The residual capacity of P , denoted by $c'(P)$, is the minimum value of $c'(v, w)$ over all edges (v, w) in the path P . The flow can be increased by $c'(P)$, by increasing the flow on each edge of P by this amount. Whenever $f(v, w)$ is changed, $f(w, v)$ is also correspondingly changed to maintain skew symmetry.

Most flow algorithms are based on the concept of augmenting paths pioneered by Ford and Fulkerson (1956). They start with an initial zero flow and augment the flow in stages. In each stage, a residual graph $G_R(f)$ with respect to the current flow function f is constructed and an augmenting path in $G_R(f)$ is found to increase the value of the flow. Flow is increased along this path until an edge in this path is saturated. The algorithms iteratively keep increasing the flow until there are no more augmenting paths in $G_R(f)$ and return the final flow f as their output.

The following lemma is fundamental in understanding the basic strategy behind these algorithms.

Lemma 5.2

Let f be any flow and f^* a maximum flow in G , and let $G_R(f)$ be the residual graph for f . The value of a maximum flow in $G_R(f)$ is $|f^*| - |f|$.

Proof Let f' be any flow in $G_R(f)$. Define $f + f'$ to be the flow defined by the flow function $f(v, w) + f'(v, w)$ for each edge (v, w) . Observe that $f + f'$ is a feasible flow in G of value $|f| + |f'|$. Since f^* is the maximum flow possible in G , $|f'| \leq |f^*| - |f|$. Similarly define $f^* - f$ to be a flow in $G_R(f)$ defined by $f^*(v, w) - f(v, w)$ in each edge (v, w) , and this is a feasible flow in $G_R(f)$ of value $|f^*| - |f|$, and it is a maximum flow in $G_R(f)$.

Blocking flow: A flow f is a *blocking flow* if every path in G from s to t contains a saturated edge.

It is important to note that a blocking flow is not necessarily a maximum flow. There may be augmenting paths that increase the flow on some edges and decrease the flow on other edges (by increasing the flow in the reverse direction).

Layered networks: Let $G_R(f)$ be the residual graph with respect to a flow f . The level of a vertex v is the length of a shortest path (using the least number of edges) from s to v in $G_R(f)$. The level graph L for f is the subgraph of $G_R(f)$ containing vertices reachable from s and only the edges (v, w) such that $\text{dist}(s, w) = 1 + \text{dist}(s, v)$. L contains all shortest-length augmenting paths and can be constructed in $O(|E|)$ time.

The maximum-flow algorithm proposed by Dinitz (1970) starts with the zero flow and iteratively increases the flow by augmenting it with a blocking flow in $G_R(f)$ until t is not reachable from s in $G_R(f)$.

At each step, the current flow is replaced by the sum of the current flow and the blocking flow. Since in each iteration the shortest distance from s to t in the residual graph increases, and the shortest path from s to t is at most $|V| - 1$, this gives an upper bound on the number of iterations of the algorithm.

An algorithm to find a blocking flow that runs in $O(|V|^2)$ time is described here, and this yields an $O(|V|^3)$ max-flow algorithm. There are a number of $O(|V|^2)$ blocking flow algorithms available (Karzanov 1974, Malhotra et al. 1978, Tarjan 1983), some of which are described in detail in Tarjan (1983).

5.7.9 Blocking Flows

Dinitz's algorithm to find a blocking flow runs in $O(|V||E|)$ time (Dinitz 1970). The main step is to find paths from the source to the sink and saturate them by pushing as much flow as possible on these paths. Every time the flow is increased by pushing more flow along an augmenting path, one of the edges on this path becomes saturated. It takes $O(|V|)$ time to compute the amount of flow that can be pushed on the path. Since there are $|E|$ edges, this yields an upper bound of $O(|V||E|)$ steps on the running time of the algorithm.

Malhotra–Kumar–Maheshwari Blocking Flow Algorithm. The algorithm has a current flow function f and its corresponding residual graph $G_R(f)$. Define for each node $v \in G_R(f)$, a quantity $tp[v]$ that specifies its maximum throughput, that is, either the sum of the capacities of the incoming arcs or the sum of the capacities of the outgoing arcs, whichever is smaller. $tp[v]$ represents the maximum flow that could pass through v in any feasible blocking flow in the residual graph. Vertices for which the throughput is zero are deleted from $G_R(f)$.

The algorithm selects a vertex u for which its throughput is a minimum among all vertices with nonzero throughput. It then greedily pushes a flow of $tp[u]$ from u toward t , level by level in the layered residual graph. This can be done by creating a queue, which initially contains u and which is assigned the task of pushing $tp[u]$ out of it. In each step, the vertex v at the front of the queue is removed and the arcs going out of v are scanned one at a time, and as much flow as possible is pushed out of them until v 's allocated flow has been pushed out. For each arc (v, w) that the algorithm pushed flow through, it updates the residual capacity of the arc (v, w) and places w on a queue (if it is not already there) and increments the net incoming flow into w . Also, $tp[v]$ is reduced by the amount of flow that was sent through it now. The flow finally reaches t , and the algorithm never comes across a vertex that has incoming flow that exceeds its outgoing capacity since u was chosen as a vertex with the smallest throughput. The preceding idea is again repeated to pull a flow of $tp[u]$ from the source s to u . Combining the two steps yields a flow of $tp[u]$ from s to t in the residual network that goes through u . The flow f is augmented by this amount. Vertex u is deleted from the residual graph, along with any other vertices that have zero throughput.

This procedure is repeated until all vertices are deleted from the residual graph. The algorithm has a blocking flow at this stage since at least one vertex is saturated in every path from s to t . In the algorithm, whenever an edge is saturated, it may be deleted from the residual graph. Since the algorithm uses a greedy strategy to send flows, at most $O(|E|)$ time is spent when an edge is saturated. When finding flow paths to push $tp[u]$, there are at most n times, one each per vertex, when the algorithm pushes a flow that does not saturate the corresponding edge. After this step, u is deleted from the residual graph. Hence, in $O(|E| + |V|^2) = O(|V|^2)$ steps, the algorithm to compute blocking flows terminates.

Goldberg and Tarjan (1988) proposed a preflow push method that runs in $O(|V||E|\log|V|^2/|E|)$ time without explicitly finding a blocking flow at each step.

5.7.10 Applications of Network Flow

There are numerous applications of the maximum-flow algorithm in scheduling problems of various kinds. See Ahuja et al. (1993) for further details.

5.8 Tour and Traversal Problems

There are many applications for finding certain kinds of paths and tours in graphs. We briefly discuss some of the basic problems.

The *traveling salesman problem (TSP)* is that of finding a shortest tour that visits all of the vertices in a given graph with weights on the edges. It has received considerable attention in the literature (Lawler et al. 1985). The problem is known to be computationally intractable (NP-hard). Several heuristics are known to solve practical instances. Considerable progress has also been made for finding optimal solutions for graphs with a few thousand vertices.

One of the first graph-theoretic problems to be studied, the *Euler tour problem*, asks for the existence of a closed walk in a given connected graph that traverses each edge exactly once. Euler proved that such a closed walk exists if and only if each vertex has even degree (Gibbons 1985). Such a graph is known as an *Eulerian graph*. Given an Eulerian graph, an Euler tour in it can be computed using DFS in linear time. Given an edge-weighted graph, the *Chinese postman problem* is that of finding a shortest closed walk that traverses each edge at least once. Although the problem sounds very similar to the TSP problem, it can be solved optimally in polynomial time by reducing it to the matching problem (Ahuja et al. 1993).

Key Terms

Assignment problem: That of finding a perfect matching of maximum (or minimum) total weight.

Augmenting path: An alternating path that can be used to augment (increase) the size of a matching.

Biconnected graph: A graph that cannot be disconnected by the removal of any single vertex.

Bipartite graph: A graph in which the vertex set can be partitioned into two sets X and Y , such that each edge connects a node in X with a node in Y .

Blocking flow: A flow function in which any directed path from s to t contains a saturated edge.

Branching: A spanning tree in a rooted graph, such that the root has a path to each vertex.

Chinese postman problem: Asks for a minimum length tour that traverses each edge at least once.

Connected: A graph in which there is a path between each pair of vertices.

Cycle: A path in which the start and end vertices of the path are identical.

Degree: The number of edges incident to a vertex in a graph.

DFS forest: A rooted forest formed by DFS.

Directed acyclic graph: A directed graph with no cycles.

Eulerian graph: A graph that has an Euler tour.

Euler tour problem: Asks for a traversal of the edges that visits each edge exactly once.

Forest: An acyclic graph.

Leaves: Vertices of degree one in a tree.

Matching: A subset of edges that do not share a common vertex.

Minimum spanning tree: A spanning tree of minimum total weight.

Network flow: An assignment of flow values to the edges of a graph that satisfies flow conservation, skew symmetry, and capacity constraints.

Path: An ordered list of edges such that any two consecutive edges are incident to a common vertex.

Perfect matching: A matching in which every node is matched by an edge to another node.

Sparse graph: A graph in which $|E| \ll |V|^2$.

s - t cut: A partitioning of the vertex set into S and T such that $s \in S$ and $t \in T$.

Strongly connected: A directed graph in which there is a directed path in each direction between each pair of vertices.

Topological order: A linear ordering of the edges of a DAG such that every edge in the graph goes from left to right.

Traveling salesman problem: Asks for a minimum length tour of a graph that visits all of the vertices exactly once.

Tree: An acyclic graph with $|V| - 1$ edges.

Walk: An ordered sequence of edges (in which edges could repeat) such that any two consecutive edges are incident to a common vertex.

Further Information

The area of graph algorithms continues to be a very active field of research. There are several journals and conferences that discuss advances in the field. Here, we name a partial list of some of the important meetings: *ACM Symposium on Theory of Computing*, *IEEE Conference on Foundations of Computer Science*, *ACM-SIAM Symposium on Discrete Algorithms*, *the International Colloquium on Automata, Languages and Programming*, and *the European Symposium on Algorithms*. There are many other regional algorithms/theory conferences that carry research papers on graph algorithms. The journals that carry articles on current research in graph algorithms are the *Journal of the ACM*, *SIAM Journal on Computing*, *SIAM Journal on Discrete Mathematics*, *Journal of Algorithms*, *Algorithmica*, *Journal of Computer and System Sciences*, *Information and Computation*, *Information Processing Letters*, and *Theoretical Computer Science*.

To find more details about some of the graph algorithms described in this chapter, we refer the reader to the books by Cormen et al. (2001), Even (1979), and Tarjan (1983). For network flows and matching, a more detailed survey regarding various approaches can be found in Tarjan (1983). Papadimitriou and Steiglitz (1982) discuss the solution of many combinatorial optimization problems using a primal-dual framework.

Current research on graph algorithms focuses on approximation algorithms (Hochbaum 1996), dynamic algorithms, and in the area of graph layout and drawing (DiBattista et al. 1994).

6.1 Introduction

Computational geometry is the branch of algorithms research that deals with problems that are geometric in nature. Its goal is to develop algorithms that are always correct and efficient. Theoretically, efficiency refers to the scaling behavior of an algorithm when the input size gets larger and larger. Furthermore, we are interested in worst-case analysis, where an upper bound on the scaling behavior is to be determined irrespective of the specific input values. The basic problem of sorting a set of values can be seen as a one-dimensional problem. Although computational geometry includes one-dimensional problems, its emphasis is on two-, three-, and higher-dimensional problems. In most cases, the dimension is constant.

Typical geometric objects involved in geometric computations are sets of points, line segments, lines or hyperplanes, sets of circles or spheres, sets of triangles or simplices, or simple polygons or polyhedra. Relationships between these objects include distances, intersections, and angles.

Geometric problems that require computation show up in many different application areas. In robot motion planning, a path must be determined that avoids walls and other obstacles. In automated cartography, text labels must be placed on a map next to the corresponding feature without overlapping other labels or other important map information. In data analysis, clusters of objects from a collection must be formed using similarity measures that involve distance in some space. To form a complex between two proteins, a good local geometric fit is required. The list of examples of such questions where geometric computations on data are necessary is endless.

6.1.1 Basic Algorithmic Problems

To get a quick feel of which problems belong to computational geometry, we list a number of these problems in this section; see also Figure 6.1.

Convex hull: Given a set P of n points in the plane or d -dimensional space, compute a representation of the boundary of the minimum convex set that contains these points.

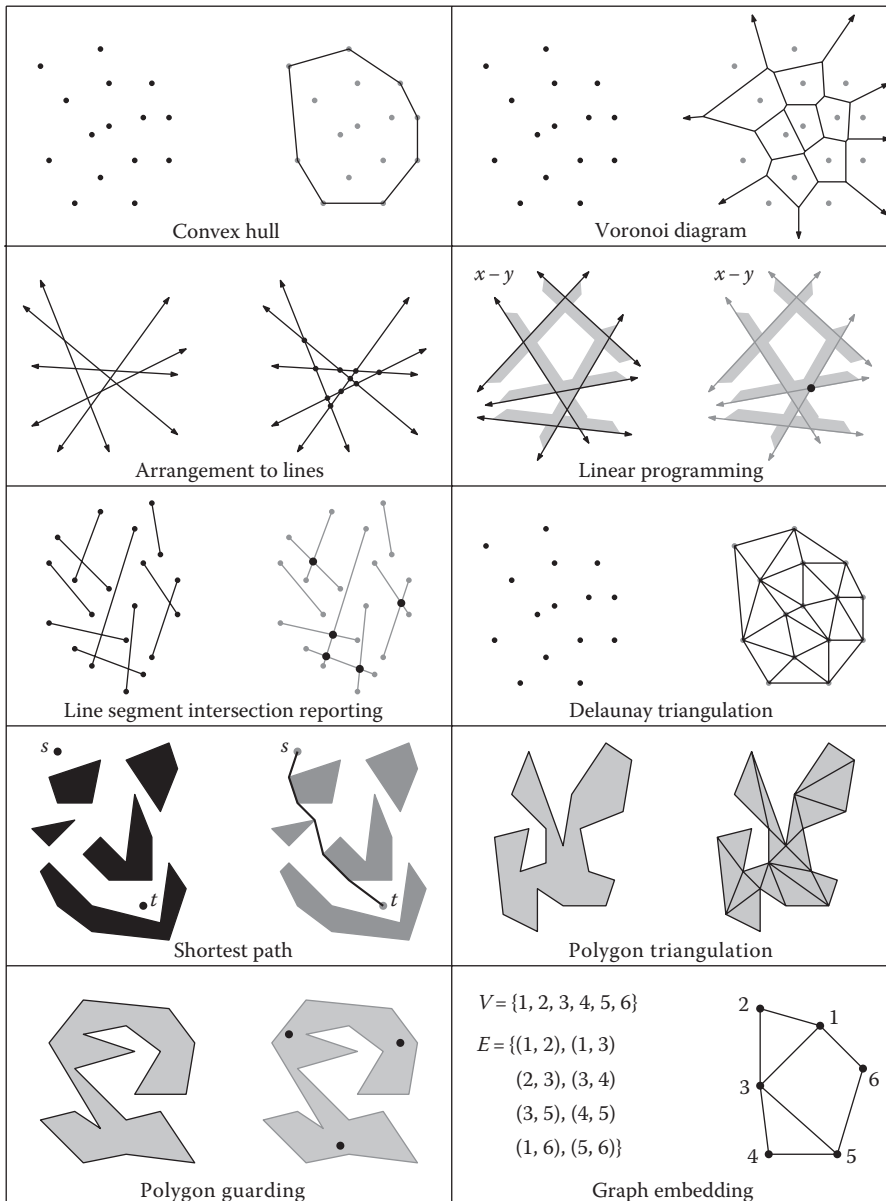

FIGURE 6.1 Ten basic problems in computational geometry. To the left the input is shown in black, and to the right the computed output is shown in black.

This problem can be solved in $O(n \log n)$ time when $d = 2$ [6,38,56,86] or $d = 3$ [35,38,86], and in $O(n^{\lfloor d/2 \rfloor})$ time when $d \geq 4$ [24].

Voronoi diagram: Given a set P of n points in the plane or d -dimensional space, compute a subdivision into cells so that any single cell represents exactly that part of the space where a single point is closest, among the points in P .

This problem can be solved in $O(n \log n)$ time when $d = 2$ [38,50,95], and in $O(n^{\lfloor d/2 \rfloor})$ time when $d \geq 3$ [22,35,94].

Arrangement of hyperplanes: Given a set H of n hyperplanes in d -dimensional space (lines in the plane, planes in three-dimensional space, etc.), compute a representation of the subdivision they induce.

This problem can be solved in $O(n^d)$ time [42,43].

Linear programming: Given a set H of n half-spaces in d -dimensional space and a linear function in the d coordinates, determine if the common intersection of the half-spaces of H is nonempty, and if so, determine a point that minimizes the linear function or report that arbitrarily low values can be realized.

This problem can be solved in $O(n)$ time [34,76,94] when d is a constant.

Intersection reporting: Given a set of n objects (line segments, rectangles, circles) in the plane, report every intersection point or every pair of intersecting objects.

This problem can be solved in $O(n \log n + k)$ time, where k is the number of pairs of intersecting objects [25,35,79].

Delaunay triangulation: Given a set P of n points in the plane or d -dimensional space, compute a maximal subdivision into triangles (simplices) whose vertices come from P such that no two triangles (simplices) intersect in their interior and the circumcircle of each triangle (circumsphere of each simplex) does not have any points of P in its interior.

This problem can be solved in $O(n \log n)$ time when $d = 2$ [38,50,95], and in $O(n^{\lfloor d/2 \rfloor})$ time when $d \geq 3$ [22,35,94].

Shortest path: Given a set P of disjoint polygons in the plane with n vertices in total and two points s and t , determine a shortest path between s and t that does not intersect the interior of any polygon of P or report that none exists.

This problem can be solved in $O(n \log n)$ time [63]. The three-dimensional version is NP-hard [19].

Polygon triangulation: Given a simple polygon P with n vertices, partition its interior into triangles using edges that connect pairs of vertices, lie inside the polygon, and do not mutually intersect.

This problem can be solved in $O(n)$ time [23], although a much simpler algorithm exists that is only slightly less efficient [93]. The three-dimensional problem is tetrahedralizing a simple polyhedron. Not all simple polyhedra can be tetrahedralized without using extra vertices, and as many as $\Omega(n^2)$ of these may be necessary for some polyhedra [21].

Polygon guarding: Given a simple polygon P with n vertices, determine a minimum-size set S of points such that any point in the interior of P can be connected to at least one point of P with a line segment that does not intersect the exterior of P .

No polynomial-time algorithm for this problem is known. The *Art Gallery Theorem* states that $\lfloor n/3 \rfloor$ point guards are always sufficient and sometimes necessary [32,82].

Graph embedding: Given a graph $G = (V, E)$, compute an embedding in the plane by assigning coordinates to each vertex, such that no two vertices have the same location, no edge has a vertex in its interior, and no pair of edges intersect in their interiors, or decide that this is not possible.

This problem can be solved in $O(n)$ time, where n is the size of the graph [12,39]. The vertices can be placed on an integer grid of size $2n - 4$ by $n - 2$.

The problems listed in the preceding text are all of the single computation type. Within computational geometry, geometric data structures have also been developed. These structures are either used

to represent a subdivision of the plane or higher-dimensional space or to allow efficient query answering. A common data structure of the former type is the doubly-connected edge list [38,78]. It records incidences of edges with vertices, faces, and other edges in a pointer-based structure, and allows easy traversal of the boundary of a face or the edges incident to some vertex. In higher dimensions we can store facets of all dimensionalities and the incidences among them [17,40].

We list a few basic data structuring problems for efficient query answering. The most important properties of the structures are the amount of storage they require and the time needed to answer a query.

Planar point location: Given a planar subdivision S represented by n vertices and edges, where each face has a label, store S in a data structure so that the following type of query can be answered efficiently: for a query point p , report the label of the face that contains p .

This problem can be solved with a data structure that uses $O(n)$ storage and answers queries in $O(\log n)$ time [37,41,66,79,91].

Orthogonal range searching: Given a set P of n points in the plane, store them in a data structure so that the following type of query can be answered efficiently: for an axis-aligned query rectangle, report all points of P that lie inside it.

This problem can be solved with a kd -tree, which requires $O(n)$ storage and can answer queries in $O(\sqrt{n} + k)$ time, where k is the number of points reported [13]. The range tree requires $O(n \log n)$ storage and answers queries in $O(\log n + k)$ time [72,109].

The d -dimensional version of the problem is solved by a kd -tree with $O(n)$ storage and query time $O(n^{1-\frac{1}{d}} + k)$, and by a range tree with $O(n \log^{d-1} n)$ storage and $O(\log^{d-1} n + k)$ query time.

Simplex range searching: Given a set P of n points in the plane or d -dimensional space, store them in a data structure so that the following type of query can be answered efficiently: for a query triangle or simplex, report all points of P that lie inside it.

This problem can be solved with $O(n)$ storage and query time $O(\sqrt{n} + k)$ [73]. Alternatively, it can be solved with $O(n^d)$ storage and query time $O(\log^{d+1} n + k)$ [73].

Algorithms for many of the problems listed in the preceding text and their running time analyses can be found in textbooks in the area of computational geometry [38,83,87]. Many more results and references can be found in the *Handbook of Discrete and Computational Geometry* [54].

6.1.2 Brief Historical Overview

There are examples of geometric algorithms developed before the 1970s, but it was in the 1970s when most of the basic geometric problems were solved in an algorithmically efficient manner. This is true for many of the problems just listed, although some, like the shortest path problem, defied an efficient solution until the 1990s. In 1985 the first textbook on computational geometry was published, and that same year the annual *ACM Symposium on Computational Geometry* was held for the first time. It was realized early that implementing geometric algorithms is highly nontrivial, since robust computation tends to be much harder than for graph algorithms, for example, or for one-dimensional problems. Another early realization was that efficiency analyses of geometric algorithms often depend on combinatorial results in geometry. For this reason, combinatorial geometry has always been considered an integral part of computational geometry.

While the range of geometric problems under consideration continues to expand to this day, much effort has also been directed to putting the theory to use in the application areas. Researchers from computational geometry have contributed to areas like computer graphics, motion planning, pattern recognition, and geographic information systems (GISs) for a long time now. Involvement in three-dimensional reconstruction and computational biology are of a more recent date, where the recent trend toward computational topology has played an important role.

6.2 Underlying Principles

Computational geometry revolves around approaches to develop geometric algorithms, analysis of these algorithms in computational models, optimization of geometric problems, and applications and software development. In this section, we treat the first three aspects; applications and software development follow in the next section.

6.2.1 Algorithmic Approaches

Several algorithmic approaches used in computational geometry are also standard approaches in other algorithmic areas. For example, incremental algorithms, divide-and-conquer algorithms, brute-force algorithms, greedy algorithms, randomized algorithms, and dynamic programming are all used to solve geometric problems.

6.2.1.1 Plane-Sweep Algorithms

One very important and typically geometric algorithmic approach is plane sweep. It is an incremental approach, but one with a specific structure that we explain next.

A plane-sweep algorithm takes a set of objects in the plane as its input. The idea is to use an imaginary line—the sweep line—that moves over all objects in the plane and computes whatever is necessary when it reaches special situations. For example, the sweep line could be a horizontal line that starts above all objects and moves downward until it is below all objects. The sweep line stops only at certain positions (y -coordinates) where something of interest happens. These positions are called *events*. At the same time, the algorithm must maintain certain essential information to be able to generate the desired output. This information changes with the position of the sweep line and is called the *status* (Figure 6.2).

In the example of computing the intersecting pairs among a set of line segments in the plane, the events occur when the sweep line starts to intersect a line segment (at the y -coordinate of its upper endpoint), when the sweep line stops intersecting a line segment (at the y -coordinate of its lower endpoint), and when two line segments intersect (at the y -coordinate of the intersection point). In a plane-sweep algorithm the sweep line moves only in one direction, so the events will occur in the order of decreasing y -coordinate. Note that the events coming from line segment endpoints can be obtained easily from the input, but the events coming from intersection points are not known yet. In fact, the whole purpose of the algorithm is to determine these intersection points (and report the intersecting pairs).

FIGURE 6.2 Plane-sweep algorithm. Positions where the sweep line has stopped are shown in gray. If the current position is the gray, bold line, then the status is $\langle s_4, s_1, s_3, s_5, s_2 \rangle$, and s_1 will be deleted at this event. Also, s_4 and s_3 become horizontally adjacent; their intersection is detected and inserted in the event structure.

The status is the situation at the current position of the sweep line. For our example, it is the set of line segments that intersect the sweep line, ordered from left to right. Observe that the status changes exactly at the events that we just listed.

The events and the status are each stored in a suitable data structure. In our example we use balanced binary search trees. The event structure stores the (known) events by y -coordinate in the tree. The status structure stores the intersected line segments by x -coordinate (valid for the current position of the sweep line) in the tree. Initially, the status structure is empty because the sweep line starts above all line segments. The event structure is initialized with all endpoints of the line segments.

The core of a plane-sweep algorithm is the handling of the events. This is where the algorithm actually does its work. The imaginary sweep line jumps from event to event and handles each one by updating the status, detecting new events that were not known yet, and generating output.

We must detect intersection point events before the sweep line reaches them. As soon as the algorithm finds out that two line segments will intersect later, the event can be inserted in the event structure. The basic idea that makes the algorithm work is the following: before two line segments can intersect, they must become horizontally adjacent first. Two line segments can become horizontally adjacent only at other, higher events (recall that the sweep line goes from top to bottom). So during the handling of any event, we also check if there are new horizontal adjacencies caused by that event, if the involved line segments intersect below the sweep line, and if so, insert the intersection point in the event structure.

The scheme described in the preceding text solves the line segment intersection reporting problem by a sequence of binary search tree operations and geometric tests. Any event is handled by a small, constant number of binary search tree operations. If the input consists of n line segments and there are k intersecting pairs that will be reported, then the algorithm runs in $O((n + k) \log n)$ time, because there are $O(n + k)$ events [14]. Unless there are many intersecting pairs, this compares favorably with the brute-force approach of testing each pair for intersection (taking $O(n^2)$ time).

Plane-sweep algorithms have been developed for computing Voronoi diagrams, Delaunay triangulations, the area of the union of a set of axis-parallel rectangles, as a step in simple polygon triangulation, and many other problems. The three-dimensional version, space sweep with a sweep plane, also exists.

6.2.1.2 Randomized Incremental Construction

Another well-known technique is *randomized incremental construction*. We illustrate this technique by two-dimensional linear programming: Given a set of n half-planes in the plane, determine a point in the common intersection of these half-planes with the lowest y -coordinate, if such a point exists. There are two reasons why such a point would not exist. Firstly, the common intersection of the half-planes may be empty. Secondly, points with arbitrarily low y -coordinates may exist in the common intersection: we say that the linear program is *unbounded*.

To initialize, we find two half-planes bounded from below such that the intersection point of their bounding lines is the solution to the linear program consisting of these two half-planes only. A straightforward scan over the half-planes achieves this. If no two half-planes exist with this property, there is no solution to the linear program. Otherwise, we proceed by putting all other $n - 2$ half-planes in random order and handling them one-by-one in this order. We always maintain the solution to the half-planes handled so far, which is some point p in the plane.

To handle the next half-plane, we test whether p lies inside this half-plane. If so, then p is the solution to the linear program with one more half-plane and we simply proceed with the next half-plane. If not, then we must find a new solution p' or decide that no solution exists. We can argue that if a solution exists, then it must lie on the line bounding the half-plane that we are handling. Hence, we can search for p' on this line, which is a one-dimensional problem that can be solved by considering all previously handled half-planes once more.

The algorithm outlined earlier takes $O(n)$ expected time in the worst case. “Worst case” refers to the fact that the time holds for any set of half-planes. “Expected” refers to the fact that the time bound

depends on the random choices made during the algorithm execution. If these choices are unlucky, then the algorithm may take quadratic time, but this is very unlikely.

The argument to prove the running time bound is as follows. We observe that if the next half-plane contains p , then this half-plane is handled in $O(1)$ time, but if it does not, then this half-plane is handled in time proportional to the number of half-planes that have been handled before. Suppose we are considering the i th half-plane. We ask ourselves what the probability is that it does not contain point p . This probability is the same as the following: after adding the i th half-plane we may have a solution p' , what is the probability that p' is no longer the solution when we remove a random half-plane from the $i - 2$ half-planes (the two initial half-planes were not put in random order so we cannot remove them). This probability is at most $2/(i - 2)$, which can be shown by studying a few geometric situations. If the probability of the expensive case, requiring us to do $O(i)$ work, is at most $2/(i - 2)$, then the expected time for handling the i th half-plane is $O(1)$. In short, every one of the $n - 2$ half-planes that is handled requires $O(1)$ expected time, so $O(n)$ time is expected to be used overall. This argument is called *backward analysis* [94].

Other geometric problems that can be solved efficiently with randomized incremental construction include computing the smallest enclosing disk, Voronoi diagram, Delaunay triangulation, convex hull, constructing a planar point location structure, deciding on red-blue point set separability, and many more [54,79,107].

6.2.1.3 Using Data Structures

Many computational-geometry problems can be solved by using data structures and querying them. As an example, we study the problem of computing the Hausdorff distance between a set R of n red points and a set B of n blue points in the plane.

The *Hausdorff distance* $H(R, B)$ between sets R and B is defined as follows:

$$H(R, B) = \max\left\{\max_{r \in R} \min_{b \in B} d(r, b), \max_{b \in B} \min_{r \in R} d(b, r)\right\}.$$

Intuitively, it is the maximum among all closest point distances from one set to the other or vice versa. The Hausdorff distance is used as a similarity measure between two point sets or simple polygons.

An algorithm to compute the Hausdorff distance between R and B is easy to describe, using the results given before. We first build the Voronoi diagram of R and preprocess it for efficient planar point location. Then we query with each point of B to find the closest point of R , and keep the maximum of these distances. Then we do the same but with the roles of R and B reversed. The overall maximum is the Hausdorff distance.

It takes $O(n \log n)$ time to build the Voronoi diagram of a set of n points. The Voronoi diagram consists of $O(n)$ line segments, and preprocessing it for planar point location takes $O(n \log n)$ time as well. We query with each point of the other set, taking n times $O(\log n)$ time. So this is $O(n \log n)$ total query time as well. Hence, we can compute the Hausdorff distance of two sets of n points in the plane in $O(n \log n)$ time.

6.2.1.4 Dynamic Programming

Dynamic programming is an important algorithmic technique for optimization problems. It can often be used if the problem has the *optimal substructure property*: an optimal solution of any subproblem is composed of optimal solutions to smaller subproblems. We discuss the problem of triangulating a simple polygon with minimum total edge length [67].

Let P be a simple polygon with vertices v_0, \dots, v_{n-1} listed clockwise. We make a table T of size $n \times n$ with an entry for each ordered pair (v_i, v_j) of vertices. This entry will store (i) whether $\overline{v_i v_j}$ is interior to P and does not intersect any of its edges. If the answer is yes we mark the pair `VALID` and we also store

FIGURE 6.3 To compute L_{ij} , there are four valid choices for v_k . The optimal choice of v_k and the optimal triangulation to the left of $\overline{v_i v_j}$ are shown to the right.

(ii) how many vertices N_{ij} , the subpolygon of P bounded by $\overline{v_i v_j}$ and to the left of $\overline{v_i v_j}$, has, and (iii) the minimum total edge length L_{ij} required to triangulate this subpolygon, excluding $\overline{v_i v_j}$.

For the pairs (v_i, v_j) where $j = i + 1 \pmod n$ we also mark them VALID with $N_{ij} = 2$ and $L_{ij} = 0$. For the pairs (v_j, v_i) where $j = i + 1 \pmod n$ we also mark them VALID with $N_{ji} = n$ and initially we set $L_{ji} = +\infty$. At the end of the algorithm, all such L_{ji} will contain the total edge length of the optimal triangulation.

The first and second pieces of information can be precomputed easily in $O(n^3)$ time overall, for all $O(n^2)$ pairs. The third piece is initialized to $+\infty$. Next we sort the ordered pairs by the value of (ii) in increasing order, ties broken arbitrarily. We treat the ones with $N_{ij} > 2$ only.

We iterate over all pairs of edges in the sorted order. Suppose we are treating a pair (v_i, v_j) , see Figure 6.3.

$$L_{ij} = \min_{1 \leq k \leq n} \{L_{ik} + L_{kj} + \|\overline{v_i v_k}\| + \|\overline{v_k v_j}\| \mid (v_i, v_k) \text{ and } (v_k, v_j) \text{ are valid and } N_{ik}, N_{kj} < N_{ij}\}.$$

The recurrence above defines the optimal substructure that polygon triangulation with minimum total edge length has. If (v_i, v_j) is valid, then there must be a triangle in the triangulation to the left of $\overline{v_i v_j}$. The recurrence optimizes over all choices of such triangles and selects the one that yields a minimum total edge length. If this triangle is $\Delta v_i v_j v_k$, then the optimal triangulation of the polygon left of $\overline{v_i v_j}$ always uses optimal triangulations of the polygons left of $\overline{v_i v_k}$ and $\overline{v_k v_j}$, and these are polygons with fewer vertices.

The algorithm essentially fills in the L -values of the table T in the order of increasing N_{ij} . To determine L_{ij} we simply read for each k the information in the entries for pairs (v_i, v_k) and (v_k, v_j) in table T . The optimal triangulation length can be found in any L_{ji} where $j = i + 1 \pmod n$.

Filling one entry takes $O(n)$ time, and hence the whole algorithm takes $O(n^3)$ time.

Other applications of dynamic programming in geometric algorithms include optimization or approximation for label placement, packing and covering, simplification, and matching.

6.2.1.5 Other Algorithmic Techniques in Computational Geometry

There are several other techniques that can be employed to develop algorithms for geometric problems. These include random sampling, prune-and-search, divide-and-conquer, and parametric search. Other techniques of importance are geometric transformations to relate problems to other problems. These include geometric duality, inversion, and Plücker coordinates. For geometric data structures, the technique of fractional cascading can help to make queries more efficient [26,27], while the topics of dynamization [30,31,84] and kinetic data structures [60,101] are also important research areas.

6.2.2 Complexity

6.2.2.1 Machine Model

The standard model of computation assumed in computational geometry is the *real RAM*. In the real RAM model, a real number can be stored in $O(1)$ storage space, and any basic operation or analytic function can be applied to real numbers in $O(1)$ time. Obviously, we can evaluate a polynomial for any real value in $O(1)$ time only if the polynomial has constant degree.

Since algorithms that handle large amounts of data are typically slowed down by disk accesses, the I/O complexity model may sometimes be more appropriate [3,106].

6.2.2.2 Hardness and Reductions

Hardness of a computational problem refers to the (im)possibility of solving that problem efficiently or solving it at all. Hardness results may be lower bounds on the time complexity to solve a problem. These can be proved directly in a model of computation or obtained using a reduction from another problem for which a lower bound is already known. It is essential to specify the model of computation in which a lower bound holds. Many models do not allow rounding of reals to the nearest integer, for example, and algorithms that make use of rounding can be more efficient than what a lower bound claims is possible (in a model without rounding).

Lower bounds on the time complexity of computational problems can be proved using *algebraic decision trees* [88,89]. Branches of such a tree represent comparisons that an algorithm might make based on the input. The longest path in a decision tree corresponds to the worst-case running time of an algorithm. Therefore, a lower bound on the depth of a decision tree for any algorithm that solves a problem is a lower bound for that problem in the decision tree model. Algebraic decision trees give an $\Omega(n \log n)$ -time lower bound for the very basic one-dimensional problem of deciding whether a set of real numbers has two elements that are the same.

A two-dimensional problem that has an $\Omega(n^2)$ -time lower bound is the following [48]: Given a set of n points in the plane, are there three of them that lie on a line? In higher dimensions, the problem of deciding whether a set of n points contains a subset of $d + 1$ points that lie on a common hyperplane has a lower bound of $\Omega(n^d)$ time.

Another type of hardness is referred to as *numerical nonrobustness*. Let P be a set of n points in the plane. To solve the facility location problem of computing a point that minimizes the sum of distances to the points of P , we must minimize an expression that is the sum of n terms with square roots. This is not possible in the usual model of computation, and hence we can only approximate the solution [10,16]. If we were interested in minimizing the sum of *squared* distances, then it would have been easy to compute the optimal location: its coordinates are the mean x and mean y values of the input point set P .

A number of geometric optimization problems are *NP-hard*. Some well-known examples are Euclidean traveling salesperson in the plane [53], Euclidean minimum Steiner tree in the plane [53], minimum-weight triangulation of a planar point set [80], and shortest path in three-dimensional space amid tetrahedra [19]. There are many more examples. Proofs of NP-hardness may use reductions from any of the known NP-hard problems. It turns out that PLANAR 3-SAT is one of the more useful problems to reduce from. PLANAR 3-SAT is a special case of the satisfiability problem where a formula has three literals per clause, and the bipartite graph that has a node for every variable and for every clause, and an edge between them if the variable occurs in the clause, is planar. See Figure 6.4.

Reductions from other problems establish that a geometric problem is at least as hard. For example, the sorting problem can be reduced to planar convex hull computation, and hence any algorithm must take $\Omega(n \log n)$ time to compute a planar convex hull in the algebraic decision tree model [110]. The 3SUM-problem is the problem of deciding, for a given set of n integers, whether it contains three elements that sum up to zero. No algorithm is known for 3SUM that is more efficient than quadratic time. It turns out that many geometric problems can be used to solve 3SUM—in other words, a reduction from 3SUM

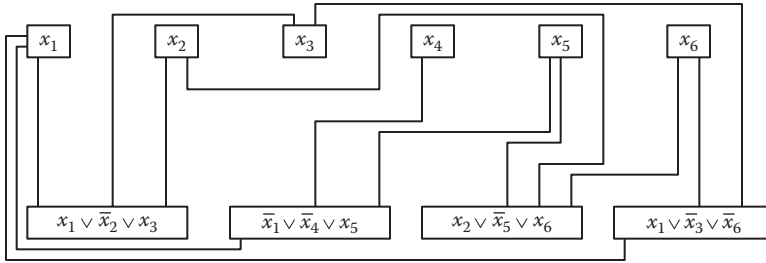

FIGURE 6.4 Planar layout of the 3-SAT expression $(x_1 \vee \bar{x}_2 \vee x_3) \wedge (\bar{x}_1 \vee \bar{x}_4 \vee x_5) \wedge (x_2 \vee \bar{x}_5 \vee x_6) \wedge (x_1 \vee \bar{x}_3 \vee \bar{x}_6)$.

to such geometric problems exists—and therefore these geometric problems are unlikely to be solvable more efficiently than in quadratic time [52]. Examples of such problems include deciding whether a planar point set contains three points that are collinear, deciding whether a line segment can be moved with translations and rotations to a given position without colliding with obstacles, and deciding whether a set of triangles in three-dimensional space occludes another triangle for a given viewpoint [52].

6.2.2.3 Realistic Input Models

It is possible that the union of a set of n triangles in the plane has descriptive complexity $\Theta(n^2)$; see Figure 6.5. Therefore, any algorithm that computes the union of n triangles must take at least quadratic time because it may have to report a shape of quadratic complexity. Now consider the problem of deciding whether a set of n triangles in the plane cover the unit square $[0:1] \times [0:1]$ completely. This problem has constant output size (yes or no), but still all known algorithms take quadratic time or more. The problem is as difficult as 3SUM [52].

In practice, however, unions of n triangles hardly ever have quadratic complexity. It is known that if there is some constant $\alpha > 0$, and all triangles have their three angles at least α , then the union complexity cannot be quadratic but always is $O(n \log \log n)$ [75]. Such triangles are called *fat*. The problem of deciding whether n fat triangles cover the unit square can be solved much faster than quadratic time. We have made an assumption on the input that (possibly) corresponds to real-world situations and stated a worst-case running time that is valid if the assumption holds. Such an assumption is called a *realistic input model*.

Other realistic input models may refer to relative sizes of the objects in the input. We could assume, for example, that a constant $c > 0$ exists so that the largest diameter of an input object is no more than c times the smallest diameter of an input object. Yet another realistic input model is the *bounded spread* of a point set: the distance between the closest two points is at least $f(n)$ times the diameter of the point set, where $f(n)$ is some function of n . With a packing argument, one can show that any d -dimensional point set has spread $\Omega(n^{1/d})$, so we cannot assume $f(n)$ to be constant.

Realistic input models are important to explain the complexity of structures or running times of problems in practice, since it is often different from the worst-case situation. For example, it is known that a three-dimensional point set may have a Delaunay tetrahedrization of size $\Theta(n^2)$, although

FIGURE 6.5 The union of n triangles can have $\Omega(n^2)$ vertices and edges in its boundary.

three-dimensional point sets that occur in practice often have a Delaunay tetrahedrization of linear size or slightly more. It has been shown that for three-dimensional point sets with spread $O(n^{1/3})$, the Delaunay tetrahedrization has size $O(n)$ in the worst case [46,47].

6.2.3 Approximation

Geometric algorithms where optimization of a measure appears inefficient may be tackled using approximation algorithms. This is the case for NP-hard problems, but approximation algorithms have also been developed to improve on quadratic running times, or even to reduce $O(n \log n)$ time bounds to linear.

An algorithm for a minimization problem A is a c -approximation algorithm for some $c > 1$ if the algorithm outputs a solution for any instance I whose value is at most c times larger than the minimum possible for instance I . For a maximization problem a c -approximation algorithm always gives a solution that has value at least the maximum divided by c . Approximation algorithms occur in all algorithms areas, but for geometric problems the proofs of approximation typically use geometric arguments involving distances or areas (packing arguments).

A geometric setting often makes a problem easier to approximate. For example, consider traveling salesperson on a graph and on a set of points in the plane. Both versions are NP-hard. Traveling salesperson on a graph cannot be approximated within a constant factor in polynomial time (unless $P = NP$), but for Euclidean traveling salesperson a simple $O(n \log n)$ -time 2-approximation algorithm exists (polynomial-time approximation schemes exist as well [7,77]).

Similarly, when a graph is induced by a geometric configuration, approximation is often simpler than on general graphs. The maximum independent set problem cannot be approximated within a constant factor, while for a graph that is the intersection graph of a set of disks in the plane, a simple 5-approximation algorithm exists. The algorithm selects the smallest disk D and puts it into the independent set, then removes all disks that intersect D and D itself from consideration, and then iterates until no disks remain. The reason why this gives a 5-approximation is the following. The smallest disk D can intersect many disks of the set, but it can intersect no more than five disks that mutually do not intersect each other because these are at least as large as D , and the kissing number of disks implies this fact. So we may have chosen one disk in the independent set while five were possible, but it cannot be worse. The kissing number argument is an example of a packing argument.

Approximation can also be used to deal with numerical nonrobustness. For example, the facility location problem of computing a point that minimizes the distance to the input points can be approximated well: for any $\epsilon > 0$, one can compute a point in $O(n)$ time whose sum of distances to the input points is at most $1 + \epsilon$ times as large as the minimum possible [16]. The idea of this solution is to replace the Euclidean distance by a different distance function that does not have algebraic hardness, and in which all distances are within a factor $1 + \epsilon$ of the Euclidean distance (we use a polygonal convex distance function).

When approximate solutions are allowed to certain queries, data structuring problems may have much more efficient solutions. Two examples are approximate range searching and approximate nearest neighbor searching. In approximate range searching, points that lie close to the boundary of the range may or may not be reported, where “close” is related to the size of the range [8]. An approximate nearest neighbor searching data structure may return a point that is a factor $1 + \epsilon$ further than the real nearest neighbor [9].

6.2.4 Combinatorial Geometry

Combinatorial bounds relating to geometric situations can help to prove efficiency bounds on geometric algorithms. For this reason, many combinatorial geometric results have been published in the area of computational geometry. We discuss some of the main results.

The number of faces of all dimensions in an arrangement of n hyperplanes in d -dimensional space is $\Theta(n^d)$ in the worst case. The total complexity of all faces incident to a single hyperplane in an arrangement is $O(n^{d-1})$, which is the most important result upon which the optimal algorithm to construct an arrangement relies [43].

The convex hull of a set of n points in d -dimensional space obviously has at most n vertices, but the total number of faces of all dimensions is $O(n^{\lfloor d/2 \rfloor})$. This result is known as the *Upper Bound Theorem*.

The maximum complexity of a single cell in an arrangement of n line segments in the plane is $\Theta(n\alpha(n))$ in the worst case, where $\alpha(n)$ is the extremely slowly growing functional inverse of the Ackermann function [59]. The upper bound proof makes use of *Davenport–Schinzel sequences*: an (n, s) -Davenport–Schinzel sequence is a sequence of symbols from an alphabet of size n such that for any two symbols a, b , there is no subsequence of the form $\dots, a, \dots, b, \dots, a, \dots, b, \dots$ (with symbols a and b alternating; in total $s + 2$ symbols a or b), and no two equal symbols are adjacent. The concept is purely combinatorial, but one can show that the total complexity of a face in an arrangement of line segments is bounded by a function linear in the maximum length of an $(n, 3)$ -Davenport–Schinzel sequence [97]. Since such a sequence has length $O(n\alpha(n))$, the upper bound on the complexity of a face follows. The matching lower bound is obtained by a clever construction [108].

The maximum number of ways to divide a set of n points in the plane by a line into a set of k points and a set of $n - k$ points is $\Omega(n \log k)$ and $O(nk^{1/3})$ in the worst case; the true bound is unknown (a slightly better lower bound, $\Omega(n2^{\sqrt{\log k}})$, is known [102]). This is known as the *k-set problem*. The maximum number of ways to separate at least one and at most k points, the $(\leq k)$ -sets, is $\Theta(nk)$ in the worst case.

For a set of n points in the plane, each moving with constant speed along some line, the maximum number of times the Voronoi diagram (or Delaunay triangulation) changes structurally is $\Omega(n^2)$ and $O(n^{3.2\alpha(n)})$ [4].

6.2.5 Computational Topology

In topology, metric aspects of geometry like distances, angles, areas, and volumes are not relevant. Computational topology deals with algorithms for problems relating to incidence structures and other objects that are invariant under continuous deformations. It is often the combination of geometry and topology that leads to new, practically relevant approaches.

As an example of such an approach, we consider α -complexes. Given a set of points in the plane, we can imagine growing a disk centered on each point. At first the disks will not intersect, but when they do we can imagine a subdivision inside the union of the disks that is the Voronoi diagram of the points. For any radius of the disks we have such a subdivision, revealing more and more of the Voronoi diagram (Figure 6.6).

We can define a structure dual to the Voronoi diagram inside the union of disks for any given radius $1/\alpha$. This structure is the α -complex and consists of vertices, edges, and triangles. The vertices are simply the points of the set. Two vertices are connected by an edge in the α -complex if the union of disks

FIGURE 6.6 Two α -complexes for the same points but different values of α .

contains a part of their bisector in the Voronoi diagram. Three vertices form a triangle in the α -complex if their points define a Voronoi vertex in the union of the disks.

When the radius of the disks grows from 0 to ∞ , the α -complex changes from the Delaunay triangulation to a set of isolated points. At certain critical radii, new edges and new triangles appear in the complex. The changes to the α -complex are topological, but they are induced by a geometric process.

The boundary of the α -complex—known as α -shape—is a simple and good shape descriptor for a set of points that could have been samples from that shape. The radius of the disks corresponds to the level of detail at which we regard the shape. A high level of detail can be realized only if the sampling density is sufficiently high.

6.2.6 Robustness

Nonrobustness is caused by using fixed-precision numbers and computations when an algorithm designed for the real RAM is implemented. It can cause an algorithm to produce a slightly incorrect value, but it can also cause inconsistent results and program crashes. Geometric algorithms appear to be more susceptible to nonrobustness than other algorithmic areas [112].

For example, when computing the Delaunay triangulation of a planar point set P , the most important test is deciding whether the circle through three points p, q, r contains any other points of the set P , because p, q, r define a Delaunay triangle if and only if this circle does not contain any other points. If P contains four points p, q, r, s that are nearly cocircular and the computation is not exact, then the test for emptiness of the circle may return true for the triples (p, q, r) , (q, r, s) , (r, s, p) , and (s, p, q) . This means that the quadrilateral p, q, r, s is covered by two pairs of triangles that overlap, and the computed Delaunay triangulation will not be a proper triangulation. It will not even be a planar graph. Other algorithms that rely on the planarity of the Delaunay triangulation may crash due to this robustness problem.

One approach to obtain robustness is using fixed precision [55,57,61]. Points and other objects must be represented using grid points with a fixed precision in some special way. For example, when *snapping* a set of line segments [62,85], their endpoints and intersections must all lie on the grid. Each line segment becomes a polygonal line whose vertices lie on the grid. A caveat is that a geometric object is moved or deformed.

Another approach is exact geometric computation [51,70,111]. Here a number may be represented implicitly by constructs that use several numbers and operations like $\sqrt{\quad}$. Any comparison that influences a branching decision in the algorithm must be exact. Since branching typically depends on comparisons using an inequality, we may achieve this by incrementally computing bits of the values on the left-hand side and right-hand side of the inequality until we can evaluate the comparison correctly.

6.3 Impact on Practice

Geometric computation is needed in many areas of science, and the range of applications is large. Fortunately, there are structures and concepts of general use for which geometric algorithms have been developed. However, due to their generality, such structures are hardly ever directly useful in a practical situation. To transfer general, theoretical results to applications, domain knowledge of the application is needed to understand when abstraction is allowed and when it would make the result lose its relevance.

We overview a number of research areas where computational geometry has made important contributions and highlight these. We also discuss the development of a general purpose, geometric algorithms library called CGAL.

6.3.1 Computer Graphics

When three-dimensional scenes that are represented in models must be displayed on a two-dimensional screen, one must compute what is visible from a given viewpoint. In the end, every pixel gets a color

based on what object is visible “beyond” that pixel and how it is illuminated. Scenes are often composed of many triangles that represent the boundaries of the objects in the scene. One of the main tasks in computer graphics is *rendering*, which is the process of getting the objects in a three-dimensional scene onto a two-dimensional image display for a given viewpoint. The operations needed are done partly in the three-dimensional object space and partly in the two-dimensional image space. Computational geometry is involved in those tasks that occur in object space.

Since graphics processors have become a lot more powerful and allow massive parallelization, there has been a trend in computer graphics to do more and more in image space. The z-buffer method is clearly the most popular method for deciding which parts of a scene are visible, especially in dynamic or interactive situations.

On the other hand, object-space computations allow a more realistic visualization via ray tracing [99], and object-space computations may still be important to reduce the number of objects to be rendered, using simplification algorithms [33]. Furthermore, morphing between two shapes can be done better in object space [36].

6.3.2 Motion Planning and Robotics

In motion planning, a robot has a number of degrees of freedom depending on its motions. For example, a robot may move around and rotate in the plane, giving it three degrees of freedom. A robot arm with four angular joints and one telescoping piece has five degrees of freedom. The different states of such a robot or robot arm can be described by a number of real values equal to the number of degrees of freedom. In an environment with other objects—referred to as obstacles—some states may not be possible because the robot would intersect an obstacle. We can capture this situation in the *configuration space*, whose dimensionality is the same as the number of degrees of freedom. A point in the configuration space is a potential state of the robot, which may be possible or impossible. All possible states form a set of points called the *free configuration space*.

Bringing a robot from one position or state to another comes down to determining a path between two points that lies completely in the free configuration space. To decide if this is possible, we can compute the cell of the configuration space that contains the starting configuration, and test whether the end configuration lies inside that cell as well.

In the case of two-dimensional translational motion planning for a polygonal robot amid polygonal obstacles, we need to solve the computational-geometry problem of computing a single cell in an arrangement of line segments [59,96]. If we want to compute the full free configuration space, we need to solve the well-known problems of computing the *Minkowski sum* of two polygons and computing the union of a set of polygonal regions [65,96].

6.3.3 Geographic Information Systems

Many computations that are done in a GIS are geometric [103]. One example is the map overlay operation, which is possibly the most important operation in a GIS. Map overlay takes two or more different thematic map layers covering the same region and performs a “spatial join.” For example, if the one map layer is current landuse and the other layer soil type (sand, clay, ...), then the overlay is a subdivision where map space is partitioned into regions with some landuse on some soil type. The standard map layer representation in GIS is similar to the doubly-connected edge list, and the standard algorithm for map overlay is based on the plane-sweep paradigm as explained in Section 6.2.1.1.

Spatial interpolation is needed when a type of data is acquired using point measurements, and we are also interested in the values at places in between where no measurements were taken. Think of data like depth to groundwater obtained from bore holes, temperature obtained from thermometers, and ground pollution obtained from soil samples. Spatial interpolation between point-based measurements

can be based on a triangulation of the points, where we can use linear interpolation over each triangle. Alternatively, one can use *natural neighbor interpolation* based on Voronoi diagrams [100].

6.3.4 Information Visualization

Information visualization is about how graphs, maps, charts, and diagrams can communicate information effectively to humans. Graph visualization occurs in workflow diagrams and VLSI design, for example. The area of graph drawing is concerned with the drawings of all types of graphs in theory and practice. Quality criteria like few edge–edge intersections, no very long edges, and large enough angles between edges incident to the same vertex determine how good a drawing of a graph is. To draw a graph, we must choose a position and shape for each vertex and edge, and methods from computational geometry are often applied.

Specialized maps like metro maps and flow maps require a highly schematized representation of cartographic information that satisfies certain conventions associated with the type of map [18,81]. The computation of these schematized representations while keeping some degree of spatial correctness requires geometric algorithms that often have a multiobjective flavor. The same is true for map annotation, also called label placement [2]. Here, text must be placed with features on a map, diagram, or graph without creating confusion as to which text belongs to which feature and without overlaps of the different texts.

Other types of information visualization involve hierarchical or clustered representations. The final geometry of the visualization should highlight the hierarchy or clustering, so again geometric computations are needed.

6.3.5 Data Analysis and Statistics

In data analysis, the objective is to find dependencies or structure in large sets of data. One of the main types of structure in data are clusters. For example, for a set of epicenters of earthquakes, one can wonder if there are subsets of epicenters that are close together, closer than would occur by a random process. Similarly, one could be interested in clusters of motion paths of hurricanes in the Atlantic. Since clustering in general involves distance in some space, it requires geometric computations, and since data sets can be large, efficient geometric algorithms are needed. Given a distance measure, there are several well-known clustering algorithms, like single-link clustering, complete-link clustering, and k -means clustering [64].

Outliers are data elements that are significantly different from the rest of the data. Outliers may be of special interest because of this, but they may also be due to erroneous measurements. In any case, it is important to be able to detect outliers, which again requires a notion of distance.

Instead of detecting and eliminating outliers, one can also devise robust statistics. The best-known example is the median of a set of numbers. A few erratic values in the set do not influence the value of the median much, so it is a robust statistic for the concept of center. For multivariate statistics, robust methods can often be seen as geometric tasks for which efficient algorithms need to be developed [90].

6.3.6 Three-Dimensional Modeling

Several data acquisition methods yield three-dimensional point clouds. These could come from an object scanned by a three-dimensional scanner or from an urban environment scanned by LiDAR methods. The construction of a three-dimensional model from such a point cloud uses geometric algorithms of various sorts. For free-form shapes, approaches may use the medial axis and prove reconstruction correctness by relating the sampling density to the curvature [5]. Often, techniques from computational topology are applied, like persistence [20].

In urban reconstruction, one can use the fact that shape information is known. In urban environments many points are approximately coplanar because they were sampled from the same facade or roof.

This makes detection of planes that lie close to many points, one of the basic steps in reconstruction [92]. Once these planes are found they must be connected where appropriate, and remaining gaps should be filled to obtain a good three-dimensional model [11,104].

6.3.7 Finite Element Methods

The *finite element method* is used to approximately solve partial differential equations, which is useful for computing and visualizing air flow around an airplane wing, stress of an object when forces are applied, heat distribution on a printed circuit board, and similar situations. One of the main ingredients for finite element methods is a subdivision of the space of interest into elements of a simple shape (triangles or convex quadrilaterals in the plane). This subdivision should respect the environment (the airplane wing for air flow, the conductive tracks on a printed circuit board, etc.), meaning that no element intersects any boundary of the environment. This subdivision is called a *mesh*, and the process is called *mesh generation* [15,98]. The quality of a mesh for the finite element method depends on the shape of its elements. Very small or large angles should be avoided. Hence, mesh generation is concerned with producing meshes with such geometric quality criteria.

6.3.8 Retrieval

Both database search and information retrieval have a geometric version of the problem domain. To search in multimedia databases of shapes, the query object may be a shape as well, and a full or partial similarity matching of the query shape and all stored shapes determines which shapes are returned and in what order [69]. The similarity measure used may be the Hausdorff distance, Fréchet distance, or Earth movers distance, for instance [105]. In geographic information retrieval the spatial component of information, often distance, is used to decide which documents or web pages are most relevant to a query [68].

6.3.9 Computational Biology

Within the area of computational biology, molecular simulation is concerned with the modeling of three-dimensional molecules and proteins, and their interactions [44]. Molecules and proteins are made up of atoms, and a standard geometric model is to take a ball for each atom and the union of these balls for the molecule or protein. The radii of the balls are often chosen to be the van der Waals radii. The shape of proteins determines for a large part its function. In particular, accessibility for solvents and docking mechanisms of proteins depend on their shape.

6.3.10 Implementation

Providing correct implementations of geometric algorithms has proved to be a challenge in the past, and it still is. This is due to two main issues. Firstly, implementations should also handle all degenerate cases, while algorithm descriptions often ignore these, and secondly, robustness of the computations should always be considered to avoid that rounding errors dramatically influence the outcome of an implementation.

In the mid-1990s, a considerable effort has been made to develop a computational-geometry algorithms library called `CGAL`, which allows robust number types and includes many basic operations that are necessary in algorithms (compute the intersection point of two line segments, construct the circle through three given points, etc.). In a layer on top of these basic operations, many data structures and algorithms are implemented in the library. These include Voronoi diagrams, Delaunay triangulations, smallest enclosing circle, the doubly-connected edge list, arrangement construction, α -shapes, and much more. The library is made accessible by extensive documentation, including manuals, tutorials, and books [49].

6.4 Research Issues

Although computational geometry deals with constant-dimensional computational problems, the curse of dimension is still an issue. Most problems are considerably harder in three-dimensional space than in the plane, and higher-dimensional problems are even harder and their solutions less well understood. It should be mentioned that they are less common in applications, and therefore the research focus has been on two- and three-dimensional problems.

A major open problem is developing a d -dimensional linear programming method that runs in time $O(f(d) \cdot n)$, where n is the number of constraints and f is a polynomial function in d . A solution exists where f is subexponential but superpolynomial [74].

There are many planar and three-dimensional problems whose algorithmic solutions are not known to be optimal. In computational geometry, there is an ongoing quest to improve existing running time bounds of algorithms, while providing better lower bounds is of equal interest but apparently much harder.

One can expect that realistic input models for three-dimensional data can lead to more results that are provable and useful; it is an important area for future research.

In combinatorial geometry, two very important open problems are finding tight bounds on the number of k -sets in the plane and on the number of changes in the Voronoi diagram or Delaunay triangulation of moving points. There are several other interesting open problems where better combinatorial upper bounds lead to more efficient algorithms.

A research direction with a lot of potential is computational topology [45]. In the last years, the interest in the area has been growing steadily, also because it provides new insight into many different application areas.

Computational geometry has not been involved much in the computations necessary in various processes or simulations. Some exceptions are forest growth simulation [1], bird flocking behavior [28,29], and docking mechanisms in computational biology [44]. An expansion of the research in this direction is challenging and exciting.

There are many challenges in the technology transfer of the ideas and methods developed in computational geometry into practice. This goes much further than making practitioners aware of existing ideas and methods in computational geometry. Similarly, there are challenges in the right formalizations of practical problems into versions that can be addressed by computational geometry but are still relevant to practice.

A general concern from practice is data imprecision. It is important to know to what extent data imprecision influences further processing, and hence a computational model of data imprecision is needed. Such a model can be statistical or combinatorial [71]. Both offer opportunities for important research to which computational geometry can contribute.

6.5 Summary

The area of computational geometry is a challenging and useful research area that includes both fundamental and applied questions. It plays a role whenever geometric data is present and methods are needed to deal with such data. Since geometric data appears in many application areas, and new functionality is needed in these applications, a need remains for new, advanced methods to supply this functionality. At the same time, much research within computational geometry is motivated by curiosity from within, and a search for the best algorithmic solution for any geometric problem.

The overview given in this chapter is just a small sample of all known results and research directions. The *Handbook of Discrete and Computational Geometry* [54] provides a much more extensive list of concepts and results, while the textbook by de Berg et al. [38] provides a good introduction in the area. The annual *Symposium on Computational Geometry* is the main event where the latest trends and results are published. Several dozens of other conferences—algorithmic and applied—regularly publish papers on computational geometry as well.

Key Terms

- α -complex:** Structure with vertices, edges, and simplicial facets of all dimensions whose adjacencies are defined by a disk of radius $1/\alpha$.
- α -shape:** Structure with vertices and edges (for the planar case) defined for a point set, where the points are the vertices and two points are connected by an edge if and only if there is a disk of radius $1/\alpha$ through both points, and with no points of the set inside it.
- Algebraic decision tree:** Tree representing the flow of a program or algorithm where nodes represent conditional statements or tests, which determine which branch under the node is taken next. These tests are algebraic equations.
- Backward analysis of a randomized incremental algorithm:** Argument used to prove the expected cost of an incremental step by considering the situation after that step and thinking backwards (What could have led to this situation?).
- Configuration space:** Space in a robot motion planning problem that has one coordinate axis for every degree of freedom of the robot.
- Convex hull:** Smallest convex set that contains a given set of points or other objects.
- Davenport–Schinzel sequence:** Sequence of symbols over an alphabet where no two adjacent symbols may be equal, and any two different symbols can occur in alternation in a limited manner.
- Delaunay triangulation of a set of points:** Maximal planar subdivision of the plane where the points are the vertices and all bounded faces are triangles, such that the circumcircle of the three vertices of any triangle does not have any of the input points inside.
- Doubly-connected edge list:** Structure to represent planar subdivisions that allows navigation to incident features (e.g., from an edge to the incident faces and vertices).
- Dynamic programming:** Algorithmic design paradigm that exploits the fact that some optimization problems have solutions that are composed of optimal solutions to smaller problems. These optimal solutions to smaller problems are often stored in tables.
- Graph embedding:** Layout of a graph where the nodes and arcs are represented as geometric objects; nodes are often points specified by their coordinates.
- Greedy algorithm:** Algorithmic design paradigm for optimization problems where locally optimal choices are made repeatedly.
- Hausdorff distance of two subsets of the plane:** Maximum distance from any point in one subset to the nearest point in the other subset.
- Minkowski sum:** Binary operator that takes two geometric objects and returns the object composed of the union of all vectors that are the sum of a vector to a point in the one object and a vector to a point in the other object.
- NP-hardness:** Informally, feature of a computational problem describing that any algorithm that solves it requires more than polynomially many operations in the worst case. However, there is no proof known that algorithms with polynomially many operations for NP-hard problems do not exist.
- Numerical nonrobustness:** Issue appearing in the design of an implementation due to the fact that computers cannot store real numbers exactly.
- Planar 3-SAT:** Satisfiability expression with three literals per clause that allows a planar layout of the graph where literals and clauses are nodes and occurrences of a literal in a clause are arcs.
- Plane sweep:** Algorithmic design paradigm where a computational problem is solved by imagining the sweep of a line over the plane.
- Randomized incremental construction:** Algorithmic design paradigm where a problem is solved incrementally using a randomized order.
- Real RAM:** Model of computation that allows the storage of any real number in a constant amount of memory and that has random access memory.
- Realistic input model:** Assumption or set of assumptions that rules out pathological input situations, in order to prove better complexity bounds.

Simple polygon: Bounded planar shape whose boundary consists of a cyclic sequence of line segments where adjacent line segments meet in a common endpoint, and no other line segments have any point in common.

Simple polyhedron: Bounded solid shape in three-dimensional space with linear boundaries that is a generalization of a simple polygon.

Simplex: Polytope in d -dimensional space that is the convex hull of $d + 1$ linearly independent points. In the plane, it is a triangle and in three-dimensional space it is a tetrahedron.

Spread of a point set: Ratio of the largest and smallest point-to-point distance.

Sweep line: Imaginary line that sweeps over the plane, for instance a horizontal line that goes from top to bottom, while computing a solution to a problem.

Upper Bound Theorem: Combinatorial result that states that the maximum number of facets of all dimensions of a d -dimensional polytope bounded by n hyperplanes is $O(n^{\lfloor d/2 \rfloor})$.

7.1 Introduction

Computational complexity is the study of the difficulty of solving computational problems, in terms of the required computational resources, such as time and space (memory). Whereas the analysis of algorithms focuses on the time or space requirements of an *individual* algorithm for a *specific* problem (such as sorting), complexity theory focuses on the **complexity class** of problems solvable in the same amount

of time or space. Most common computational problems fall into a small number of complexity classes. Two important complexity classes are \mathbb{P} , the set of problems that can be solved in polynomial time, and \mathbb{NP} , the set of problems whose solutions can be verified in polynomial time.

By quantifying the resources required to solve a problem, complexity theory has profoundly affected our thinking about computation. Computability theory establishes the existence of undecidable problems, which cannot be solved in principle regardless of the amount of time invested. However, computability theory fails to find meaningful distinctions among decidable problems. In contrast, complexity theory establishes the existence of decidable problems that, although solvable in principle, cannot be solved in practice, because the time and space required would be larger than the age and size of the known universe (Stockmeyer and Chandra, 1979). Thus, complexity theory characterizes the computationally feasible problems.

The quest for the boundaries of the set of feasible problems has led to the most important unsolved question in all of computer science: Is \mathbb{P} different from \mathbb{NP} ? Hundreds of fundamental problems, including many ubiquitous optimization problems of operations research, are **NP-complete**; they are the hardest problems in \mathbb{NP} . If someone could find a polynomial-time algorithm for any one NP-complete problem, then there would be polynomial-time algorithms for all of them. Despite the concerted efforts of many scientists over several decades, no polynomial-time algorithm has been found for any NP-complete problem. Although we do not yet know whether \mathbb{P} is different from \mathbb{NP} , showing that a problem is NP-complete provides strong evidence that the problem is computationally infeasible and justifies the use of heuristics for solving the problem.

In this chapter, we define \mathbb{P} , \mathbb{NP} , and related complexity classes. We illustrate the use of **diagonalization** and **padding** techniques to prove relationships between classes. Next, we define NP-completeness, and we show how to prove that a problem is NP-complete. Finally, we define complexity classes for probabilistic and interactive computations.

Throughout this chapter, all numeric functions take integer arguments and produce integer values. All logarithms are taken to base 2. In particular, $\log n$ means $\lceil \log_2 n \rceil$.

7.2 Models of Computation

To develop a theory of the difficulty of computational problems, we need to specify precisely what a problem is, what an algorithm is, and what a measure of difficulty is. For simplicity, complexity theorists have chosen to represent problems as languages (i.e., as sets of strings of symbols), model algorithms by off-line multi-tape **Turing machines**, and measure computational difficulty by the time and space required by a Turing machine. To justify these choices, some theorems of complexity theory show how to translate statements about, say, the time complexity of language recognition by Turing machines into statements about computational problems on more realistic models of computation. These theorems imply that the principles of complexity theory are not artifacts of Turing machines, but instead are intrinsic properties of computation.

This section defines different kinds of Turing machines. The *deterministic* Turing machine models actual computers. The *nondeterministic* Turing machine is not a realistic model, but it helps classify the complexity of important computational problems. The *alternating* Turing machine models a form of parallel computation, and it helps elucidate the relationship between time and space.

7.2.1 Computational Problems and Languages

Computer scientists have invented many elegant formalisms for representing data and control structures. Fundamentally, all representations are patterns of symbols. Therefore, we represent an instance of a computational problem as a sequence of symbols.

Let Σ be a finite set, called the *alphabet*. A *word* over Σ is a finite sequence of symbols from Σ . Sometimes a word is called a *string*. Let Σ^* denote the set of all words over Σ . For example, if $\Sigma = \{0, 1\}$, then

$$\Sigma^* = \{\lambda, 0, 1, 00, 01, 10, 11, 000, \dots\}$$

is the set of all binary words, including the empty word λ . The *length* of a word w , denoted by $|w|$, is the number of symbols in w . A *language* over Σ is a subset of Σ^* .

A *decision problem* is a computational problem whose answer is simply *yes* or *no*. For example: Is the input graph connected? or Is the input a sorted list of integers? A decision problem can be expressed as a membership problem for a language A : for an input x , does x belong to A ? For a language A that represents connected graphs, the input word x might represent an input graph G , and $x \in A$ if and only if G is connected.

For every decision problem, the representation should allow for easy parsing, to determine whether a word represents a legitimate instance of the problem. Furthermore, the representation should be concise. In particular, it would be unfair to encode the answer to the problem into the representation of an instance of the problem; for example, for the problem of deciding whether an input graph is connected, the representation should not have an extra bit that tells whether the graph is connected. A set of integers $S = \{x_1, \dots, x_m\}$ is represented by listing the binary representation of each x_i , with the representations of consecutive integers in S separated by a nonbinary symbol. A graph is naturally represented by giving either its adjacency matrix or a set of adjacency lists, where the list for each vertex v specifies the vertices adjacent to v .

Whereas the solution to a decision problem is *yes* or *no*, the solution to an optimization problem is more complicated; for example, determine the shortest path from vertex u to vertex v in an input graph G . Nevertheless, for every optimization (minimization) problem, with objective function g , there is a corresponding decision problem that asks whether there exists a feasible solution z such that $g(z) \leq k$, where k is a given target value. Clearly, if there is an algorithm that solves an optimization problem, then that algorithm can be used to solve the corresponding decision problem. Conversely, if algorithm solves the decision problem, then with a binary search on the range of values of g , we can determine the optimal value. Moreover, using a decision problem as a subroutine often enables us to construct an optimal solution; for example, if we are trying to find a shortest path, we can use a decision problem that determines if a shortest path starting from a given vertex uses a given edge. Therefore, there is little loss of generality in considering only decision problems, represented as language membership problems.

7.2.2 Turing Machines

This section and the next three give precise, formal definitions of Turing machines and their variants. These sections are intended for reference. For the rest of this chapter, the reader need not understand these definitions in detail, but may generally substitute “program” or “computer” for each reference to “Turing machine.”

A k -worktape **Turing machine** M consists of the following:

- A finite set of states Q , with special states q_0 (initial state), q_A (accept state), and q_R (reject state).
- A finite alphabet Σ , and a special blank symbol $\square \notin \Sigma$.
- The $k + 1$ linear tapes, each divided into cells. Tape 0 is the *input tape*, and tapes 1, ..., k are the *worktapes*. Each tape is infinite to the left and to the right. Each cell holds a single symbol from $\Sigma \cup \{\square\}$. By convention, the input tape is read only. Each tape has an access head, and at every instant, each access head scans one cell. See Figure 7.1.
- A finite transition table δ , which comprises tuples of the form

$$(q, s_0, s_1, \dots, s_k, q', s'_1, \dots, s'_k, d_0, d_1, \dots, d_k)$$

where $q, q' \in Q$, each $s_i, s'_i \in \Sigma \cup \{\square\}$, and each $d_i \in \{-1, 0, +1\}$.

A tuple specifies a step of M : if the current state is q , and s_0, s_1, \dots, s_k are the symbols in the cells scanned by the access heads, then M replaces s_i by s'_i for $i = 1, \dots, k$ simultaneously, changes state to q' , and

FIGURE 7.1 A two-tape Turing machine.

moves the head on tape i one cell to the left ($d_i = -1$) or right ($d_i = +1$) or not at all ($d_i = 0$) for $i = 0, \dots, k$. Note that M cannot write on tape 0, that is, M may write only on the worktapes, not on the input tape.

- No tuple contains q_A or q_R as its first component. Thus, once M enters state q_A or state q_R , it stops.
- Initially, M is in state q_0 , an input word in Σ^* is inscribed on contiguous cells of the input tape, the access head on the input tape is on the leftmost symbol of the input word, and all other cells of all tapes contain the blank symbol \square .

The Turing machine M that we have defined is *nondeterministic*: δ may have several tuples with the same combination of state q and symbols s_0, s_1, \dots, s_k as the first $k + 2$ components, so that M may have several possible next steps. A machine M is *deterministic* if for every combination of state q and symbols s_0, s_1, \dots, s_k at most one tuple in δ contains the combination as its first $k + 2$ components. A deterministic machine always has at most one possible next step.

A *configuration* of a Turing machine M specifies the current state, the contents of all tapes, and the positions of all access heads.

A *computation path* is a sequence of configurations $C_0, C_1, \dots, C_p, \dots$, where C_0 is the initial configuration of M , and each C_{j+1} follows from C_j in one step by applying the changes specified by a tuple in δ . If no tuple is applicable to C_p , then C_p is *terminal*, and the computation path is *halting*. If M has no infinite computation paths, then M *always halts*.

A halting computation path is *accepting* if the state in the last configuration C_t is q_A ; otherwise it is *rejecting*. By adding tuples to the program if needed, we can ensure that every rejecting computation ends in state q_R . This leaves the question of computation paths that do not halt. In complexity theory we rule this out by considering only machines whose computation paths *always halt*. M *accepts* an input word x if there exists an accepting computation path that starts from the initial configuration in which x is on the input tape. For nondeterministic M , it does not matter if some other computation paths end at q_R . If M is deterministic, then there is at most one halting computation path, hence at most one accepting path.

The *language accepted by M* , written $L(M)$, is the set of words accepted by M . If $A = L(M)$, and M always halts, then M *decides A* .

In addition to deciding languages, deterministic Turing machines can compute functions. Designate tape 1 to be the *output tape*. If M halts on input word x , then the nonblank word on tape 1 in the final configuration is the output of M . A function f is *computable* if there exists a deterministic Turing machine M that always halts such that for each input word x , the output of M is the value of $f(x)$.

Almost all results in complexity theory are insensitive to minor variations in the underlying computational models. For example, we could have chosen Turing machines whose tapes are restricted to be only one-way infinite or whose alphabet is restricted to $\{0, 1\}$. It is straightforward to simulate a Turing machine as defined by one of these restricted Turing machines, one step at a time: each step of the original machine can be simulated by $O(1)$ steps of the restricted machine.

7.2.3 Universal Turing Machines

Chapter 8 states that there exists a *universal Turing machine* U , which takes as input a string $\langle M, x \rangle$ that encodes a Turing machine M and a word x , and simulates the operation of M on x , and U accepts $\langle M, x \rangle$ if and only if M accepts x . For our purposes here, we also need that U simulates M *efficiently*: A theorem of Hennie and Stearns (1966) implies that the machine U can be constructed to have only two worktapes, such that U can simulate any t steps of M in only $O(t \log t)$ steps of its own, using only $O(1)$ times the worktape cells used by M . The constants implicit in these big- O bounds may depend on M .

We can think of U with a fixed M as a machine U_M and define $L(U_M) = \{x : U \text{ accepts } \langle M, x \rangle\}$. Then $L(U_M) = L(M)$. If M always halts, then U_M always halts, and if M is deterministic, then U_M is deterministic.

7.2.4 Alternating Turing Machines

By definition, a nondeterministic Turing machine M accepts its input word x if there exists an accepting computation path, starting from the initial configuration with x on the input tape. Let us call a *configuration* C accepting if there is a computation path of M that starts in C and ends in a configuration whose state is q_A . Equivalently, a configuration C is accepting if either the state in C is q_A or there exists an accepting configuration C' reachable from C by one step of M . Then, M accepts x if the initial configuration with input word x is accepting.

The *alternating Turing machine* generalizes this notion of acceptance. In an alternating Turing machine M , each state is labeled either existential or universal. (Do not confuse the universal state in an alternating Turing machine with the universal Turing machine.) A nonterminal configuration C is existential (respectively, universal) if the state in C is labeled existential (universal). A terminal configuration is accepting if its state is q_A . A nonterminal existential configuration C is accepting if there *exists* an accepting configuration C' reachable from C by one step of M . A nonterminal universal configuration C is accepting if for *every* configuration C' reachable from C by one step of M , the configuration C' is accepting. Finally, M accepts x if the initial configuration with input word x is an accepting configuration.

A nondeterministic Turing machine is thus a special case of an alternating Turing machine in which every state is existential.

The computation of an alternating Turing machine M alternates between existential states and universal states. Intuitively, from an existential configuration, M guesses a step that leads toward acceptance; from a universal configuration, M checks whether each possible next step leads toward acceptance—in a sense, M checks all possible choices in parallel. An alternating computation captures the essence of a two-player game: player 1 has a winning strategy if there exists a move for player 1 such that for every move by player 2, there exists a subsequent move by player 1, etc., such that player 1 eventually wins.

7.2.5 Oracle Turing Machines

Complexity theoreticians have found it very useful to have a mechanism to describe when it is helpful to have a subroutine for some problem A , when trying to solve another problem. The language A is called an **oracle**. Conceptually, an algorithm queries the oracle whether a word w is in A , and it receives the correct answer in one step.

An *oracle Turing machine* is a Turing machine M with a special *oracle tape* and special states QUERY, YES, and NO. The computation of the oracle Turing machine M^A , with oracle language A , is the same as that of an ordinary Turing machine, except that when M enters the QUERY state with a word w on the oracle tape, in one step, M enters either the YES state if $w \in A$ or the NO state if $w \notin A$. Furthermore, during this step, the oracle tape is erased, so that the time for setting up each query is accounted separately.

7.3 Resources and Complexity Classes

In this section, we define the measures of difficulty of solving computational problems. We introduce complexity classes, which enable us to classify problems according to the difficulty of their solution.

7.3.1 Time and Space

We measure the difficulty of a computational problem by the running time and the space (memory) requirements of an algorithm that solves the problem.

We express the complexity of a problem, in terms of the growth of the required time or space, as a function of the length n of the input word that encodes a problem instance. We consider the worst-case complexity, that is, for each n , the maximum time or space required among all inputs of length n .

Let M be a Turing machine that always halts. The *time* taken by M on input word x , denoted by $\text{Time}_M(x)$, is defined as follows:

- If M accepts x , then $\text{Time}_M(x)$ is the number of steps in the shortest accepting computation path for x .
- If M rejects x , then $\text{Time}_M(x)$ is the number of steps in the longest computation path for x .

For a deterministic machine M , for every input x , there is at most one halting computation path, and its length is $\text{Time}_M(x)$. For a nondeterministic machine M , if $x \in L(M)$, then M can guess the correct steps to take toward an accepting configuration, and $\text{Time}_M(x)$ measures the length of the path on which M always makes the best guess.

The *space* used by a Turing machine M on input x , denoted $\text{Space}_M(x)$, is defined as follows. The space used by a halting computation path is the number of worktape cells visited by the worktape heads of M during the computation path. Because the space occupied by the input word is not counted, a machine can use a sublinear ($o(n)$) amount of space.

- If M accepts x , then $\text{Space}_M(x)$ is the minimum space used among all accepting computation paths for x .
- If M rejects x , then $\text{Space}_M(x)$ is the maximum space used among all computation paths for x .

The **time complexity** of a machine M is the function

$$t(n) = \max\{\text{Time}_M(x) : |x| = n\}$$

We assume that M reads all of its input word and the blank symbol after the right end of the input word, so $t(n) \geq n + 1$. The **space complexity** of M is the function

$$s(n) = \max\{\text{Space}_M(x) : |x| = n\}$$

Because few interesting languages can be decided by machines of sublogarithmic space complexity, we henceforth assume that $s(n) \geq \log n$.

A function $f(x)$ is *computable in polynomial time* if there exists a deterministic Turing machine M of polynomial-time complexity such that for each input word x , the output of M is $f(x)$.

7.3.2 Complexity Classes

Having defined the time complexity and space complexity of individual Turing machines, we now define classes of languages with particular complexity bounds. These definitions will lead to definitions of \mathcal{P} and \mathcal{NP} .

Let $t(n)$ and $s(n)$ be numeric functions. Define the following classes of languages:

- $\text{DTIME}[t(n)]$ is the class of languages decided by deterministic Turing machines of time complexity $O(t(n))$.
- $\text{NTIME}[t(n)]$ is the class of languages decided by nondeterministic Turing machines of time complexity $O(t(n))$.
- $\text{DSPACE}[s(n)]$ is the class of languages decided by deterministic Turing machines of space complexity $O(s(n))$.
- $\text{NSPACE}[s(n)]$ is the class of languages decided by nondeterministic Turing machines of space complexity $O(s(n))$.

We sometimes abbreviate $\text{DTIME}[t(n)]$ to $\text{DTIME}[t]$ (and so on) when t is understood to be a function, and when no reference is made to the input length n .

The following are the **canonical complexity classes**:

- $\mathcal{L} = \text{DSPACE}[\log n]$ (deterministic log space)
- $\mathcal{NL} = \text{NSPACE}[\log n]$ (nondeterministic log space)
- $\mathcal{P} = \text{DTIME}[n^{O(1)}] = \bigcup_{k \geq 1} \text{DTIME}[n^k]$ (polynomial time)
- $\mathcal{NP} = \text{NTIME}[n^{O(1)}] = \bigcup_{k \geq 1} \text{NTIME}[n^k]$ (nondeterministic polynomial time)
- $\mathcal{PSPACE} = \text{DSPACE}[n^{O(1)}] = \bigcup_{k \geq 1} \text{DSPACE}[n^k]$ (polynomial space)
- $\mathcal{E} = \text{DTIME}[2^{O(n)}] = \bigcup_{k \geq 1} \text{DTIME}[k^n]$
- $\mathcal{NE} = \text{NTIME}[2^{O(n)}] = \bigcup_{k \geq 1} \text{NTIME}[k^n]$
- $\mathcal{EXP} = \text{DTIME}[2^{n^{O(1)}}] = \bigcup_{k \geq 1} \text{DTIME}[2^{n^k}]$ (deterministic exponential time)
- $\mathcal{NEXP} = \text{NTIME}[2^{n^{O(1)}}] = \bigcup_{k \geq 1} \text{NTIME}[2^{n^k}]$ (nondeterministic exponential time)

The class \mathcal{PSPACE} is defined in terms of the DSPACE complexity measure. By Savitch's Theorem (see Theorem 7.2), the NSPACE measure with polynomial bounds also yields \mathcal{PSPACE} .

The class \mathcal{P} contains many familiar problems that can be solved efficiently, such as (decision problem versions of) finding shortest paths in networks, parsing for context-free languages, sorting, matrix multiplication, and linear programming. Consequently, \mathcal{P} has become accepted as representing the set of computationally feasible problems. Although one could legitimately argue that a problem whose best algorithm has time complexity $\Theta(n^{99})$ is really infeasible, in practice, the time complexities of the vast majority of natural polynomial-time problems have low degrees: they have algorithms that run in $O(n^4)$ time or less. Moreover, \mathcal{P} is a robust class: though defined by Turing machines, \mathcal{P} remains the same when defined by other models of sequential computation. For example, random-access machines (RAMs) (a more realistic model of computation defined in Chapter 8) can be used to define \mathcal{P} , because Turing machines and RAMs can simulate each other with polynomial-time overhead.

The class \mathcal{NP} can also be defined by means other than nondeterministic Turing machines. \mathcal{NP} equals the class of problems whose solutions can be *verified* quickly, by deterministic machines in polynomial time. Equivalently, \mathcal{NP} comprises those languages whose membership proofs can be checked quickly.

For example, one language in \mathcal{NP} is the set of satisfiable Boolean formulas, called SAT . A Boolean formula ϕ is satisfiable if there exists a way of assigning `true` or `false` to each variable such that under this truth assignment, the value of ϕ is `true`. For example, the formula $x \wedge (\bar{x} \vee y)$ is satisfiable, but $x \wedge \bar{y} \wedge (\bar{x} \vee y)$ is not satisfiable. A nondeterministic Turing machine M , after checking the syntax of ϕ and counting the number n of variables, can nondeterministically write down an n -bit 0-1 string a on its tape, and then deterministically (and easily) evaluate ϕ for the truth assignment denoted by a .

The computation path corresponding to each individual a accepts if and only if $\phi(a) = \text{true}$, and so M itself accepts ϕ if and only if ϕ is satisfiable; that is, $L(M) = \text{SAT}$. Again, this checking of given assignments differs significantly from trying to *find* an accepting assignment.

Another language in NP is the set of undirected graphs with a *Hamiltonian circuit*, that is, a path of edges that visits each vertex exactly once and returns to the starting point. If a solution exists and is given, its correctness can be verified quickly. Finding such a circuit, however, or proving one does not exist, appears to be computationally difficult.

The characterization of NP as the set of problems with easily verified solutions is formalized as follows: $A \in \text{NP}$ if and only if there exist a language $A' \in \text{P}$ and a polynomial p such that for every x , $x \in A$ if and only if there exists a y such that $|y| \leq p(|x|)$ and $(x, y) \in A'$. Here, whenever x belongs to A , y is interpreted as a positive solution to the problem represented by x , or equivalently, as a proof that x belongs to A . The difference between P and NP is that between solving and checking, or between finding a proof of a mathematical theorem and testing whether a candidate proof is correct. In essence, NP represents all sets of theorems with proofs that are short (i.e., of polynomial length) and checkable quickly (i.e., in polynomial time), while P represents those statements that can be proved or refuted quickly from scratch.

Further motivation for studying L , NL , and PSPACE comes from their relationships to P and NP . Namely, L and NL are the largest space-bounded classes known to be contained in P , and PSPACE is the smallest space-bounded class known to contain NP . (It is worth mentioning here that NP does not stand for “nonpolynomial time”; the class P is a subclass of NP .) Similarly, EXP is of interest primarily because it is the smallest deterministic time class known to contain NP . The closely related class E is not known to contain NP .

7.4 Relationships between Complexity Classes

The P vs. NP question asks about the relationship between these complexity classes: Is P a proper subset of NP , or does $\text{P} = \text{NP}$? Much of complexity theory focuses on the relationships between complexity classes, because these relationships have implications for the difficulty of solving computational problems. In this section, we summarize important known relationships. We demonstrate two techniques for proving relationships between classes: diagonalization and padding.

7.4.1 Constructibility

The most basic theorem that one should expect from complexity theory would say, “If you have more resources, you can do more.” Unfortunately, if we are not careful with our definitions, then this claim is false:

Theorem 7.1 (Gap Theorem)

There is a computable, strictly increasing time bound $t(n)$ such that $\text{DTIME}[t(n)] = \text{DTIME}[2^{2^{t(n)}}]$ (Borodin, 1972).

That is, there is an empty gap between time $t(n)$ and time doubly exponentially greater than $t(n)$, in the sense that anything that can be computed in the larger time bound can already be computed in the smaller time bound. That is, even with much more time, you cannot compute more. This gap can be made much larger than doubly exponential; for any computable r , there is a computable time bound t such that $\text{DTIME}[t(n)] = \text{DTIME}[r(t(n))]$. Exactly analogous statements hold for the NTIME , DSPACE , and NSPACE measures.

Fortunately, the gap phenomenon cannot happen for time bounds t that anyone would ever be interested in. Indeed, the proof of the Gap Theorem proceeds by showing that one can define a time bound t such that no machine has a running time that is between $t(n)$ and $2^{2^{t(n)}}$. This theorem indicates the need for formulating only those time bounds that actually describe the complexity of some machine.

A function $t(n)$ is **time-constructible** if there exists a deterministic Turing machine that halts after exactly $t(n)$ steps for every input of length n . A function $s(n)$ is **space-constructible** if there exists a deterministic Turing machine that uses exactly $s(n)$ worktape cells for every input of length n . (Most authors consider only functions $t(n) \geq n + 1$ to be time-constructible, and many limit attention to $s(n) \geq \log n$ for space bounds. There do exist sublogarithmic space-constructible functions, but we prefer to avoid the tricky theory of $o(\log n)$ space bounds.)

For example, $t(n) = n + 1$ is time-constructible. Furthermore, if $t_1(n)$ and $t_2(n)$ are time-constructible, then so are the functions $t_1 + t_2$, $t_1 t_2$, t_1^2 , and c^{t_1} for every integer $c > 1$. Consequently, if $p(n)$ is a polynomial, then $p(n) = \Theta(t(n))$ for some time-constructible polynomial function $t(n)$. Similarly, $s(n) = \log n$ is space-constructible, and if $s_1(n)$ and $s_2(n)$ are space-constructible, then so are the functions $s_1 + s_2$, $s_1 s_2$, s_1^2 , and c^{s_1} for every integer $c > 1$. Many common functions are space-constructible: for example, $n \log n$, n^3 , 2^n , $n!$

Constructibility helps eliminate an arbitrary choice in the definition of the basic time and space classes. For general time functions t , the classes $\text{DTIME}[t]$ and $\text{NTIME}[t]$ may vary depending on whether machines are required to halt within t steps on all computation paths or just on those paths that accept. If t is time-constructible and s is space-constructible, however, then $\text{DTIME}[t]$, $\text{NTIME}[t]$, $\text{DSPACE}[s]$, and $\text{NSPACE}[s]$ can be defined without loss of generality in terms of Turing machines that always halt.

As a general rule, any function $t(n) \geq n + 1$ and any function $s(n) \geq \log n$ that one is interested in as a time or space bound is time- or space-constructible, respectively. As we have seen, little of interest can be proved without restricting attention to constructible functions. This restriction still leaves a rich class of resource bounds.

7.4.2 Basic Relationships

Clearly, for all time functions $t(n)$ and space functions $s(n)$, $\text{DTIME}[t(n)] \subseteq \text{NTIME}[t(n)]$ and $\text{DSPACE}[s(n)] \subseteq \text{NSPACE}[s(n)]$, because a deterministic machine constitutes a special case of a nondeterministic machine. Furthermore, $\text{DTIME}[t(n)] \subseteq \text{DSPACE}[t(n)]$ and $\text{NTIME}[t(n)] \subseteq \text{NSPACE}[t(n)]$, because at each step, a k -tape Turing machine can write on at most $k = O(1)$ previously unwritten cells. The next theorem presents additional important relationships between classes.

Theorem 7.2

Let $t(n)$ be a time-constructible function, and let $s(n)$ be a space-constructible function, $s(n) \geq \log n$.

- (a) $\text{NTIME}[t(n)] \subseteq \text{DTIME}[2^{O(t(n))}]$.
- (b) $\text{NSPACE}[s(n)] \subseteq \text{DTIME}[2^{O(s(n))}]$.
- (c) $\text{NTIME}[t(n)] \subseteq \text{DSPACE}[t(n)]$.
- (d) (**Savitch's Theorem**) $\text{NSPACE}[s(n)] \subseteq \text{DSPACE}[s(n)^2]$ (Savitch, 1970).

As a consequence of the first part of this theorem, $\text{NP} \subseteq \text{EXP}$. No better general upper bound on deterministic time is known for languages in NP . See Figure 7.2 for other known inclusion relationships between canonical complexity classes.

Although we do not know whether allowing nondeterminism strictly increases the class of languages decided in polynomial time, Savitch's Theorem says that for space classes, nondeterminism does not help by more than a polynomial amount.

FIGURE 7.2 Inclusion relationships among the canonical complexity classes.

7.4.3 Complementation

For a language A over an alphabet Σ , define \bar{A} to be the complement of A in the set of words over Σ : that is, $\bar{A} = \Sigma^* - A$. For a class of languages \mathcal{C} , define $\text{co-}\mathcal{C} = \{\bar{A} : A \in \mathcal{C}\}$. If $\mathcal{C} = \text{co-}\mathcal{C}$, then \mathcal{C} is **closed under complementation**.

In particular, co-NP is the class of languages that are complements of languages in NP . For the language SAT of satisfiable Boolean formulas, $\overline{\text{SAT}}$ is essentially the set of unsatisfiable formulas, whose value is false for every truth assignment, together with the syntactically incorrect formulas. A closely related language in co-NP is the set of Boolean tautologies, namely, those formulas whose value is true for every truth assignment. The question of whether NP equals co-NP comes down to whether every tautology has a short (i.e., polynomial-sized) proof. The only obvious general way to prove a tautology ϕ in m variables is to verify all 2^m rows of the truth table for ϕ , taking exponential time. Most complexity theorists believe that there is no general way to reduce this time to polynomial, hence that $\text{NP} \neq \text{co-NP}$.

Questions about complementation bear directly on the P vs. NP question. It is easy to show that P is closed under complementation (see Theorem 7.3). Consequently, if $\text{NP} \neq \text{co-NP}$, then $\text{P} \neq \text{NP}$.

Theorem 7.3 (Complementation Theorems)

Let t be a time-constructible function, and let s be a space-constructible function, with $s(n) \geq \log n$ for all n . Then,

1. $\text{DTIME}[t]$ is closed under complementation.
2. $\text{DSPACE}[s]$ is closed under complementation.
3. $\text{NSPACE}[s]$ is closed under complementation (Immerman, 1988; Szelepcsényi, 1988).

The Complementation Theorems are used to prove the Hierarchy Theorems in the next section.

7.4.4 Hierarchy Theorems and Diagonalization

A hierarchy theorem is a theorem that says “If you have more resources, you can compute more.” As we saw in Section 7.4.1, this theorem is possible only if we restrict attention to constructible time and space bounds. Next, we state hierarchy theorems for deterministic and nondeterministic time and space classes. In the following, \subset denotes *strict* inclusion between complexity classes.

Theorem 7.4 (Hierarchy Theorems)

Let t_1 and t_2 be time-constructible functions, and let s_1 and s_2 be space-constructible functions, with $s_1(n), s_2(n) \geq \log n$ for all n .

- (a) If $t_1(n) \log t_1(n) = o(t_2(n))$, then $\text{DTIME}[t_1] \subset \text{DTIME}[t_2]$.
- (b) If $t_1(n + 1) = o(t_2(n))$, then $\text{NTIME}[t_1] \subset \text{NTIME}[t_2]$ (Seiferas et al., 1978).
- (c) If $s_1(n) = o(s_2(n))$, then $\text{DSPACE}[s_1] \subset \text{DSPACE}[s_2]$.
- (d) If $s_1(n) = o(s_2(n))$, then $\text{NSPACE}[s_1] \subset \text{NSPACE}[s_2]$.

As a corollary of the Hierarchy Theorem for DTIME ,

$$\text{P} \subseteq \text{DTIME}[n^{\log n}] \subset \text{DTIME}[2^n] \subseteq \text{E}$$

hence we have the strict inclusion $\text{P} \subset \text{E}$. Although we do not know whether $\text{P} \subset \text{NP}$, there exists a problem in E that cannot be solved in polynomial time. Other consequences of the Hierarchy Theorems are $\text{NE} \subset \text{NEXP}$ and $\text{NL} \subset \text{PSPACE}$.

In the Hierarchy Theorem for DTIME , the hypothesis on t_1 and t_2 is $t_1(n) \log t_1(n) = o(t_2(n))$, instead of $t_1(n) = o(t_2(n))$, for technical reasons related to the simulation of machines with multiple worktapes by a single universal Turing machine with a fixed number of worktapes. Other computational models, such as RAMs, enjoy tighter time hierarchy theorems.

All proofs of the Hierarchy Theorems use the technique of **diagonalization**. For example, the proof for DTIME constructs a Turing machine M of time complexity t_2 that considers all machines M_1, M_2, \dots whose time complexity is t_1 ; for each i , the proof finds a word x_i that is accepted by M if and only if $x_i \notin L(M_i)$, the language decided by M_i . Consequently, $L(M)$, the language decided by M , differs from each $L(M_i)$, hence $L(M) \notin \text{DTIME}[t_1]$. The diagonalization technique resembles the classic method used to prove that the real numbers are uncountable, by constructing a number whose j th digit differs from the j th digit of the j th number on the list. To illustrate the diagonalization technique, we outline the proof of the Hierarchy Theorem for DSPACE . In this section, $\langle i, x \rangle$ stands for the string $0^i 1x$, and $\text{zeroes}(y)$ stands for the number of 0's that a given string y starts with. Note that $\text{zeroes}(\langle i, x \rangle) = i$.

Proof. (of the DSPACE Hierarchy Theorem)

We construct a deterministic Turing machine M that decides a language A such that $A \in \text{DSPACE}[s_2] - \text{DSPACE}[s_1]$.

Let U be a deterministic universal Turing machine, as described in Section 7.2.3. On input x of length n , machine M performs the following:

1. Lay out $s_2(n)$ cells on a worktape.
2. Let $i = \text{zeroes}(x)$.
3. Simulate the universal machine U on input $\langle i, x \rangle$. Accept x if U tries to use more than s_2 worktape cells. (We omit some technical details, such as the way in which the constructibility of s_2 is used to ensure that this process halts.)
4. If U accepts $\langle i, x \rangle$, then reject; if U rejects $\langle i, x \rangle$, then accept.

Clearly, M always halts and uses space $O(s_2(n))$. Let $A = L(M)$.

Suppose $A \in \text{DSPACE}[s_1(n)]$. Then there is some Turing machine M_j accepting A using space at most $s_1(n)$. Since the space used by U is $O(1)$ times the space used by M_j , there is a constant k depending only on j (in fact, we can take $k = |j|$), such that U , on inputs z of the form $z = \langle j, x \rangle$, uses at most $ks_1(|x|)$ space.

Since $s_1(n) = o(s_2(n))$, there is an n_0 such that $ks_1(n) \leq s_2(n)$ for all $n \geq n_0$. Let x be a string of length greater than n_0 such that the first $j + 1$ symbols of x are 0^j1 . Note that the universal Turing machine U , on input $\langle j, x \rangle$, simulates M_j on input x and uses space at most $ks_1(n) \leq s_2(n)$. Thus, when we consider the machine M defining A , we see that on input x the simulation does not stop in step 3 but continues on to step 4, and thus $x \in A$ if and only if U rejects $\langle j, x \rangle$. Consequently, M_j does not accept A , contrary to our assumption. Thus $A \notin \text{DSPACE}[s_1(n)]$. \square

Although the diagonalization technique successfully separates some pairs of complexity classes, diagonalization does not seem strong enough to separate P from NP (see Theorem 7.11).

7.4.5 Padding Arguments

A useful technique for establishing relationships between complexity classes is the **padding argument**. Let A be a language over alphabet Σ , and let $\#$ be a symbol not in Σ . Let f be a numeric function. The **f -padded version of A** is the language

$$A' = \{x\#^{f(n)} : x \in A \text{ and } n = |x|\}$$

That is, each word of A' is a word in A concatenated with $f(n)$ consecutive $\#$ symbols. The padded version A' has the same information content as A , but because each word is longer, the computational complexity of A' is smaller.

The proof of the next theorem illustrates the use of a padding argument.

Theorem 7.5

If $\text{P} = \text{NP}$, then $\text{E} = \text{NE}$ (Book, 1974).

Proof. Since $\text{E} \subseteq \text{NE}$, we prove that $\text{NE} \subseteq \text{E}$.

Let $A \in \text{NE}$ be decided by a nondeterministic Turing machine M in at most $t(n) = k^n$ time for some constant integer k . Let A' be the $t(n)$ -padded version of A . From M , we construct a nondeterministic Turing machine M' that decides A' in linear time: M' checks that its input has the correct format, using the time-constructibility of t ; then M' runs M on the prefix of the input preceding the first $\#$ symbol. Thus, $A' \in \text{NP}$.

If $\text{P} = \text{NP}$, then there is a deterministic Turing machine D' that decides A' in at most $p'(n)$ time for some polynomial p' . From D' , we construct a deterministic Turing machine D that decides A , as follows. On input x of length n , since $t(n)$ is time-constructible, machine D constructs $x\#^{t(n)}$, whose length is $n + t(n)$, in $O(t(n))$ time. Then D runs D' on this input word. The time complexity of D is at most $O(t(n)) + p'(n + t(n)) = 2^{O(n)}$. Therefore, $\text{NE} \subseteq \text{E}$. \square

A similar argument shows that the $\text{E} = \text{NE}$ question is equivalent to the question of whether $\text{NP} = \text{P}$ contains a subset of 1^* , that is, a language over a single-letter alphabet.

7.5 Reducibility and Completeness

In this section, we discuss relationships between problems: informally, if one problem reduces to another problem, then, in a sense, the second problem is harder than the first. The hardest problems in NP are the NP -complete problems. We define NP -completeness precisely, and we show how to prove that a problem is

NP-complete. The theory of NP-completeness, together with the many known NP-complete problems, is perhaps the best justification for interest in the classes P and NP. All of the other canonical complexity classes listed earlier have natural and important problems that are complete for them; we give some of these as well.

7.5.1 Resource-Bounded Reducibilities

In mathematics, as in everyday life, a typical way to solve a new problem is to reduce it to a previously solved problem. Frequently, an instance of the new problem is expressed completely in terms of an instance of the prior problem, and the solution is then interpreted in the terms of the new problem. For example, the maximum matching problem for bipartite graphs reduces to the network flow problem (see Chapter 5). This kind of reduction is called **many-one reducibility** and is defined after the next paragraph.

A different way to solve the new problem is to use a subroutine that solves the prior problem. For example, we can solve an optimization problem whose solution is feasible and maximizes the value of an objective function g by repeatedly calling a subroutine that solves the corresponding decision problem of whether there exists a feasible solution x whose value $g(x)$ satisfies $g(x) \geq k$. This kind of reduction is called **Turing reducibility** and is also defined after the next paragraph.

Let A_1 and A_2 be languages. A_1 is many-one reducible to A_2 , written $A_1 \leq_m A_2$, if there exists a computable function f such that for all x , $x \in A_1$ if and only if $f(x) \in A_2$. The function f is called the **transformation function**. A_1 is Turing reducible to A_2 , written $A_1 \leq_T A_2$, if A_1 can be decided by a deterministic oracle Turing machine M using A_2 as its oracle, that is, $A_1 = L(M^{A_2})$. (Computable functions and oracle Turing machines are defined in Section 7.2.) The oracle for A_2 models a hypothetical efficient subroutine for A_2 .

If f or M above consumes too much time or space, the reductions they compute are not helpful. To study complexity classes defined by bounds on time and space resources, it is natural to consider resource-bounded reducibilities. Let A_1 and A_2 be languages.

- A_1 is **Karp reducible** to A_2 , written $A_1 \leq_m^p A_2$, if A_1 is many-one reducible to A_2 via a transformation function that is computable deterministically in polynomial time.
- A_1 is **log-space reducible** to A_2 , written $A_1 \leq_m^{\log} A_2$, if A_1 is many-one reducible to A_2 via a transformation function that is computable deterministically in $O(\log n)$ space.
- A_1 is **Cook reducible** to A_2 , written $A_1 \leq_T^p A_2$, if A_1 is Turing reducible to A_2 via a deterministic oracle Turing machine of polynomial-time complexity.

The term “polynomial-time reducibility” usually refers to Karp reducibility. If $A_1 \leq_m^p A_2$ and $A_2 \leq_m^p A_1$, then A_1 and A_2 are **equivalent** under Karp reducibility. Equivalence under Cook reducibility is defined similarly.

Karp and Cook reductions are useful for finding relationships between languages of high complexity, but they are not useful at all for distinguishing between problems in P, because all problems in P are equivalent under Karp (and hence Cook) reductions. (Here and later we ignore the special cases $A_1 = \emptyset$ and $A_1 = \Sigma^*$, and consider them to reduce to any language.) Since there are interesting distinctions to be made among problems in P, it is useful to have a more restrictive notion of reducibility.

Log-space reducibility (Jones, 1975) is just such a notion. Although it is not known whether log-space reducibility is different from Karp reducibility (just as it is not known whether L is a proper subset of P), this is widely believed to be true. (However, in practice, most problems that can be shown to be NP-complete under Karp reductions remain complete under log-space reductions.)

Theorem 7.6

Log-space reducibility implies Karp reducibility, which implies Cook reducibility:

1. If $A_1 \leq_m^{\log} A_2$, then $A_1 \leq_m^p A_2$.
2. If $A_1 \leq_m^p A_2$, then $A_1 \leq_T^p A_2$.

Theorem 7.7

Log-space reducibility, Karp reducibility, and Cook reducibility are transitive:

1. If $A_1 \leq_m^{\log} A_2$ and $A_2 \leq_m^{\log} A_3$, then $A_1 \leq_m^{\log} A_3$.
2. If $A_1 \leq_m^p A_2$ and $A_2 \leq_m^p A_3$, then $A_1 \leq_m^p A_3$.
3. If $A_1 \leq_T^p A_2$ and $A_2 \leq_T^p A_3$, then $A_1 \leq_T^p A_3$.

The key property of Cook and Karp reductions is that they preserve polynomial-time feasibility. Suppose $A_1 \leq_m^p A_2$ via a transformation f . If M_2 decides A_2 , and M_f computes f , then to decide whether an input word x is in A_1 , we may use M_f to compute $f(x)$, and then run M_2 on input $f(x)$. If the time complexities of M_2 and M_f are bounded by polynomials t_2 and t_f , respectively, then on each input x of length $n = |x|$, the time taken by this method of deciding A_1 is at most $t_f(n) + t_2(t_f(n))$, which is also a polynomial in n . In summary, if A_2 is feasible, and there is an efficient reduction from A_1 to A_2 , then A_1 is feasible. Although this is a simple observation, this fact is important enough to state as a theorem (Theorem 7.8). First, though, we need the concept of “closure.”

A class of languages \mathcal{C} is **closed under a reducibility** \leq_r if for all languages A_1 and A_2 , whenever $A_1 \leq_r A_2$ and $A_2 \in \mathcal{C}$, necessarily $A_1 \in \mathcal{C}$.

Theorem 7.8

1. P is closed under log-space reducibility, Karp reducibility, and Cook reducibility.
2. NP is closed under log-space reducibility and Karp reducibility.
3. L and NL are closed under log-space reducibility.

We shall see the importance of closure under a reducibility in conjunction with the concept of completeness, which we define in the next section.

7.5.2 Complete Languages

Let \mathcal{C} be a class of languages that represent computational problems. A language A_0 is **\mathcal{C} -hard** under a reducibility \leq_r if for all A in \mathcal{C} , $A \leq_r A_0$. A language A_0 is **\mathcal{C} -complete** under \leq_r if A_0 is \mathcal{C} -hard, and $A_0 \in \mathcal{C}$. Informally, if A_0 is \mathcal{C} -hard, then A_0 represents a problem that is at least as difficult to solve as any problem in \mathcal{C} . If A_0 is \mathcal{C} -complete, then in a sense, A_0 is one of the most difficult problems in \mathcal{C} .

There is another way to view completeness. Completeness provides us with tight lower bounds on the complexity of problems. If a language A is complete for complexity class \mathcal{C} , then we have a lower bound on its complexity. Namely, A is as hard as the most difficult problem in \mathcal{C} , assuming that the complexity of the reduction itself is small enough not to matter. The lower bound is tight because A is in \mathcal{C} ; that is, the upper bound matches the lower bound.

In the case $\mathcal{C} = \text{NP}$, the reducibility \leq_r is usually taken to be Karp reducibility unless otherwise stated. Thus we say

- A language A_0 is **NP-hard** if A_0 is NP-hard under Karp reducibility.
- A_0 is **NP-complete** if A_0 is NP-complete under Karp reducibility.

Note, however, that some sources use the term “NP-hard” to refer to Cook reducibility.

Many important languages are now known to be NP-complete. Before we get to them, let us discuss some implications of the statement “ A_0 is NP-complete,” and also some things this statement does *not* mean.

The first implication is that if there exists a deterministic Turing machine that decides A_0 in polynomial time—that is, if $A_0 \in \text{P}$ —then because P is closed under Karp reducibility (Theorem 7.8) it would follow

that $\text{NP} \subseteq \mathcal{P}$, hence $\mathcal{P} = \text{NP}$. In essence, the question of whether \mathcal{P} is the same as NP comes down to the question of whether any particular NP -complete language is in \mathcal{P} . Put another way, *all* of the NP -complete languages stand or fall together: if one is in \mathcal{P} , then all are in \mathcal{P} ; if one is not, then all are not. Another implication, which follows by a similar closure argument applied to co-NP , is that if $A_0 \in \text{co-NP}$ then $\text{NP} = \text{co-NP}$. It is also believed unlikely that $\text{NP} = \text{co-NP}$, as was noted in Section 7.4.3 in connection with whether all tautologies have short proofs.

A common misconception is that the above property of NP -complete languages is actually their definition, namely: if $A \in \text{NP}$, and $A \in \mathcal{P}$ implies $\mathcal{P} = \text{NP}$, then A is NP -complete. This “definition” is wrong if $\mathcal{P} \neq \text{NP}$. A theorem due to Ladner (1975) shows that $\mathcal{P} \neq \text{NP}$ if and only if there exists a language A' in $\text{NP} - \mathcal{P}$ such that A' is not NP -complete. Thus, if $\mathcal{P} \neq \text{NP}$, then A' is a counterexample to the “definition.”

Another common misconception arises from a misunderstanding of the statement “If A_0 is NP -complete, then A_0 is one of the most difficult problems in NP .” This statement is true on one level: if there is any problem at all in NP that is not in \mathcal{P} , then the NP -complete language A_0 is one such problem. However, note that there are NP -complete problems in $\text{NTIME}[n]$ —and these problems are, in some sense, much *simpler* than many problems in $\text{NTIME}[n^{10^{500}}]$.

7.5.3 Cook–Levin Theorem

Interest in NP -complete problems started with a theorem of Cook (1971), proved independently by Levin (1973). Recall that SAT is the language of Boolean formulas $\phi(z_1, \dots, z_r)$ such that there exists a truth assignment to the variables z_1, \dots, z_r that makes ϕ true.

Theorem 7.9 (Cook–Levin Theorem)

SAT is NP -complete.

Proof. We know already that SAT is in NP , so to prove that SAT is NP -complete, we need to take an arbitrary given language A in NP and show that $A \leq_m^p \text{SAT}$. Take N to be a nondeterministic Turing machine that decides A in polynomial time. Then the relation $R(x, y) = “y$ is a computation path of N that leads it to accept $x”$ is decidable in deterministic polynomial time depending only on $n = |x|$. We can assume that the length m of possible y ’s encoded as binary strings depends only on n and not on a particular x .

It is straightforward to show that there is a polynomial p and for each n a Boolean circuit C_n^R with $p(n)$ wires, with $n + m$ input wires labeled $x_1, \dots, x_n, y_1, \dots, y_m$ and one output wire w_0 , such that $C_n^R(x, y)$ outputs 1 if and only if $R(x, y)$ holds. (We describe circuits in more detail in the following text, and state a theorem for this principle as Part 1 of Theorem 7.15) Importantly, C_n^R itself can be designed in time polynomial in n , and – by the universality of NAND – may be composed entirely of binary NAND gates. Label the wires by variables $x_1, \dots, x_n, y_1, \dots, y_m, w_0, w_1, \dots, w_{p(n)-n-m-1}$. These become the variables of our Boolean formulas. For each NAND gate g with input wires u and v , and for each output wire w of g , write down the subformula

$$\phi_{g,w} = (u \vee w) \wedge (v \vee w) \wedge (\bar{u} \vee \bar{v} \vee \bar{w}).$$

This subformula is satisfied by precisely those assignments to u, v, w that give $w = u \text{ NAND } v$. The conjunction ϕ_0 of $\phi_{g,w}$ over the polynomially many gates g and their output wires w thus is satisfied only by assignments that set every gate’s output correctly given its inputs. Thus for any binary strings x and y of lengths n, m respectively, the formula $\phi_1 = \phi_0 \wedge w_0$ is satisfiable by a setting of the wire variables $w_0, w_1, \dots, w_{p(n)-n-m-1}$ if and only if $C_n^R(x, y) = 1$ —that is, if and only if $R(x, y)$ holds.

Now given any fixed x and taking $n = |x|$, the Karp reduction computes ϕ_1 as mentioned earlier and finally outputs the Boolean formula ϕ obtained by substituting the bit-values of x into ϕ_1 . This ϕ has variables $y_1, \dots, y_m, w_0, w_1, \dots, w_{p(n)-n-m-1}$ and the computation of ϕ from x runs in deterministic polynomial time. Then $x \in A$ if and only if N accepts x , if and only if there exists y such that $R(x, y)$ holds, if and only if there exists an assignment to the variables $w_0, w_1, \dots, w_{p(n)-n-m-1}$, and y_1, \dots, y_m that satisfies ϕ , if and only if $\phi \in \text{SAT}$. This shows $A \leq_m^p \text{SAT}$. \square

We have actually proved that SAT remains NP-complete even when the given instances ϕ are *restricted* to Boolean formulas that are a conjunction of *clauses*, where each clause consists of (here, at most three) disjuncted literals. Such formulas are said to be in *conjunctive normal form*. Theorem 7.9 is also commonly known as **Cook's Theorem**.

7.5.4 Proving NP-Completeness

After one language has been proved complete for a class, others can be proved complete by constructing transformations. For NP, if A_0 is NP-complete, then to prove that another language A_1 is NP-complete, it suffices to prove that $A_1 \in \text{NP}$ and to construct a polynomial-time transformation that establishes $A_0 \leq_m^p A_1$. Since A_0 is NP-complete, for every language A in NP, $A \leq_m^p A_0$, hence, by transitivity (Theorem 7.7), $A \leq_m^p A_1$.

Beginning with Cook (1971) and Karp (1972), hundreds of computational problems in many fields of science and engineering have been proved to be NP-complete, almost always by reduction from a problem that was previously known to be NP-complete. The following NP-complete decision problems are frequently used in these reductions—the language corresponding to each problem is the set of instances whose answers are *yes*.

- 3-SATISFIABILITY (3SAT)

Instance: A Boolean expression ϕ in conjunctive normal form with three literals per clause [e.g., $(w \vee x \vee \bar{y}) \wedge (\bar{x} \vee y \vee z)$]

Question: Is ϕ satisfiable?

- VERTEX COVER

Instance: A graph G and an integer k

Question: Does G have a set W of k vertices such that every edge in G is incident on a vertex of W ?

- CLIQUE

Instance: A graph G and an integer k

Question: Does G have a set U of k vertices such that every two vertices in U are adjacent in G ?

- INDEPENDENT SET

Instance: A graph G and an integer k

Question: Does G have a set U of k vertices such that no two vertices in U are adjacent in G ?

- HAMILTONIAN CIRCUIT

Instance: A graph G

Question: Does G have a circuit that includes every vertex exactly once?

- THREE-DIMENSIONAL MATCHING

Instance: Sets W, X, Y with $|W| = |X| = |Y| = q$ and a subset $S \subseteq W \times X \times Y$

Question: Is there a subset $S' \subseteq S$ of size q such that no two triples in S' agree in any coordinate?

- PARTITION

Instance: A set S of positive integers

Question: Is there a subset $S' \subseteq S$ such that the sum of the elements of S' equals the sum of the elements of $S - S'$?

Note that our ϕ in the above proof of the Cook–Levin Theorem already meets a form of the definition of 3SAT relaxed to allow “at most 3 literals per clause.” Padding ϕ with some extra variables to bring up the number in each clause to exactly three, while preserving whether the formula is satisfiable or not, is not difficult and establishes the NP-completeness of 3SAT. Below we use this in showing the NP-completeness of INDEPENDENT SET.

Some NP-completeness proofs require only “minor adjustments” even between different-looking problems. Consider CLIQUE, INDEPENDENT SET, and VERTEX COVER. A graph G has a clique of size k if and only if its complementary graph G' has an independent set of size k . It follows that the function f defined by $f(G, k) = (G', k)$ is a Karp reduction from INDEPENDENT SET to CLIQUE. To forge a link to the VERTEX COVER problem, note that all vertices *not* in a given vertex cover form an independent set, and vice versa. Thus a graph G on n vertices has a vertex cover of size at most k if and only if G has an independent set of size at least $n - k$. Hence the function $g(G, k) = (G, n - k)$ is a Karp reduction from INDEPENDENT SET to VERTEX COVER.

Here is another example of an NP-completeness proof, for the following decision problem:

- TRAVELING SALESMAN PROBLEM (TSP)

Instance: A set of m “cities” C_1, \dots, C_m , with an integer distance $d(i, j)$ between every pair of cities C_i and C_j , and an integer D .

Question: Is there a tour of the cities whose total length is at most D , that is, a permutation c_1, \dots, c_m of $\{1, \dots, m\}$, such that

$$d(c_1, c_2) + \dots + d(c_{m-1}, c_m) + d(c_m, c_1) \leq D?$$

First, it is easy to see that TSP is in NP: a nondeterministic Turing machine simply guesses a tour and checks that the total length is at most D .

Next, we construct a reduction from Hamiltonian Circuit to TSP. (The reduction goes from the known NP-complete problem, Hamiltonian Circuit, to the new problem, TSP, not vice versa.)

From a graph G on m vertices v_1, \dots, v_m , define the distance function d as follows:

$$d(i, j) = \begin{cases} 1 & \text{if } (v_i, v_j) \text{ is an edge in } G \\ m + 1 & \text{otherwise} \end{cases}$$

Set $D = m$. Clearly, d and D can be computed in polynomial time from G . Each vertex of G corresponds to a city in the constructed instance of TSP.

If G has a Hamiltonian circuit, then the length of the tour that corresponds to this circuit is exactly m . Conversely, if there is a tour whose length is at most m , then each step of the tour must have distance 1, not $m + 1$. Thus, each step corresponds to an edge of G , and the corresponding sequence of vertices in G is a Hamiltonian circuit.

7.5.5 NP-Completeness by Combinatorial Transformation

The following example shows how the combinatorial mechanism of one problem (here, 3SAT) can be *transformed* by a reduction into the seemingly much different mechanism of another problem.

Theorem 7.10

INDEPENDENT SET is NP-complete. Hence also CLIQUE and VERTEX COVER are NP-complete.

Proof. We have remarked already that the languages of these three problems belong to NP and shown already that INDEPENDENT SET \leq_m^p CLIQUE and INDEPENDENT SET \leq_m^p VERTEX COVER. It suffices to show that 3SAT \leq_m^p INDEPENDENT SET.

FIGURE 7.3 Construction in the proof of NP-completeness of INDEPENDENT SET for the formula $(x_1 \vee x_2 \vee \bar{x}_3) \wedge (x_1 \vee \bar{x}_2 \vee x_3)$. The independent set of size 5 corresponding to the satisfying assignment $x_1 = \text{false}$, $x_2 = \text{true}$, and $x_3 = \text{true}$ is shown by nodes marked *I*.

Construction. Let the Boolean formula ϕ be a given instance of 3SAT with variables x_1, \dots, x_n and clauses C_1, \dots, C_m . The graph G_ϕ we build consists of a “ladder” on $2n$ vertices labeled $x_1, \bar{x}_1, \dots, x_n, \bar{x}_n$, with edges (x_i, \bar{x}_i) for $1 \leq i \leq n$ forming the “rungs,” and m “clause components.” Here the component for each clause C_j has one vertex for each literal x_i or \bar{x}_i in the clause, and all pairs of vertices within each clause component are joined by an edge. Finally, each clause-component node with a label x_i is connected by a “crossing edge” to the node with the opposite label \bar{x}_i in the i th “rung,” and similarly each occurrence of \bar{x}_i in a clause is joined to the rung node x_i . This finishes the construction of G_ϕ . See Figure 7.3.

Also set $k = n + m$. Then the reduction function f is defined for all arguments ϕ by $f(\phi) = (G_\phi, k)$.

Complexity. It is not hard to see that f is computable in polynomial time given (a straightforward encoding of) ϕ .

Correctness. To complete the proof, we need to argue that ϕ is satisfiable if and only if G_ϕ has an independent set of size $n + m$. To see this, first note that any independent set I of that size must contain exactly one of the two nodes from each “rung,” and exactly one node from each clause component—because the edges in the rungs and the clause component prevent any more nodes from being added. And if I selects a node labeled x_i in a clause component, then I must also select x_i in the i th rung. If I selects \bar{x}_i in a clause component, then I must also select \bar{x}_i in the rung. In this manner I induces a truth assignment in which $x_i = \text{true}$ and $x_j = \text{false}$, and so on for all variables. This assignment satisfies ϕ , because the node selected from each clause component tells how the corresponding clause is satisfied by the assignment. Going the other way, if ϕ has a satisfying assignment, then that assignment yields an independent set I of size $n + m$ in like manner. \square

7.5.6 Complete Problems for Other Classes

Besides NP, the following canonical complexity classes have natural complete problems. The three problems now listed are complete for their respective classes under log-space reducibility.

- NL: GRAPH ACCESSIBILITY PROBLEM
Instance: A directed graph G with nodes $1, \dots, N$
Question: Does G have a directed path from node 1 to node N ?
- P: CIRCUIT VALUE PROBLEM
Instance: A Boolean circuit (see Section 7.9) with output node u , and an assignment I of $\{0, 1\}$ to each input node
Question: Is 1 the value of u under I ?

- PSPACE: QUANTIFIED BOOLEAN FORMULAS

Instance: A Boolean expression with all variables quantified with either \forall or \exists [e.g., $\forall x \forall y \exists z (x \wedge (\bar{y} \vee z))$]

Question: Is the expression true?

These problems can be used to prove that other problems are NL-complete, P-complete, and PSPACE-complete, respectively.

Stockmeyer and Meyer (1973) defined a natural decision problem that they proved to be complete for NE. If this problem were in P, then by closure under Karp reducibility (Theorem 7.8), we would have $NE \subseteq P$, a contradiction of the hierarchy theorems (Theorem 7.4). Therefore, this decision problem is infeasible: it has no polynomial-time algorithm. In contrast, decision problems in $NEXP - P$ that have been constructed by diagonalization are artificial problems that nobody would want to solve anyway. Although diagonalization produces unnatural problems by itself, the combination of diagonalization and completeness shows that *natural* problems are intractable.

The next section points out some limitations of current diagonalization techniques.

7.6 Relativization of the P vs. NP Problem

Let A be a language. Define P^A (respectively, NP^A) to be the class of languages accepted in polynomial time by deterministic (nondeterministic) oracle Turing machines with oracle A .

Proofs that use the diagonalization technique on Turing machines without oracles generally carry over to oracle Turing machines. Thus, for instance, the proof of the DTIME hierarchy theorem also shows that, for *any* oracle A , $DTIME^A[n^2]$ is properly contained in $DTIME^A[n^3]$. This can be seen as a *strength* of the diagonalization technique, since it allows an argument to “relativize” to computation carried out relative to an oracle. In fact, there are examples of lower bounds (for deterministic, “unrelativized” circuit models) that make crucial use of the fact that the time hierarchies relativize in this sense.

But it can also be seen as a weakness of the diagonalization technique. The following important theorem demonstrates why.

Theorem 7.11

There exist languages A and B such that $P^A = NP^A$, and $P^B \neq NP^B$ (Baker et al., 1975).

This shows that resolving the P vs. NP question requires techniques that do not relativize, that is, that do not apply to oracle Turing machines too. Thus, diagonalization as we currently know it is unlikely to succeed in separating P from NP, because the diagonalization arguments we know (and in fact *most* of the arguments we know) relativize. Important nonrelativizing proof techniques were discovered in the early 1990s, in connection with interactive proof systems (Section 7.12.1).

7.7 The Polynomial Hierarchy

Let \mathcal{C} be a class of languages. Define

- $NP^{\mathcal{C}} = \bigcup_{A \in \mathcal{C}} NP^A$
- $\Sigma_0^P = \Pi_0^P = P$

and for $k \geq 0$, define

- $\Sigma_{k+1}^P = NP^{\Sigma_k^P}$
- $\Pi_{k+1}^P = \text{co-}\Sigma_{k+1}^P$

Observe that $\Sigma_1^P = \text{NP}^P = \text{NP}$, because each of polynomially many queries to an oracle language in P can be answered directly by a (nondeterministic) Turing machine in polynomial time. Consequently, $\Pi_1^P = \text{co-NP}$. For each k , $\Sigma_k^P \cup \Pi_k^P = \Sigma_{k+1}^P \cap \Pi_{k+1}^P$, but this inclusion is not known to be strict.

The classes Σ_k^P and Π_k^P constitute the **polynomial hierarchy**. Define

$$\text{PH} = \bigcup_{k \geq 0} \Sigma_k^P$$

It is straightforward to prove that $\text{PH} \subseteq \text{PSPACE}$, but it is not known whether the inclusion is strict. In fact, if $\text{PH} = \text{PSPACE}$, then the polynomial hierarchy collapses to some level, that is, $\text{PH} = \Sigma_m^P$ for some m . In the next section, we define the polynomial hierarchy in two other ways, one of which is in terms of alternating Turing machines.

7.8 Alternating Complexity Classes

In this section, we define time and space complexity classes for alternating Turing machines, and we show how these classes are related to the classes introduced already. The possible computations of an alternating Turing machine M on an input word x can be represented by a tree T_x in which the root is the initial configuration, and the children of a nonterminal node C are the configurations reachable from C by one step of M . For a word x in $L(M)$, define an **accepting subtree** S of T_x to be a subtree of T_x with the following properties:

- S is finite.
- The root of S is the initial configuration with input word x .
- If S has an existential configuration C , then S has exactly one child of C in T_x ; if S has a universal configuration C , then S has all children of C in T_x .
- Every leaf is a configuration whose state is the accepting state q_A .

Observe that each node in S is an accepting configuration.

We consider only alternating Turing machines that always halt. For $x \in L(M)$, define the time taken by M to be the height of the shortest accepting tree for x , and the space to be the maximum number of worktape cells visited along any path in an accepting tree that minimizes this number. For $x \notin L(M)$, define the time to be the height of T_x , and the space to be the maximum number of worktape cells visited along any path in T_x .

Let $t(n)$ be a time-constructible function, and let $s(n)$ be a space-constructible function. Define the following complexity classes:

- $\text{ATIME}[t(n)]$ is the class of languages decided by alternating Turing machines of time complexity $O(t(n))$.
- $\text{ASPACE}[s(n)]$ is the class of languages decided by alternating Turing machines of space complexity $O(s(n))$.

Because a nondeterministic Turing machine is a special case of an alternating Turing machine, for every $t(n)$ and $s(n)$, $\text{NTIME}[t] \subseteq \text{ATIME}[t]$ and $\text{NSPACE}[s] \subseteq \text{ASPACE}[s]$. The next theorem states further relationships between computational resources used by alternating Turing machines and resources used by deterministic and nondeterministic Turing machines.

Theorem 7.12 (Alternation Theorems)

Let $t(n)$ be a time-constructible function, and let $s(n)$ be a space-constructible function, $s(n) \geq \log n$ (Chandra et al., 1981).

- (a) $\text{NSPACE}[s(n)] \subseteq \text{ATIME}[s(n)^2]$.
- (b) $\text{ATIME}[t(n)] \subseteq \text{DSpace}[t(n)]$.
- (c) $\text{ASPACE}[s(n)] \subseteq \text{DTIME}[2^{O(s(n))}]$.
- (d) $\text{DTIME}[t(n)] \subseteq \text{ASPACE}[\log t(n)]$.

In other words, space on deterministic and nondeterministic Turing machines is polynomially related to time on alternating Turing machines. Space on alternating Turing machines is exponentially related to time on deterministic Turing machines. The following corollary is immediate.

Theorem 7.13

- (a) $\text{ASPACE}[O(\log n)] = \text{P}$.
- (b) $\text{ATIME}[n^{O(1)}] = \text{PSPACE}$.
- (c) $\text{ASPACE}[n^{O(1)}] = \text{EXP}$.

In Section 7.7, we defined the classes of the polynomial hierarchy in terms of oracles, but we can also define them in terms of alternating Turing machines with restrictions on the number of alternations between existential and universal states. Define a *k-alternating Turing machine* to be a machine such that on every computation path, the number of changes from an existential state to a universal state, or from a universal state to an existential state, is at most $k - 1$. Thus, a nondeterministic Turing machine, which stays in existential states, is a 1-alternating Turing machine.

Theorem 7.14

For any language A , the following are equivalent (Stockmeyer, 1976; Wrathall, 1976):

1. $A \in \Sigma_k^P$.
2. A is decided in polynomial time by a k -alternating Turing machine that starts in an existential state.
3. There exists a language B in P and a polynomial p such that for all x , $x \in A$ if and only if

$$(\exists y_1 : |y_1| \leq p(|x|)) (\forall y_2 : |y_2| \leq p(|x|)) \cdots (Qy_k : |y_k| \leq p(|x|)) [(x, y_1, \dots, y_k) \in B]$$

where the quantifier Q is \exists if k is odd, \forall if k is even.

Alternating Turing machines are closely related to Boolean circuits, which are defined in Section 7.9.

7.9 Circuit Complexity

The hardware of electronic digital computers is based on digital logic gates, connected into combinational circuits (see Chapter 17). Here, we specify a model of computation that formalizes the combinational circuit.

A *Boolean circuit* on n input variables x_1, \dots, x_n is a directed acyclic graph with exactly n input nodes of indegree 0 labeled x_1, \dots, x_n and other nodes of indegree 1 or 2, called *gates*, labeled with the Boolean operators in $\{\wedge, \vee, \neg\}$. One node is designated as the output of the circuit. See Figure 7.4. Without loss of generality, we assume that there are no extraneous nodes; there is a directed path from each node to the output node. The indegree of a gate is also called its *fan-in*.

An *input assignment* is a function I that maps each variable x_i to either 0 or 1. The value of each gate g under I is obtained by applying the Boolean operation that labels g to the values of the immediate predecessors of g . The function computed by the circuit is the value of the output node for each input assignment.

FIGURE 7.4 A Boolean circuit.

A Boolean circuit computes a finite function: a function of only n binary input variables. To decide membership in a language, we need a circuit for each input length n .

A *circuit family* is an infinite set of circuits $C = \{c_1, c_2, \dots\}$ in which each c_n is a Boolean circuit on n inputs. C *decides* a language $A \subseteq \{0, 1\}^*$ if for every n and every assignment a_1, \dots, a_n of $\{0, 1\}$ to the n inputs, the value of the output node of c_n is **1** if and only if the word $a_1 \dots a_n \in A$. The *size complexity* of C is the function $z(n)$ that specifies the number of nodes in each c_n . The *depth complexity* of C is the function $d(n)$ that specifies the length of the longest directed path in c_n . Clearly, since the fan-in of each gate is at most 2, $d(n) \geq \log z(n) \geq \log n$. The class of languages decided by polynomial-size circuits is denoted by \mathbb{P}/poly .

With a different circuit for each input length, a circuit family could solve an undecidable problem such as the halting problem (see Chapter 8). For each input length, a table of all answers for machine descriptions of that length could be encoded into the circuit. Thus, we need to restrict our circuit families. The most natural restriction is that all circuits in a family should have a concise, uniform description, to disallow a different answer table for each input length. Several uniformity conditions have been studied; the following is the easiest to present:

A circuit family $\{c_1, c_2, \dots\}$ of size complexity $z(n)$ is *log-space uniform* if there exists a deterministic Turing machine M such that on each input of length n , machine M produces a description of c_n , using space $O(\log z(n))$.

Now we define complexity classes for uniform circuit families and relate these classes to previously defined classes. Define the following complexity classes:

- $\text{SIZE}[z(n)]$ is the class of languages decided by log-space uniform circuit families of size complexity $O(z(n))$.
- $\text{DEPTH}[d(n)]$ is the class of languages decided by log-space uniform circuit families of depth complexity $O(d(n))$.

In our notation, $\text{SIZE}[n^{O(1)}]$ equals \mathbb{P} , which is a proper subclass of \mathbb{P}/poly .

Theorem 7.15

1. If $t(n)$ is a time-constructible function, then $\text{DTIME}[t(n)] \subseteq \text{SIZE}[t(n)\log t(n)]$ (Pippenger and Fischer, 1979).
2. $\text{SIZE}[z(n)] \subseteq \text{DTIME}[z(n)^{O(1)}]$.
3. If $s(n)$ is a space-constructible function and $s(n) \geq \log n$, then $\text{NSPACE}[s(n)] \subseteq \text{DEPTH}[s(n)^2]$ (Borodin, 1977).
4. If $d(n) \geq \log n$, then $\text{DEPTH}[d(n)] \subseteq \text{DSPACE}[d(n)]$ (Borodin, 1977).

The next theorem shows that size and depth on Boolean circuits are closely related to space and time on alternating Turing machines, provided that we permit sublinear running times for alternating Turing machines, as follows. We augment alternating Turing machines with a random-access input capability.

To access the cell at position j on the input tape, M writes the binary representation of j on a special tape, in $\log j$ steps, and enters a special reading state to obtain the symbol in cell j .

Theorem 7.16

(Ruzzo, 1979). Let $t(n) \geq \log n$ and $s(n) \geq \log n$ be such that the mapping $n \mapsto (t(n), s(n))$ (in binary) is computable in time $s(n)$.

1. Every language decided by an alternating Turing machine of simultaneous space complexity $s(n)$ and time complexity $t(n)$ can be decided by a log-space uniform circuit family of simultaneous size complexity $2^{O(s(n))}$ and depth complexity $O(t(n))$.
2. If $d(n) \geq (\log z(n))^2$, then every language decided by a log-space uniform circuit family of simultaneous size complexity $z(n)$ and depth complexity $d(n)$ can be decided by an alternating Turing machine of simultaneous space complexity $O(\log z(n))$ and time complexity $O(d(n))$.

The correspondence between time on alternating Turing machines and depth on log-space uniform circuits breaks down for time and depth less than $\log^2 n$, primarily because L is not known to be contained in $\text{ATIME}(o(\log^2 n))$. This has motivated the adoption of more restrictive notions of uniformity (see, e.g., Ruzzo, 1981; Vollmer, 1999). When researchers mention small uniform circuit classes, they usually are referring to these more restrictive notions of uniformity. (For depths at least $\log n$, the complexity classes obtained via these different notions of uniformity coincide.)

In a sense, the Boolean circuit family is a model of parallel computation, because all gates compute independently, in parallel. For each $k \geq 0$, NC^k denotes the class of languages decided by uniform bounded-fan-in circuits of polynomial size and depth $O((\log n)^k)$, and AC^k is defined analogously for unbounded fan-in circuits. In particular, AC^k is the same as the class of languages decided by a parallel machine model called the CRCW PRAM with polynomially many processors in parallel time $O((\log n)^k)$ (Stockmeyer and Vishkin, 1984).

7.10 Probabilistic Complexity Classes

Since the 1970s, with the development of randomized algorithms for computational problems (see Chapter 11), complexity theorists have placed randomized algorithms on a firm intellectual foundation. In this section, we outline some basic concepts in this area.

A **probabilistic Turing machine** M can be formalized as a nondeterministic Turing machine with exactly two choices at each step. During a computation, M chooses each possible next step with independent probability $1/2$. Intuitively, at each step, M flips a fair coin to decide what to do next. The probability of a computation path of t steps is $1/2^t$. The probability that M accepts an input string x , denoted by $p_M(x)$, is the sum of the probabilities of the accepting computation paths.

Throughout this section, we consider only machines whose time complexity $t(n)$ is time-constructible. Without loss of generality, we may assume that every computation path of such a machine halts in exactly t steps.

Let A be a language. A probabilistic Turing machine M decides A with

		for all $x \in A$	for all $x \notin A$
Unbounded two-sided error	if	$p_M(x) > 1/2$	$p_M(x) \leq 1/2$
Bounded two-sided error	if	$p_M(x) > 1/2 + \epsilon$	$p_M(x) < 1/2 - \epsilon$
		for some positive constant ϵ	
One-sided error	if	$p_M(x) > 1/2$	$p_M(x) = 0$.

Many practical and important probabilistic algorithms make one-sided errors. For example, in the primality testing algorithm of Solovay and Strassen (1977), when the input x is a prime number, the algorithm *always* says “prime”; when x is composite, the algorithm *usually* says “composite,” but may occasionally say “prime.” Using the definitions above, this means that the Solovay–Strassen algorithm is a one-sided error algorithm for the set A of composite numbers. It also is a bounded two-sided error algorithm for \bar{A} , the set of prime numbers.

These three kinds of errors suggest three complexity classes:

- PP is the class of languages decided by probabilistic Turing machines of polynomial-time complexity with unbounded two-sided error.
- BPP is the class of languages decided by probabilistic Turing machines of polynomial-time complexity with bounded two-sided error.
- RP is the class of languages decided by probabilistic Turing machines of polynomial-time complexity with one-sided error.

In the literature, RP has also sometimes been called R.

A probabilistic Turing machine M is a **PP-machine** (respectively, a **BPP-machine**, an **RP-machine**) if M has polynomial-time complexity, and M decides with two-sided error (bounded two-sided error, one-sided error).

Through repeated Bernoulli trials, we can make the error probabilities of BPP-machines and RP-machines arbitrarily small, as stated in the following theorem. (Among other things, this theorem implies that $\text{RP} \subseteq \text{BPP}$.)

Theorem 7.17

If $A \in \text{BPP}$, then for every polynomial $q(n)$, there exists a BPP-machine M such that $p_M(x) > 1 - 1/2^{q(n)}$ for every $x \in A$, and $p_M(x) < 1/2^{q(n)}$ for every $x \notin A$.

If $L \in \text{RP}$, then for every polynomial $q(n)$, there exists an RP-machine M such that $p_M(x) > 1 - 1/2^{q(n)}$ for every x in L .

It is important to note just how minuscule the probability of error is (provided that the coin flips are truly random). If the probability of error is less than $1/2^{5000}$, then it is less likely that the algorithm produces an incorrect answer than that the computer will be struck by a meteor. An algorithm whose probability of error is $1/2^{5000}$ is essentially as good as an algorithm that makes no errors. For this reason, many computer scientists consider BPP to be the class of practically feasible computational problems.

Next, we define a class of problems that have probabilistic algorithms that make no errors. Define

- $\text{ZPP} = \text{RP} \cap \text{co-RP}$.

The letter Z in ZPP is for zero probability of error, as we now demonstrate. Suppose $A \in \text{ZPP}$. Here is an algorithm that checks membership in A . Let M be an RP-machine that decides A , and let M' be an RP-machine that decides \bar{A} . For an input string x , alternately run M and M' on x , repeatedly, until a computation path of one machine accepts x . If M accepts x , then accept x ; if M' accepts x , then reject x . This algorithm works correctly because when an RP-machine accepts its input, it does not make a mistake. This algorithm might not terminate, but with very high probability, the algorithm terminates after a few iterations.

The next theorem expresses some known relationships between probabilistic complexity classes and other complexity classes, such as classes in the polynomial hierarchy. See Section 7.7 and Figure 7.5.

FIGURE 7.5 Probabilistic complexity classes.

Theorem 7.18

- $P \subseteq ZPP \subseteq RP \subseteq BPP \subseteq PP \subseteq PSPACE$ (Gill, 1977).
- $RP \subseteq NP \subseteq PP$ (Gill, 1977).
- $BPP \subseteq \Sigma_2^P \cap \Pi_2^P$ (Lautemann, 1983; Sipser, 1983).
- $BPP \subset P/poly$.
- $PH \subseteq P^{PP}$ (Toda, 1991).

An important recent research area called **de-randomization** studies whether randomized algorithms can be converted to deterministic ones of the same or comparable efficiency. For example, if there is a language in E that requires Boolean circuits of size $2^{\Omega(n)}$ to decide it, then $BPP = P$ (Impagliazzo and Wigderson, 1997).

7.11 Quantum Computation

A probabilistic computer enables one to sample efficiently over exponentially many possible computation paths. However, if $BPP = P$ then the added capability is weak. A *quantum computer*, however, can harness parallelism and randomness in ways that appear theoretically to be much more powerful, ways that are able to solve problems believed not to lie in BPP . A key difference is that by quantum *interference*, opening up new computation paths may cause the probabilities of some other paths to *vanish*, whereas for a BPP -machine those probabilities would remain positive.

- BQP is the class of languages decided by quantum machines of polynomial-time complexity with bounded two-sided error.

A prime motivation for studying BQP is that it includes language versions of the integer factoring and discrete logarithm problems, which are not known to belong to BPP . The public-key cryptosystems in common use today rely on the presumed intractability of these problems and are theoretically breakable by eavesdroppers armed with quantum computers. This is one of several reasons why the interplay of quantum mechanics and computational complexity is important to cryptographers.

In terms of the complexity classes depicted in Figure 7.5, the only inclusions that are known involving BQP are

$$\text{BPP} \subseteq \text{BQP} \subseteq \text{PP}.$$

In particular, it is important to emphasize that it is *not* generally believed that quantum computers can solve NP-complete problems quickly.

7.12 Interactive Models and Complexity Classes

7.12.1 Interactive Proofs

In Section 7.3.2, we characterized NP as the set of languages whose membership proofs can be checked quickly, by a deterministic Turing machine M of polynomial-time complexity. A different notion of proof involves interaction between two parties, a prover P and a verifier V , who exchange messages. In an **interactive proof system** (Goldwasser et al., 1989), the prover is an all-powerful machine, with unlimited computational resources, analogous to a teacher. The verifier is a computationally limited machine, analogous to a student. Interactive proof systems are also called “Arthur–Merlin games”: the wizard Merlin corresponds to P and the impatient Arthur corresponds to V (Babai and Moran, 1988).

Formally, an **interactive proof system** comprises the following:

- A read-only input tape on which an input string x is written.
- A *verifier* V , which is a probabilistic Turing machine augmented with the capability to send and receive messages. The running time of V is bounded by a polynomial in $|x|$.
- A *prover* P , which receives messages from V and sends messages to V .
- A tape on which V writes messages to send to P , and a tape on which P writes messages to send to V . The length of every message is bounded by a polynomial in $|x|$.

A computation of an interactive proof system (P, V) proceeds in rounds, as follows. For $j = 1, 2, \dots$, in round j , V performs some steps, writes a message m_j , and temporarily stops. Then P reads m_j and responds with a message m'_j , which V reads in round $j + 1$. An interactive proof system (P, V) **accepts** an input string x if the probability of acceptance by V satisfies $p_V(x) > 1/2$.

In an interactive proof system, a prover can convince the verifier about the truth of a statement without exhibiting an entire proof, as the following example illustrates.

Consider the graph nonisomorphism problem: the input consists of two graphs G and H , and the decision is **yes** if and only if G is not isomorphic to H . Although there is a short proof that two graphs *are* isomorphic (namely: the proof consists of the isomorphism mapping G onto H), nobody has found a general way of proving that two graphs are *not* isomorphic that is significantly shorter than listing all $n!$ permutations and showing that each fails to be an isomorphism. (That is, the graph nonisomorphism problem is in co-NP but is not known to be in NP.) In contrast, the verifier V in an interactive proof system is able to take statistical evidence into account, and determine “beyond all reasonable doubt” that two graphs are nonisomorphic, using the following protocol.

In each round, V randomly chooses either G or H with equal probability; if V chooses G , then V computes a random permutation G' of G , presents G' to P , and asks P whether G' came from G or from H (and similarly H' if V chooses H). If G and H are nonisomorphic, then P always answers correctly. If G and H are isomorphic, then after k consecutive rounds, the probability that P always answers correctly is $1/2^k$. (To see this, it is important to understand that the prover P does not see the coins that V flips in making its random choices; P sees only the graphs G' and H' that V sends as messages.) V accepts the interaction with P as “proof” that G and H are nonisomorphic if P is able to pick the correct graph for 100 consecutive rounds. Note that V has ample grounds to accept this as a

convincing demonstration: if the graphs are indeed isomorphic, the prover P would have to have an incredible streak of luck to fool V .

It is important to comment that de-randomization techniques applied to these proof systems have shown that under plausible hardness assumptions, proofs of nonisomorphism of subexponential length (or even polynomial length) do exist (Klivans and van Melkebeek, 2002). Thus many complexity theoreticians now conjecture that the graph isomorphism problem lies in $\text{NP} \cap \text{co-NP}$.

The complexity class IP comprises the languages A for which there exists a verifier V and a positive ϵ such that

- There exists a prover \hat{P} such that for all x in A , the interactive proof system (\hat{P}, V) accepts x with probability greater than $1/2 + \epsilon$
- For every prover P and every $x \notin A$, the interactive proof system (P, V) rejects x with probability greater than $1/2 + \epsilon$

By substituting random choices for existential choices in the proof that $\text{ATIME}(t) \subseteq \text{DSPACE}(t)$ (Theorem 7.12), it is straightforward to show that $\text{IP} \subseteq \text{PSPACE}$. It was originally believed likely that IP was a small subclass of PSPACE . Evidence supporting this belief was the construction of an oracle language B for which $\text{co-NP}^B - \text{IP}^B \neq \emptyset$ (Fortnow and Sipser, 1988), so that IP^B is strictly included in PSPACE^B . Using a proof technique that does not relativize, however, Shamir (1992) proved that in fact, IP and PSPACE are the same class.

Theorem 7.19

$\text{IP} = \text{PSPACE}$ (Shamir, 1992).

If NP is a proper subset of PSPACE , as is widely believed, then Theorem 7.19 says that interactive proof systems can decide a larger class of languages than NP .

7.12.2 Probabilistically Checkable Proofs

In an interactive proof system, the verifier does not need a complete conventional proof to become convinced about the membership of a word in a language, but uses random choices to query parts of a proof that the prover may know. This interpretation inspired another notion of “proof”: a proof consists of a (potentially) large amount of information that the verifier need only inspect in a few places in order to become convinced. The following definition makes this idea more precise.

A language A has a **probabilistically checkable proof** if there exists an oracle BPP-machine M such that

- For all $x \in A$, there exists an oracle language B_x such that M^{B_x} accepts x with probability 1.
- For all $x \notin A$, and for every language B , machine M^B accepts x with probability strictly less than $1/2$.

Intuitively, the oracle language B_x represents a proof of membership of x in A . Notice that B_x can be finite since the length of each possible query during a computation of M^{B_x} on x is bounded by the running time of M . The oracle language takes the role of the prover in an interactive proof system—but in contrast to an interactive proof system, the prover cannot change strategy adaptively in response to the questions that the verifier poses. This change results in a potentially stronger system, since a machine M that has bounded error probability relative to all languages B might not have bounded error probability relative to some adaptive prover. Although this change to the proof system framework may seem modest, it leads to a characterization of a class that seems to be much larger than PSPACE .

Theorem 7.20

A has a probabilistically checkable proof if and only if $A \in \text{NEXP}$ (Babai et al., 1991).

Although the notion of probabilistically checkable proofs seems to lead us away from feasible complexity classes, by considering natural restrictions on how the proof is accessed, we can obtain important insights into familiar complexity classes.

Let $\text{PCP}[r(n), q(n)]$ denote the class of languages with probabilistically checkable proofs in which the probabilistic oracle Turing machine M makes $r(n)$ random binary choices and queries its oracle $q(n)$ times. (For this definition, we assume that M has either one or two choices for each step.) It follows from the definitions that $\text{BPP} = \text{PCP}[n^{O(1)}, 0]$, and $\text{NP} = \text{PCP}[0, n^{O(1)}]$.

Theorem 7.21 (The PCP Theorem)

$\text{NP} = \text{PCP}[O(\log n), O(1)]$ (Arora et al., 1998).

Theorem 7.21 asserts that for every language A in NP , a proof that $x \in A$ can be encoded so that the verifier can be convinced of the correctness of the proof (or detect an incorrect proof) by using only $O(\log n)$ random choices and inspecting only a *constant* number of bits of the proof.

7.13 Kolmogorov Complexity

Until now, we have considered only dynamic complexity measures, namely, the time and space used by Turing machines. Kolmogorov complexity is a static complexity measure that captures the difficulty of describing a string. For example, the string consisting of three million zeroes can be described with fewer than three million symbols (as in this sentence). In contrast, for a string consisting of three million randomly generated bits, with high probability there is no shorter description than the string itself.

Our goal will be to equate the complexity of a string with the length of its shortest “description”—but this raises the question of what class of “descriptions” should be considered. Given any Turing machine M , one can define a measure $C_M(x)$ to be the length of the shortest input d (the “description”) such that $M(d) = x$. At first, this might not seem to be a very promising approach, because using different machines M_1 and M_2 will yield measures C_{M_1} and C_{M_2} that differ wildly (or worse, are undefined for those x that are never produced as output). Fortunately, the next theorem shows that if one chooses a *universal* Turing machine U to define a measure $C_U(x)$ in this way, the resulting measure is roughly the same as that obtained by using any other universal machine.

Theorem 7.22 (Invariance Theorem)

There exists a universal Turing machine U such that for every universal Turing machine U' , there is a constant c such that for all y , $C_U(y) \leq C_{U'}(y) + c$.

Henceforth, let C be defined by the universal Turing machine of Theorem 7.22. For every integer n and every binary string y of length n , because y can be described by giving itself explicitly, $C(y) \leq n + c'$ for a constant c' . Call y **incompressible** if $C(y) \geq n$. Since there are 2^n binary strings of length n and only $2^n - 1$ possible shorter descriptions, there exists an incompressible string for every length n .

Kolmogorov complexity gives a precise mathematical meaning to the intuitive notion of “randomness.” If someone flips a coin 50 times and it comes up “heads” each time, then intuitively, the sequence of flips is not random—although from the standpoint of probability theory the all-heads sequence is precisely as likely as any other sequence. Probability theory does not provide the tools for calling one sequence “more random” than another; Kolmogorov complexity theory does.

Kolmogorov complexity provides a useful framework for presenting combinatorial arguments. For example, when one wants to prove that an object with some property P exists, then it is sufficient to show that any object that does *not* have property P has a short description; thus any incompressible (or “random”) object must have property P . This sort of argument has been useful in proving lower bounds in complexity theory.

7.14 Research Issues and Summary

The core research questions in complexity theory are expressed in terms of separating complexity classes:

- Is L different from NL ?
- Is P different from RP or BPP ?
- Is P different from NP ?
- Is NP different from $PSPACE$?

Motivated by these questions, much current research is devoted to efforts to understand the power of nondeterminism, randomization, and interaction. In these studies, researchers have gone well beyond the theory presented in this chapter:

- Beyond Turing machines and Boolean circuits, to restricted and specialized models in which nontrivial lower bounds on complexity can be proved
- Beyond deterministic reducibilities, to nondeterministic and probabilistic reducibilities, and refined versions of the reducibilities considered here
- Beyond worst-case complexity, to average case complexity

Recent research in complexity theory has had direct applications to other areas of computer science and mathematics. Probabilistically checkable proofs were used to show that obtaining approximate solutions to some optimization problems is as difficult as solving them exactly. Complexity theory has provided new tools for studying questions in finite model theory, a branch of mathematical logic. Fundamental questions in complexity theory are intimately linked to practical questions about the use of cryptography for computer security, such as the existence of one-way functions and the strength of public-key cryptosystems.

This last point illustrates the urgent practical need for progress in computational complexity theory. Many popular cryptographic systems in current use are based on unproven assumptions about the difficulty of computing certain functions (such as the factoring and discrete logarithm problems). All of these systems are thus based on wishful thinking and conjecture. Research is needed to resolve these open questions and replace conjecture with mathematical certainty.

Key Terms

Complexity class: A set of languages that are decided within a particular resource bound. For example, $NTIME(n^2 \log n)$ is the set of languages decided by nondeterministic Turing machines within $O(n^2 \log n)$ time.

Constructibility: A function $f(n)$ is time (respectively, space) constructible if there exists a deterministic Turing machine that halts after exactly $f(n)$ steps [after using exactly $f(n)$ worktape cells] for every input of length n .

Diagonalization: A technique for constructing a language A that differs from every $L(M_i)$ for a list of machines M_1, M_2, \dots

NP-complete: A language A_0 is NP-complete if $A_0 \in \text{NP}$ and $A \leq_m^p A_0$ for every A in NP; that is, for every A in NP, there exists a function f computable in polynomial time such that for every x , $x \in A$ if and only if $f(x) \in A_0$.

Oracle: An oracle is a language A to which a machine presents queries of the form “Is w in A ” and receives each correct answer in one step.

Padding: A technique for establishing relationships between complexity classes that uses padded versions of languages, in which each word is padded out with multiple occurrences of a new symbol—the word x is replaced by the word $x\#^{f(|x|)}$ for a numeric function f —in order to artificially lower the complexity of the language.

Reduction: A language A reduces to a language B if a machine that decides B can be used to decide A efficiently.

Time and space complexity: The time (respectively, space) complexity of a deterministic Turing machine M is the maximum number of steps taken (worktape cells visited) by M among all input words of length n .

Turing machine: A Turing machine M is a model of computation with a read-only input tape and multiple worktapes. At each step, M reads the tape cells on which its access heads are located, and depending on its current state and the symbols in those cells, M changes state, writes new symbols on the worktape cells, and moves each access head one cell left or right or not at all.

Further Information

This chapter is a short version of three chapters written by the same authors for the *Algorithms and Theory of Computation Handbook* (Allender et al., 1999).

The formal theoretical study of computational complexity began with the paper of Hartmanis and Stearns (1965), who introduced the basic concepts and proved the first results. For historical perspectives on complexity theory, see Stearns (1990), Sipser (1992), Hartmanis (1994), Wigderson (2006), Allender (2009), and Fortnow (2009).

Contemporary textbooks on complexity theory are by Moore and Mertens (2011), Homer and Selman (2011), Arora and Barak (2009), Goldreich (2008), while venerable texts include Sipser (2005), Hopcroft et al. (2000), Hemaspaandra and Ogihara (2002), and Papadimitriou (1994). A good general reference is the *Handbook of Theoretical Computer Science* (van Leeuwen, 1990), volume A.

The text by Garey and Johnson (1979) explains NP-completeness thoroughly, with examples of NP-completeness proofs, and a collection of hundreds of NP-complete problems. Li and Vitányi (2008) provide a comprehensive scholarly treatment of Kolmogorov complexity, with many applications.

Five organizations and mainstay websites that promote research in computational complexity online sources are the ACM Special Interest Group on Algorithms and Computation Theory (SIGACT), the European Association for Theoretical Computer Science (EATCS), the annual IEEE Conference on Computational Complexity, the “Complexity Zoo,” and the theory section of StackExchange:

<http://sigact.org/>

<http://www.eatcs.org/>

<http://www.computationalcomplexity.org/>

<http://www.complexityzoo.com/>

<http://cstheory.stackexchange.com/>

The *Electronic Colloquium on Computational Complexity* maintained at the University of Trier, Germany at <http://ecc.hpi-web.de/> and <http://arxiv.org/> run by Cornell University include downloadable current research papers in the field, often with updates and revisions. Most individual researchers have websites with their work, and some also write blogs where news and ideas can be found. Among the most prominent blogs are:

Computational Complexity, <http://blog.computationalcomplexity.org/>, by Lance Fortnow and William Gasarch.

Shtetl-Optimized, <http://www.scottaaronson.com/blog/>, by Scott Aaronson.

Gödel's Lost Letter and P=NP, <http://rjlipton.wordpress.com/>, by Richard Lipton and the third author of this chapter.

Research papers on complexity theory are presented at several annual conferences, including the ACM Symposium on Theory of Computing (STOC); the IEEE Symposium on Foundations of Computer Science (FOCS), the International Colloquium on Automata, Languages, and Programming (ICALP) sponsored by EATCS, and the Symposium on Theoretical Aspects of Computer Science (STACS). The annual Conference on Computational Complexity (formerly Structure in Complexity Theory), also sponsored by the IEEE, is entirely devoted to complexity theory. Journals in which complexity research often appears include: *Chicago Journal on Theoretical Computer Science*, *Computational Complexity*, *Information and Computation*, *Journal of the ACM*, *Journal of Computer and System Sciences*, *SIAM Journal on Computing*, *Theoretical Computer Science*, *Theory of Computing Systems* (formerly *Mathematical Systems Theory*), *ACM Transactions on Computation Theory*, and *Theory of Computing*. Each issue of *ACM SIGACT News* and *Bulletin of the EATCS* contains a column on complexity theory.

8.1 Introduction

The concept of *algorithms* is perhaps almost as old as human civilization. The famous Euclid algorithm is more than 2000 years old. Angle trisection, solving Diophantine equations, and finding polynomial roots in terms of radicals of coefficients are some well-known examples of algorithmic questions. However, until the 1930s, the notion of algorithms was used informally (or rigorously but in a limited context). It was a major triumph of logicians and mathematicians of the last century to offer a rigorous definition of this fundamental concept. The revolution that resulted in this triumph was a collective achievement of many mathematicians, notably Church, Gödel, Kleene, Post, and Turing. Of particular interest is a machine model proposed by Turing (1936), which has come to be known as the *Turing machine (TM)*.

This particular achievement had numerous significant consequences. It led to the concept of a general-purpose computer or universal computation, a revolutionary idea originally anticipated by Babbage in the 1800s. It is widely acknowledged that the development of a universal TM was prophetic of the modern all-purpose digital computer and played a key role in the thinking of pioneers in the development of modern computers such as von Neumann (Davis 1980). From a mathematical point of view, however, a more interesting consequence was that it was now possible to show the *nonexistence* of algorithms, hitherto impossible due to their elusive nature. In addition, many apparently different definitions of an algorithm proposed by different researchers in different continents turned out to be equivalent

(in a precise technical sense, explained later). This equivalence led to the widely held hypothesis known as the *Church–Turing thesis* that mechanical solvability is the same as solvability on a TM.

Formal languages are closely related to algorithms. They were introduced as a way to convey mathematical proofs without errors. Although the concept of a formal language dates back at least to the time of Leibniz, a systematic study of them did not begin until the beginning of the last century. It became a vigorous field of study when Chomsky formulated simple grammatical rules to describe the syntax of a language (Chomsky 1956). *Grammars* and *formal languages* entered into computability theory when Chomsky and others found ways to use them to classify algorithms.

The main theme of this chapter is about formal models, which include TMs (and their variants) as well as grammars. In fact, the two concepts are intimately related. Formal computational models are aimed at providing a framework for computational problem solving, much as electromagnetic theory provides a framework for problems in electrical engineering. Thus, formal models guide the way to build computers and the way to program them. At the same time, new models are motivated by advances in the technology of computing machines. In this chapter, we will discuss only the most basic computational models and use these models to classify problems into some fundamental classes. In doing so, we hope to provide the reader with a conceptual basis with which to read other chapters in this handbook.

8.2 Computability and a Universal Algorithm

Turing’s notion of mechanical computation was based on identifying the basic steps of such computations. He reasoned that an operation such as multiplication is not primitive because it can be divided into more basic steps such as digit-by-digit multiplication, shifting, and adding. Addition itself can be expressed in terms of more basic steps such as add the lowest digits, compute, carry, and move to the next digit. Turing thus reasoned that the most basic features of mechanical computation are the abilities to read and write on a storage medium (which he chose to be a linear tape divided into cells or squares) and to make some simple logical decisions. He also restricted each tape cell to hold only one among a finite number of symbols (which we call the *tape alphabet*).^{*} The decision step enables the computer to control the sequence of actions. To make things simple, Turing restricted the next action to be performed on a cell neighboring the one on which the current action occurred. He also introduced an instruction that told the computer to stop. In summary, Turing proposed a model to characterize mechanical computation as being carried out as a sequence of instructions of the following form: write a symbol (such as 0 or 1) on the tape cell, move to the next cell, observe the symbol currently scanned and choose the next step accordingly, or stop.

These operations define a language we call the GOTO language.[†] Its instructions are

```
PRINT i (i is a tape symbol)
GO RIGHT
GO LEFT
GO TO STEP j IF i IS SCANNED
STOP
```

A *program* in this language is a sequence of instructions (written one per line) numbered 1 – *k*. To run a program written in this language, we should provide the *input*. We will assume that the input is a string of symbols from a finite input alphabet (which is a subset of the tape alphabet), which is stored on the tape before the computation begins. How much memory should we allow the computer to use? Although we do not want to place any bounds on it, allowing an infinite tape is not realistic. This problem is circumvented by allowing *expandable memory*. In the beginning, the tape containing the input defines its boundary. When the machine moves beyond the current boundary, a new memory cell will

^{*} This bold step of using a discrete model was perhaps the harbinger of the digital revolution that was soon to follow.

[†] Turing’s original formulation is closer to our presentation in Section 8.5. But the GOTO language presents an equivalent model.

1	PRINT 0
2	GO LEFT
3	GO TO STEP 2 IF 1 IS SCANNED
4	PRINT 1
5	GO RIGHT
6	GO TO STEP 5 IF 1 IS SCANNED
7	PRINT 1
8	GO RIGHT
9	GO TO STEP 1 IF 1 IS SCANNED
10	STOP

FIGURE 8.1 The doubling program in the GOTO language.

be attached with a special symbol B (blank) written on it. Finally, we define the result of computation as the contents of the tape when the computer reaches the STOP instruction.

We will present an example program written in the GOTO language. This program accomplishes the simple task of doubling the number of 1s (Figure 8.1). More precisely, on the input containing k 1s, the program produces $2k$ 1s. Informally, the program achieves its goal as follows. When it reads a 1, it changes the 1 to 0, moves left looking for a new cell, writes a 1 in the cell, returns to the starting cell and rewrites as 1, and repeats this step for each 1. Note the way the GOTO instructions are used for repetition. This feature is the most important aspect of programming and can be found in all of the imperative style programming languages.

The simplicity of the GOTO language is rather deceptive. There is strong reason to believe that it is powerful enough that any mechanical computation can be expressed by a suitable program in the GOTO language. Note also that the programs written in the GOTO language may not always halt, that is, on certain inputs, the program may never reach the STOP instruction. In this case, we say that the output is undefined.

We can now give a precise definition of what an algorithm is. An algorithm is any program written in the GOTO language with the additional property that it halts on all inputs. Such programs will be called *halting programs*. Throughout this chapter, we will be interested mainly in computational problems of a special kind called *decision problems* that have a yes/no answer. We will modify our language slightly when dealing with decision problems. We will augment our instruction set to include ACCEPT and REJECT (and omit STOP). When the ACCEPT (REJECT) instruction is reached, the machine will output yes or 1 (no or 0) and halt.

8.2.1 Some Computational Problems

We will temporarily shift our focus from the tool for problem solving (the computer) to the problems themselves. Throughout this chapter, a computational problem refers to an input/output relationship. For example, consider the problem of squaring an integer input. This problem assigns to each integer (such as 22) its square (in this case 484). In technical terms, this input/output relationship defines a function. Therefore, solving a computational problem is the same as computing the function defined by the problem. When we say that an algorithm (or a program) solves a problem, what we mean is that, for all inputs, the program halts and produces the correct output. We will allow inputs of arbitrary size and place no restrictions. A reader with primary interest in software applications is apt to question the validity (or even the meaningfulness) of allowing inputs of arbitrary size because it makes the set of all *possible* inputs infinite, and thus unrealistic, in real-world programming. But there are no really good alternatives. Any finite bound is artificial and is likely to become obsolete as the technology and our requirements change. Also, in practice, we do not know how to take advantage of restrictions on the size of the inputs. (See the discussion about nonuniform models in Section 8.5.) Problems (functions) that can be solved by an algorithm (or a halting GOTO program) are called *computable*.

As already remarked, we are interested mainly in decision problems. A decision problem is said to be decidable if there is a halting GOTO program that solves it correctly on all inputs. An important class of problems called *partially decidable decision problems* can be defined by relaxing our requirement a little bit; a decision problem is partially decidable if there is a GOTO program that halts and outputs 1 on all inputs for which the output should be 1 and either halts and outputs 0 or loops forever on the other inputs.

This means that the program may never give a wrong answer but is not required to halt on negative inputs (i.e., inputs with 0 as output).

We now list some problems that are fundamental either because of their inherent importance or because of their historical roles in the development of computation theory:

Problem 1 (halting problem). The input to this problem is a program P in the GOTO language and a binary string x . The expected output is 1 (or yes) if the program P halts when run on the input x , 0 (or no) otherwise.

Problem 2 (universal computation problem). A related problem takes as input a program P and an input x and produces as output what (if any) P would produce on input x . (Note that this is a decision problem if P is restricted to a yes/no program.)

Problem 3 (string compression). For a string x , we want to find the shortest program in the GOTO language that when started with the empty tape (i.e., tape containing one B symbol) halts and prints x . Here shortest means the total number of symbols in the program is as small as possible.

Problem 4 (tiling). A tile* is a square card of unit size (i.e., 1×1) divided into four quarters by two diagonals, each quarter colored with some color (selected from a finite set of colors). The tiles have fixed orientation and cannot be rotated. Given some finite set T of such tiles as input, the program is to determine if finite rectangular areas of all sizes (i.e., $k \times m$ for all positive integers k and m) can be tiled using only the given tiles such that the colors on any two touching edges are the same. It is assumed that an unlimited number of basic tiles of each type are available. Figure 8.2b shows how the base set of tiles given in Figure 8.2a can be used to tile a 5×5 square area.

Problem 5 (linear programming). Given a system of linear inequalities (called constraints), such as $3x - 4y \leq 13$ with integer coefficients, the goal is to find if the system has a solution satisfying all of the constraints.

FIGURE 8.2 An example of tiling. (a) Basic tiles and (b) 5×5 square composed of basic tiles.

* More precisely, a Wang tile, after Hao Wang, who wrote the first research paper on it.

Some remarks must be made about the preceding problems. The problems in our list include non-numerical problems and *meta-problems*, which are problems about other problems. The first two problems are motivated by a quest for reliable program design. An algorithm for problem 1 (if it exists) can be used to test if a program contains an infinite loop. Problem 2 is motivated by an attempt to design a *universal algorithm*, which can simulate any other. This problem was first attempted by Babbage, whose analytical engine had many ingredients of a modern electronic computer (although it was based on mechanical devices). Problem 3 is an important problem in information theory and arises in the following setting. Physical theories are aimed at creating simple laws to explain large volumes of experimental data. A famous example is Kepler's laws, which explained Tycho Brahe's huge and meticulous observational data. Problem 3 asks if this compression process can be automated. When we allow the inference rules to be sufficiently strong, this problem becomes *undecidable*. We will not discuss this problem further in this section but will refer the reader to some related formal systems discussed in Li and Vitányi (1993). The tiling problem is not merely an interesting puzzle. It is an art form of great interest to architects and painters. Tiling has recently found applications in crystallography. Linear programming is a problem of central importance in economics, game theory, and operations research.

In the remainder of the section, we will present some basic algorithm design techniques and sketch how these techniques can be used to solve some of the problems listed (or their special cases). The main purpose of this discussion is to present techniques for showing the decidability (or partial decidability) of these problems. The reader can learn more advanced techniques of algorithm design in some later sections of this chapter as well as in many other chapters of this volume.

8.2.1.1 Table Lookup

The basic idea is to create a table for a function f , which needs to be computed by tabulating in one column an input x and the corresponding $f(x)$ in a second column. Then the table itself can be used as an algorithm. This method cannot be used directly because the set of all inputs is infinite. Therefore, it is not very useful, although it can be made to work in conjunction with the technique described subsequently.

8.2.1.2 Bounding the Search Domain

The difficulty of establishing the decidability of a problem is usually caused by the fact that the object we are searching for may have no known upper limit. Thus, if we can place such an upper bound (based on the structure of the problem), then we can reduce the search to a finite domain. Then table lookup can be used to complete the search (although there may be better methods in practice). For example, consider the following special case of the tiling problem: Let k be a fixed integer, say 1000. Given a set of tiles, we want to determine whether all rectangular rooms of shape $k \times n$ can be tiled for all n . (Note the difference between this special case and the general problem. The general one allows k and n both to have unbounded value. But here we allow only n to be unbounded.) It can be shown (see Section 8.5 for details) that there are two bounds n_0 and n_1 (they depend on k) such that if there is at least one tile of size $k \times t$ that can be tiled for some $n_0 \leq t \leq n_1$, then every tile of size $k \times n$ can be tiled. If no $k \times t$ tile can be tiled for any t between n_0 and n_1 , then obviously the answer is no. Thus, we have reduced an infinite search domain to a finite one.

As another example, consider the linear programming problem. The set of possible solutions to this problem is infinite, and thus a table search cannot be used. But it is possible to reduce the search domain to a finite set using the geometric properties of the set of solutions of the linear programming problem. The fact that the set of solutions is convex makes the search especially easy.

8.2.1.3 Use of Subroutines

This is more of a program design tool than a tool for algorithm design. A central concept of programming is repetitive (or iterative) computation. We already observed how GOTO statements can be used

to perform a sequence of steps repetitively. The idea of a subroutine is another central concept of programming. The idea is to make use of a program P itself as a single step in another program Q . Building programs from simpler programs is a natural way to deal with the complexity of programming tasks. We will illustrate the idea with a simple example. Consider the problem of multiplying two positive integers i and j . The input to the problem will be the form $11 \dots 1011 \dots 1$ (i 1s followed by a 0, followed by j 1s) and the output will be $i \times j$ 1s (with possibly some 0s on either end). We will use the notation $1^i 0 1^j$ to denote the starting configuration of the tape. This just means that the tape contains i 1s followed by a 0 followed by j 1s.

The basic idea behind a GOTO program for this problem is simple; add j 1s on the right end of tape exactly $i - 1$ times and then erase the original sequence of i 1s on the left. A little thought reveals that the subroutine we need here is to duplicate a string of 1s so that if we start with $x 0 2^k 1^j$ a call to the subroutine will produce $x 0 2^{k+j} 1^j$. Here x is just any sequence of symbols. Note the role played by the symbol 2. As new 1s are created on the right, the old 1s change to 2s. This will ensure that there are exactly j 1s on the right end of the tape all of the time. This duplication subroutine is very similar to the doubling program, and the reader should have very little difficulty writing this program. Finally, the multiplication program can be done using the copy subroutine ($i - 1$) times.

8.2.2 A Universal Algorithm

We will now present in some detail a (partial) solution to problem 2 by arguing that there is a program U written in the GOTO language, which takes as input a program P (also written using the GOTO language) and an input x and produces as output $P(x)$, the output of P on input x . For convenience, we will assume that all programs written in the GOTO language use a fixed alphabet containing just 0, 1, and B . Because we have assumed this for all programs in the GOTO language, we should first address the issue of how an input to program U will look. We cannot directly place a program P on the tape because the alphabet used to write the program P uses letters G, O, T, O, etc. This minor problem can be easily circumvented by coding. The idea is to represent each instruction using only 0 and 1. One such coding scheme is shown in Table 8.1.

To encode an entire program, we simply write down in order (without the line numbers) the code for each instruction as given in the table. For example, here is the code for the doubling program shown in Figure 8.1:

0001001011110110001101001111111011000110100111011100

Note that the encoded string contains all of the information about the program so that the encoding is completely reversible. From now on, if P is a program in the GOTO language, then $\text{code}(P)$ will denote its binary code as just described. When there is no confusion, we will identify P and $\text{code}(P)$.

TABLE 8.1 Coding the GOTO Instructions

Instruction	Code
PRINT i	0001^{i+1}
GO LEFT	001
GO RIGHT	010
GO TO j IF i IS SCANNED	$0111^j 01^{i+1}$
STOP	100

Before proceeding further, the reader may want to test his/her understanding of the encoding/decoding process by decoding the following string: 010011101100.

The basic idea behind the construction of a universal algorithm is simple, although the details involved in actually constructing one are enormous. We will present the central ideas and leave out the actual construction. Such a construction was carried out in complete detail by Turing himself and was simplified by others.* U has as its input $\text{code}(P)$ followed by the string x . U simulates the computational steps of P on input x . It divides the input tape into three segments, one containing the program P , the second one essentially containing the contents of the tape of P as it changes with successive moves, and the third one containing the line number in program P of the instruction being currently simulated (similar to a *program counter* in an actual computer).

We now describe a *cycle* of computation by U , which is similar to a central processing unit (CPU) cycle in a real computer. A single instruction of P is implemented by U in one cycle. First, U should know which location on the tape that P is currently reading. A simple artifact can handle this as follows: U uses in its tape alphabet two special symbols $0'$ and $1'$. U stores the tape of P in the tape segment alluded to in the previous paragraph exactly as it would appear when the program P is run on the input x with one minor modification. The symbol currently being read by program P is stored as the *primed version* ($0'$ is the primed version of 0). For example, suppose after completing 12 instructions P is reading the fourth symbol (from left) on its tape containing 01001001. Then, the tape region of U after 12 cycles looks like 0100'1001. At the beginning of a new cycle, U uses a subroutine to move to the region of the tape that contains the i th instruction of program P where i is the value of the program counter. It then decodes the i th instruction. Based on what type it is, U proceeds as follows: If it is a PRINT i instruction, then U scans the tape until the unique primed symbol in the *tape region* is reached and rewrites it as instructed. If it is a GO LEFT or GO RIGHT symbol, U locates the primed symbol, unprimes it, and primes its left or right neighbor, as instructed. In both cases, U returns to the program counter and increments it. If the instruction is GO TO i IF j IS SCANNED, U reads the primed symbol, and if it is j' , U changes the program counter to i . This completes a cycle. Note that the three regions may grow and contract while U executes the cycles of computation just described. This may result in one of them running into another. U must then shift one of them to the left or right and make room as needed.

It is not too difficult to see that all of the steps described can be done using the instructions of the GOTO language. The main point to remember is that these actions will have to be coded as a single program, which has nothing whatsoever to do with program P . In fact, the program U is totally independent of P . If we replace P with some other program Q , it should simulate Q as well. The preceding argument shows that problem 2 is partially decidable. But it does not show that this problem is decidable. Why? It is because U may not halt on all inputs; specifically, consider an input consisting of a program P and a string x such that P does not halt on x . Then, U will also keep executing cycle after cycle the moves of P and will never halt. In fact, in Section 8.3, we will show that problem 2 is not decidable.

8.3 Undecidability

Recall the definition of an undecidable problem. In this section, we will establish the undecidability of problem 2, Section 8.2. The simplest way to establish the existence of undecidable problems is as follows: There are more problems than there are programs, the former set being uncountable, whereas the latter is countably infinite.† But this argument is purely existential and does not identify any specific problem as undecidable. In what follows, we will show that problem 2 introduced in Section 8.2 is one such problem.

* A particularly simple exposition can be found in Robinson (1991).

† The reader who does not know what countable and uncountable infinities are can safely ignore this statement; the rest of the section does not depend on it.

8.3.1 Diagonalization and Self-Reference

Undecidability is inextricably tied to the concept of self-reference, and so we begin by looking at this rather perplexing and sometimes paradoxical concept. The idea of self-reference seems to be many centuries old and may have originated with a barber in ancient Greece who had a sign board that read: “I shave all those who do not shave themselves.” When the statement is applied to the barber himself, we get a self-contradictory statement. Does he shave himself? If the answer is yes, then he is one of those who shaves himself, and so the barber should not shave him. The contrary answer no is equally untenable. So neither yes nor no seems to be the correct answer to the question; this is the essence of the paradox. The barber’s paradox has made entry into modern mathematics in various forms. We will present some of them in the next few paragraphs.*

The first version, called Berry’s paradox, concerns English descriptions of natural numbers. For example, the number 7 can be described by many different phrases: seven, six plus one, the fourth smallest prime, etc. We are interested in the *shortest* of such descriptions, namely, the one with the fewest letters in it. Clearly, there are (infinitely) many positive integers whose shortest descriptions exceed 100 letters. (A simple counting argument can be used to show this. The set of positive integers is infinite, but the set of positive integers with English descriptions in fewer than or equal to 100 letters is finite.) Let D denote the set of positive integers that do not have English descriptions with fewer than 100 letters. Thus, D is not empty. It is a well-known fact in set theory that any nonempty subset of positive integers has a smallest integer. Let x be the smallest integer in D . Does x have an English description with fewer than or equal to 100 letters? By the definition of the set D and x , we have the following: x is “the smallest positive integer that cannot be described in English in fewer than 100 letters.” This is clearly absurd because part of the last sentence in quotes is a description of x and it contains fewer than 100 letters in it. A similar paradox was found by the British mathematician Bertrand Russell when he considered the set of all sets that do not include themselves as elements, that is, $S = \{x \mid x \notin x\}$. The question “Is $S \in S$?” leads to a similar paradox.

As a last example, we will consider a charming self-referential paradox due to mathematician William Zwicker. Consider the collection of all two-person games (such as chess, tic-tac-toe) in which players make alternate moves until one of them loses. Call such a game *normal* if it has to end in a finite number of moves, no matter what strategies the two players use. For example, tic-tac-toe must end in at most nine moves and so it is normal. Chess is also normal because the 50-move rule ensures that the game cannot go forever. Now here is *hypergame*. In the first move of the hypergame, the first player calls out a normal game, and then the two players go on to play the game, with the second player making the first move. The question is: “Is hypergame normal?” Suppose it is normal. Imagine two players playing hypergame. The first player can call out hypergame (since it is a normal game). This makes the second player call out the name of a normal game; hypergame can be called out again and they can keep saying hypergame without end, and this contradicts the definition of a normal game. On the other hand, suppose it is not a normal game. But now in the first move, player 1 cannot call out hypergame and would call a normal game instead, and so the infinite move sequence just given is not possible and so hypergame is normal after all!

In the rest of the section, we will show how these paradoxes can be modified to give nonparadoxical but surprising conclusions about the decidability of certain problems. Recall the encoding we presented in Section 8.2 that encodes any program written in the GOTO language as a binary string. Clearly this encoding is reversible in the sense that if we start with a program and encode it, it is possible to decode it back to the program. However, not every binary string corresponds to a program because there are many strings that cannot be decoded in a meaningful way, for example, 11010011000110. For the purposes

* The most enchanting discussions of self-reference are due to the great puzzlist and mathematician R. Smullyan who brings out the breadth and depth of this concept in such delightful books as *What is the name of this book?* published by Prentice-Hall in 1978 and *Satan, Cantor, and Infinity* published by Alfred A. Knopf in 1992. We heartily recommend them to anyone who wants to be amused, entertained, and, more importantly, educated on the intricacies of mathematical logic and computability.

of this section, however, it would be convenient if we can treat *every* binary string as a program. Thus, we will simply stipulate that any undecodable string be decoded to the program containing the single statement.

1. REJECT

In the following discussion, we will identify a string x with a GOTO program to which it decodes. Now define a function f_D as follows: $f_D(x) = 1$ if x , decoded into a GOTO program, does not halt when started with x itself as the input. Note the self-reference in this definition. Although the definition of f_D seems artificial, its importance will become clear in the next section when we use it to show the undecidability of problem 2. First, we will prove that f_D is not computable. Actually, we will prove a stronger statement, namely, that f_D is not even partially decidable. [Recall that a function is partially decidable if there is a GOTO program (not necessarily halting) that computes it. An important distinction between computable and semicomputable functions is that a GOTO program for the latter need not halt on inputs with output = 0.]

Theorem 8.1

Function f_D is not partially decidable

The proof is by contradiction. Suppose a GOTO program P' computes the function f_D . We will modify P' into another program P in the GOTO language such that P computes the same function as P' but has the additional property that it will never terminate its computation by ending up in a REJECT statement.* Thus, P is a program with the property that it computes f_D and halts on an input y if and only if $f_D(y) = 1$. We will complete the proof by showing that there is at least one input in which the program produces a wrong output, that is, there is an x such that $f_D(x) \neq P(x)$.

Let x be the encoding of program P . Now consider the following question: Does P halt when given x as input? Suppose the answer is yes. Then, by the way we constructed P , here $P(x) = 1$. On the other hand, the definition of f_D implies that $f_D(x) = 0$. (This is the punch line in this proof. We urge the reader to take a few moments and read the definition of f_D a few times and make sure that he or she is convinced about this fact!) Similarly, if we start with the assumption that $P(x) = 0$, we are led to the conclusion that $f_D(x) = 1$. In both cases, $f_D(x) \neq P(x)$ and thus P is not the correct program for f_D . Therefore, P' is not the correct program for f_D either because P and P' compute the same function. This contradicts the hypothesis that such a program exists, and the proof is complete.

Note the crucial difference between the paradoxes we presented earlier and the proof of this theorem. Here, we do not have a paradox because our conclusion is of the form $f_D(x) = 0$ if and only if $P(x) = 1$ and not $f_D(x) = 1$ if and only if $f_D(x) = 0$. But in some sense, the function f_D was motivated by Russell's paradox. We can similarly create another function f_Z (based on Zwicker's paradox of hypergame). Let f be any function that maps binary strings to $\{0, 1\}$. We will describe a method to generate successive functions f_1, f_2, \dots , as follows: Suppose $f(x) = 0$ for all x . Then we cannot create any more functions, and the sequence stops with f . On the other hand, if $f(x) = 1$ for some x , then choose one such x and decode it as a GOTO program. This defines another function; call it f_1 and repeat the same process with f_1 in the place of f . We call f a *normal function* if no matter how x is selected at each step the process terminates after a finite number of steps. A simple example of a nonnormal function is as follows: Suppose $P(Q) = 1$ for some program P and input Q and at the same time $Q(P) = 1$ (note that we are using a program and its code interchangeably), then it is easy to see that the functions defined by both P and Q are not normal. Finally, define $f_Z(X) = 1$ if X is a normal program, 0 if it is not. We leave it as an instructive exercise to the reader

* The modification needed to produce P from P' is straightforward. If P' did not have any REJECT statements at all, then no modification would be needed. If it had, then we would have to replace each one by a looping statement, which keeps repeating the same instruction forever.

to show that f_Z is not semicomputable. A perceptive reader will note the connection between Berry's paradox and problem 3 in our list (string compression problem) just as f_Z is related to Zwicker's paradox. Such a reader should be able to show the undecidability of problem 3 by imitating Berry's paradox.

8.3.2 Reductions and More Undecidable Problems

Theory of computation deals not only with the behavior of individual problems but also with relations among them. A *reduction* is a simple way to relate two problems so that we can deduce the (un)decidability of one from the (un)decidability of the other. Reduction is similar to using a subroutine. Consider two problems A and B . We say that problem A can be reduced to problem B if there is an algorithm for B provided that A has one. To define the reduction (also called a *Turing reduction*) precisely, it is convenient to augment the instruction set of the GOTO programming language to include a new instruction CALL X, i, j where X is a (different) GOTO program and i and j are line numbers. In detail, the execution of such augmented programs is carried out as follows: When the computer reaches the instruction CALL X, i, j , the program will simply start executing the instructions of the program from line 1, treating whatever is on the tape currently as the input to the program X . When (if at all) X finishes the computation by reaching the ACCEPT statement, the execution of the original program continues at line number i and, if it finishes with REJECT, the original program continues from line number j .

We can now give a more precise definition of a reduction between two problems. Let A and B be two computational problems. We say that A is reducible to B if there is a halting program Y in the GOTO language for problem A in which calls can be made to a halting program X for problem B . The algorithm for problem A described in the preceding reduction does not assume the availability of program X and cannot use the details behind the design of this algorithm. The right way to think about a reduction is as follows: Algorithm Y , from time to time, needs to know the solutions to different instances of problem B . It can query an algorithm for problem B (as a black box) and use the answer to the query for making further decisions. An important point to be noted is that the program Y actually can be implemented even if program X was never built as long as someone can correctly answer some questions asked by program Y about the output of problem B for certain inputs. Programs with such calls are sometimes called *oracle programs*. Reduction is rather difficult to assimilate at the first attempt, and so we will try to explain it using a puzzle. How do you play two chess games, one each with Kasparov and Anand (two of the world's best players), and ensure that you get at least one point? (You earn one point for a win, 0 for a loss, and 1/2 for a draw.) Because you are a novice and are pitted against two Goliaths, you are allowed a concession. You can choose to play white or black on either board. The well-known answer is the following: Take white against one player, say Anand, and black against the other, namely, Kasparov. Watch the first move of Kasparov (as he plays white) and make the same move against Anand, get his reply and play it back to Kasparov, and keep playing back and forth like this. It takes only a moment's thought that you are guaranteed to win (exactly) 1 point. The point is that your game involves taking the position of one game, applying the algorithm of one player, getting the result, and applying it to the other board, and you do not even have to know the rules of chess to do this. This is exactly how algorithm Y is required to use algorithm X .

We will use reductions to show the undecidability as follows: Suppose A can be reduced to B as in the preceding definition. If there is an algorithm for problem B , it can be used to design a program for A by essentially imitating the execution of the augmented program for A (with calls to the oracle for B) as just described. But we will turn it into a negative argument as follows: If A is undecidable, then so is B . Thus, a reduction from a problem known to be undecidable to problem B will prove B 's undecidability.

First we define a new problem, problem 2', which is a special case of problem 2. Recall that in problem 2 the input is (the code of) a program P in GOTO language and a string x . The output required is $P(x)$. In problem 2', the input is (only) the code of a program P and the output required is $P(P)$, that is, instead of requiring P to run on a given input, this problem requires that it be run on its own code. This is clearly a special case of problem 2. The reader may readily see the self-reference in problem 2' and

suspect that it may be undecidable; therefore, the more general problem 2 may be undecidable as well. We will establish these claims more rigorously as follows.

We first observe a general statement about the decidability of a function f (or problem) and its *complement*. The complement function is defined to take value 1 on all inputs for which the original function value is 0 and vice versa. The statement is that a function f is decidable if and only if the complement \bar{f} is decidable. This can be easily proved as follows. Consider a program P that computes f . Change P into \bar{P} by interchanging all of the ACCEPT and REJECT statements. It is easy to see that \bar{P} actually computes \bar{f} . The converse also is easily seen to hold. It readily follows that the function defined by problem 2' is undecidable because it is, in fact, the complement of f_D .

Finally, we will show that problem 2 is uncomputable. The idea is to use a reduction from problem 2' to problem 2. (Note the direction of reduction. This always confuses a beginner.) Suppose there is an algorithm for problem 2. Let X be the GOTO language program that implements this algorithm. X takes as input $\text{code}(P)$ (for any program P) followed by x , produces the result $P(x)$, and halts. We want to design a program Y that takes as input $\text{code}(P)$ and produce the output $P(P)$ using calls to program X . It is clear what needs to be done. We just create the input in proper form $\text{code}(P)$ followed by $\text{code}(P)$ and call X . This requires first duplicating the input, but this is a simple programming task similar to the one we demonstrated in our first program in Section 8.2. Then a call to X completes the task. This shows that problem 2' reduces to problem 2, and thus the latter is undecidable as well.

By a more elaborate reduction (from f_D), it can be shown that tiling is not partially decidable. We will not do it here and refer the interested reader to Harel (1992). But we would like to point out how the undecidability result can be used to infer a result about tiling. This deduction is of interest because the result is an important one and is hard to derive directly. We need the following definition before we can state the result. A different way to pose the tiling problem is whether a given set of tiles can tile *an entire plane* in such a way that all of the adjacent tiles have the same color on the meeting quarter. (Note that this question is different from the way we originally posed it: Can a given set of tiles tile any *finite* rectangular region? Interestingly, the two problems are identical in the sense that the answer to one version is yes if and only if it is yes for the other version.) Call a tiling of the plane periodic if one can identify a $k \times k$ square such that the entire tiling is made by repeating this $k \times k$ square tile. Otherwise, call it *aperiodic*. Consider the following question: Is there a (finite) set of unit tiles that can tile the plane but only aperiodically? The answer is yes and it can be shown from the total undecidability of the tiling problem. Suppose the answer is no. Then, for any given set of tiles, the entire plane can be tiled if and only if the plane can be tiled periodically. But a periodic tiling can be found, if one exists, by trying to tile a $k \times k$ region for successively increasing values of k . This process will eventually succeed (in a finite number of steps) if the tiling exists. This will make the tiling problem partially decidable, which contradicts the total undecidability of the problem. This means that the assumption that the entire plane can be tiled if and only if some $k \times k$ region can be tiled is wrong. Thus, there exists a (finite) set of tiles that can tile the entire plane but only aperiodically.

8.4 Formal Languages and Grammars

The universe of strings is probably the most general medium for the representation of information. This section is concerned with sets of strings called *languages* and certain systems generating these languages such as *grammars*. Every programming language including Pascal, C, or Fortran can be precisely described by a grammar. Moreover, the grammar allows us to write a computer program (called the *lexical analyzer* in a compiler) to determine if a piece of code is syntactically correct in the programming language. Would not it be nice to also have such a grammar for English and a corresponding computer program that can tell us what English sentences are grammatically correct?* The focus of this brief

* Actually, English and the other natural languages have grammars; but these grammars are not precise enough to tell apart the correct and incorrect sentences with 100% accuracy. The main problem is that *there is no universal agreement* on what are grammatically correct English sentences.

exposition is the formalism and mathematical properties of various languages and grammars. Many of the concepts have applications in domains including natural language and computer language processing and string matching. We begin with some standard definitions about languages.

Definition 8.1

An *alphabet* is a finite nonempty set of *symbols*, which are assumed to be *indivisible*.

For example, the alphabet for English consists of 26 uppercase letters A, B, \dots, Z and 26 lowercase letters a, b, \dots, z . We usually use the symbol Σ to denote an alphabet.

Definition 8.2

A *string* over an alphabet Σ is a finite sequence of symbols of Σ .

The number of symbols in a string x is called its *length*, denoted $|x|$. It is convenient to introduce an empty string, denoted ϵ , which contains no symbols at all. The length of ϵ is 0.

Definition 8.3

Let $x = a_1 a_2 \dots a_n$ and $y = b_1 b_2 \dots b_m$ be two strings. The *concatenation* of x and y , denoted xy , is the string $a_1 a_2 \dots a_n b_1 b_2 \dots b_m$.

Thus, for any string x , $\epsilon x = x\epsilon = x$. For any string x and integer $n \geq 0$, we use x^n to denote the string formed by sequentially concatenating n copies of x .

Definition 8.4

The set of all strings over an alphabet Σ is denoted Σ^* and the set of all nonempty strings over Σ is denoted Σ^+ . The empty set of strings is denoted \emptyset .

Definition 8.5

For any alphabet Σ , a *language* over Σ is a set of strings over Σ . The members of a language are also called the *words* of the language.

Example 8.1

The sets $L_1 = \{01, 11, 0110\}$ and $L_2 = \{0^n 1^n \mid n \geq 0\}$ are two languages over the binary alphabet $\{0, 1\}$. The string 01 is in both languages, whereas 11 is in L_1 but not in L_2 .

Because languages are just sets, standard set operations such as union, intersection, and complementation apply to languages. It is useful to introduce two more operations for languages: *concatenation* and *Kleene closure*.

Definition 8.6

Let L_1 and L_2 be two languages over Σ . The concatenation of L_1 and L_2 , denoted $L_1 L_2$, is the language $\{xy \mid x \in L_1, y \in L_2\}$.

Definition 8.7

Let L be a language over Σ . Define $L^0 = \{\epsilon\}$ and $L^i = LL^{i-1}$ for $i \geq 1$. The Kleene closure of L , denoted L^* , is the language

$$L^* = \bigcup_{i \geq 0} L^i$$

and the *positive closure* of L , denoted L^+ , is the language

$$L^+ = \bigcup_{i \geq 1} L^i$$

In other words, the Kleene closure of language L consists of all strings that can be formed by concatenating some words from L . For example, if $L = \{0, 01\}$, then $LL = \{00, 001, 010, 0101\}$ and L^* includes all binary strings in which every 1 is preceded by a 0. L^+ is the same as L^* except it excludes ϵ in this case. Note that, for any language L , L^* always contains ϵ and L^+ contains ϵ if and only if L does. Also note that Σ^* is in fact the Kleene closure of the alphabet Σ when viewed as a language of words of length 1, and Σ^+ is just the positive closure of Σ .

8.4.1 Representation of Languages

In general, a language over an alphabet Σ is a subset of Σ^* . How can we describe a language rigorously so that we know if a given string belongs to the language or not? As shown in the preceding paragraphs, a finite language such as L_1 in Example 8.1 can be explicitly defined by enumerating its elements, and a simple infinite language such as L_2 in the same example can be described using a rule characterizing all members of L_2 . It is possible to define some more systematic methods to represent a wide class of languages. In the following, we will introduce three such methods: regular expressions, pattern systems, and grammars. The languages that can be described by this kind of system are often referred to as *formal languages*.

Definition 8.8

Let Σ be an alphabet. The *regular expressions* over Σ and the languages they represent are defined inductively as follows:

1. The symbol \emptyset is a regular expression, denoting the empty set.
2. The symbol ϵ is a regular expression, denoting the set $\{\epsilon\}$.
3. For each $a \in \Sigma$, a is a regular expression, denoting the set $\{a\}$.
4. If r and s are regular expressions denoting the languages R and S , then $(r + s)$, (rs) , and (r^*) are regular expressions that denote the sets $R \cup S$, RS , and R^* , respectively.

For example, $((0(0 + 1)^*) + ((0 + 1)^*0))$ is a regular expression over $\{0, 1\}$, and it represents the language consisting of all binary strings that begin or end with a 0. Because the set operations union and concatenation are both associative, many parentheses can be omitted from regular expressions if we assume that the Kleene closure has higher precedence than concatenation and concatenation has higher precedence than union. For example, the preceding regular expression can be abbreviated as $0(0 + 1)^* + (0 + 1)^*0$. We will also abbreviate the expression rr^* as r^+ . Let us look at a few more examples of regular expressions and the languages they represent.

Example 8.2

The expression $0(0 + 1)^*1$ represents the set of all strings that begin with a 0 and end with a 1.

Example 8.3

The expression $0 + 1 + 0(0 + 1)^*0 + 1(0 + 1)^*1$ represents the set of all nonempty binary strings that begin and end with the same bit.

Example 8.4

The expressions 0^* , 0^*10^* , and $0^*10^*10^*$ represent the languages consisting of strings that contain no 1, exactly one 1, and exactly two 1s, respectively.

Example 8.5

The expressions $(0 + 1)^*1(0 + 1)^*1(0 + 1)^*$, $(0 + 1)^*10^*1(0 + 1)^*$, $0^*10^*1(0 + 1)^*$, and $(0 + 1)^*10^*10^*$ all represent the same set of strings that contain at least two 1s.

For any regular expression r , the language represented by r is denoted as $L(r)$. Two regular expressions representing the same language are called *equivalent*. It is possible to introduce some identities to algebraically manipulate regular expressions to construct equivalent expressions, by tailoring the set identities for the operations union, concatenation, and Kleene closure to regular expressions. For more details, see Salomaa (1966). For example, it is easy to prove that the expressions $r(s + t)$ and $rs + rt$ are equivalent and $(r^*)^*$ is equivalent to r^* .

Example 8.6

Let us construct a regular expression for the set of all strings that contain no consecutive 0s. A string in this set may begin and end with a sequence of 1s. Because there are no consecutive 0s, every 0 that is not the last symbol of the string must be followed by at least a 1. This gives us the expression $1^*(01^+)^*1^*(\epsilon + 0)$. It is not hard to see that the second 1^* is redundant, and thus the expression can in fact be simplified to $1^*(01^+)^*(\epsilon + 0)$.

Regular expressions were first introduced in Kleene (1956) for studying the properties of neural nets. The preceding examples illustrate that regular expressions often give very clear and concise representations of languages. Unfortunately, not every language can be represented by regular expressions. For example, it will become clear that there is no regular expression for the language $\{0^n 1^n \mid n \geq 1\}$. The languages represented by regular expressions are called the *regular languages*. Later, we will see that

regular languages are exactly the class of languages generated by the so-called *right-linear grammars*. This connection allows one to prove some interesting mathematical properties about regular languages as well as to design an efficient algorithm to determine whether a given string belongs to the language represented by a given *regular expression*.

Another way of representing languages is to use *pattern systems* (Angluin 1980, Jiang et al. 1995).

Definition 8.9

A *pattern system* is a triple (Σ, V, p) , where Σ is the alphabet, V is the set of *variables* with $\Sigma \cap V = \emptyset$, and p is a string over $\Sigma \cup V$ called the *pattern*.

An example pattern system is $(\{0, 1\}, \{v_1, v_2\}, v_1 v_1 0v_2)$.

Definition 8.10

The language generated by a pattern system (Σ, V, p) consists of all strings over Σ that can be obtained from p by replacing each variable in p with a string over Σ .

For example, the language generated by $(\{0, 1\}, \{v_1, v_2\}, v_1 v_1 0v_2)$ contains words 0, 00, 01, 000, 001, 010, 011, 110, etc., but does not contain strings 1, 10, 11, 100, 101, etc. The pattern system $(\{0, 1\}, \{v_1\}, v_1 v_1)$ generates the set of all strings, which is the concatenation of two equal substrings, that is, the set $\{xx \mid x \in \{0, 1\}^*\}$. The languages generated by pattern systems are called the *pattern languages*.

Regular languages and pattern languages are really different. One can prove that the pattern language $\{xx \mid x \in \{0, 1\}^*\}$ is not a regular language and the set represented by the regular expression 0^*1^* is not a pattern language. Although it is easy to write an algorithm to decide if a string is in the language generated by a given pattern system, such an algorithm most likely would have to be very inefficient (Angluin 1980).

Perhaps the most useful and general system for representing languages is based on grammars, which are extensions of the pattern systems.

Definition 8.11

A grammar is a quadruple (Σ, N, S, P) , where

1. Σ is a finite nonempty set called the alphabet. The elements of Σ are called the *terminals*
2. N is a finite nonempty set disjoint from Σ . The elements of N are called the *nonterminals* or *variables*
3. $S \in N$ is a distinguished nonterminal called the *start symbol*
4. P is a finite set of *productions* (or *rules*) of the form

$$\alpha \rightarrow \beta$$

where $\alpha \in (\Sigma \cup N)^* N (\Sigma \cup N)^*$ and $\beta \in (\Sigma \cup N)^*$, that is, α is a string of terminals and nonterminals containing at least one nonterminal and α is a string of terminals and nonterminals.

Example 8.7

Let $G_1 = (\{0, 1\}, \{S, T, O, I\}, S, P)$, where P contains the following productions:

$$\begin{aligned} S &\rightarrow OT \\ S &\rightarrow OI \\ T &\rightarrow SI \\ O &\rightarrow 0 \\ I &\rightarrow 1 \end{aligned}$$

As we shall see, the grammar G_1 can be used to describe the set $\{0^n 1^n \mid n \geq 1\}$.

Example 8.8

Let $G_2 = (\{0, 1, 2\}, \{S, A\}, S, P)$, where P contains the following productions:

$$\begin{aligned} S &\rightarrow 0SA2 \\ S &\rightarrow \varepsilon \\ 2A &\rightarrow A2 \\ 0A &\rightarrow 01 \\ 1A &\rightarrow 11 \end{aligned}$$

This grammar G_2 can be used to describe the set $\{0^n 1^n 2^n \mid n \geq 0\}$.

Example 8.9

To construct a grammar G_3 to describe English sentences, the alphabet Σ contains all words in English.

N would contain nonterminals, which correspond to the structural components in an English sentence, for example, $\langle \text{sentence} \rangle$, $\langle \text{subject} \rangle$, $\langle \text{predicate} \rangle$, $\langle \text{noun} \rangle$, $\langle \text{verb} \rangle$, and $\langle \text{article} \rangle$. The start symbol would be $\langle \text{sentence} \rangle$. Some typical productions are

$$\begin{aligned} \langle \text{sentence} \rangle &\rightarrow \langle \text{subject} \rangle \langle \text{predicate} \rangle \\ \langle \text{subject} \rangle &\rightarrow \langle \text{noun} \rangle \\ \langle \text{predicate} \rangle &\rightarrow \langle \text{verb} \rangle \langle \text{article} \rangle \langle \text{noun} \rangle \\ \langle \text{noun} \rangle &\rightarrow \text{mary} \\ \langle \text{noun} \rangle &\rightarrow \text{algorithm} \\ \langle \text{verb} \rangle &\rightarrow \text{wrote} \\ \langle \text{article} \rangle &\rightarrow \text{an} \end{aligned}$$

The rule $\langle \text{sentence} \rangle \rightarrow \langle \text{subject} \rangle \langle \text{predicate} \rangle$ follows from the fact that a sentence consists of a subject phrase and a predicate phrase. The rules $\langle \text{noun} \rangle \rightarrow \text{mary}$ and $\langle \text{noun} \rangle \rightarrow \text{algorithm}$ mean that both mary and algorithms are possible nouns.

To explain how a grammar represents a language, we need the following concepts.

Definition 8.12

Let (Σ, N, S, P) be a grammar. A *sentential form* of G is any string of terminals and nonterminals, that is, a string over $\Sigma \cup N$.

Definition 8.13

Let (Σ, N, S, P) be a grammar and γ_1 and γ_2 two sentential forms of G . We say that γ_1 *directly derives* γ_2 , denoted $\gamma_1 \Rightarrow \gamma_2$, if $\gamma_1 = \sigma\alpha\tau$, $\gamma_2 = \sigma\beta\tau$, and $\alpha \rightarrow \beta$ is a production in P .

For example, the sentential form 00S11 directly derives the sentential form 00OT11 in grammar G_1 , and A2A2 directly derives AA22 in grammar G_2 .

Definition 8.14

Let γ_1 and γ_2 be two sentential forms of a grammar G . We say that γ_1 *derives* γ_2 , denoted $\gamma_1 \xRightarrow{*} \gamma_2$, if there exists a sequence of (zero or more) sentential forms $\sigma_1, \dots, \sigma_n$ such that

$$\gamma_1 \Rightarrow \sigma_1 \Rightarrow \dots \Rightarrow \sigma_n \Rightarrow \gamma_2$$

The sequence $\gamma_1 \Rightarrow \sigma_1 \Rightarrow \dots \Rightarrow \sigma_n \Rightarrow \gamma_2$ is called a derivation from γ_1 to γ_2 . For example, in grammar G_1 , $S \xRightarrow{*} 0011$ because

$$S \Rightarrow \underline{0T} \Rightarrow \underline{0I} \Rightarrow \underline{0SI} \Rightarrow \underline{0S1} \Rightarrow \underline{0OI1} \Rightarrow \underline{0OI1} \Rightarrow 0011$$

and in grammar G_2 , $S \xRightarrow{*} 001122$ because

$$S \Rightarrow \underline{0SA2} \Rightarrow \underline{00SA2A2} \Rightarrow \underline{00A2A2} \Rightarrow \underline{0012A2} \Rightarrow \underline{0011A22} \Rightarrow 001122$$

Here the left-hand side of the relevant production in each derivation step is underlined for clarity.

Definition 8.15

Let (Σ, N, S, P) be a grammar. The language generated by G , denoted $L(G)$, is defined as

$$L(G) = \{x \mid x \in \Sigma^*, S \xRightarrow{*} x\}$$

The words in $L(G)$ are also called the *sentences* of $L(G)$.

Clearly, $L(G_1)$ contains all strings of the form $0^n 1^n$, $n \geq 1$, and $L(G_2)$ contains all strings of the form $0^n 1^n 2^n$, $n \geq 0$. Although only a partial definition of G_3 is given, we know that $L(G_3)$ contains sentences such as “mary wrote an algorithm” and “algorithm wrote an algorithm” but does not contain sentences such as “an wrote algorithm.”

The introduction of formal grammars dates back to the 1940s (Post 1943), although the study of rigorous description of languages by grammars did not begin until the 1950s (Chomsky 1956). In the Section 8.4.2, we consider various restrictions on the form of productions in a grammar and see how these restrictions can affect the power of a grammar in representing languages. In particular, we will know that regular languages and pattern languages can all be generated by grammars under different restrictions.

8.4.2 Hierarchy of Grammars

Grammars can be divided into four classes by gradually increasing the restrictions on the form of the productions. Such a classification is due to Chomsky (1956, 1963) and is called the *Chomsky hierarchy*.

Definition 8.16

Let $G = (\Sigma, N, S, P)$ be a grammar.

1. G is also called a *type-0 grammar* or an *unrestricted grammar*.
2. G is *type-1* or *context sensitive* if each production $\alpha \rightarrow \beta$ in P either has the form $S \rightarrow \epsilon$ or satisfies $|\alpha| \leq |\beta|$.
3. G is *type-2* or *context-free* if each production $\alpha \rightarrow \beta$ in P satisfies $|\alpha| = 1$, that is, α is a nonterminal.
4. G is *type-3* or *right linear* or *regular* if each production has one of the following three forms:

$$A \rightarrow aB, \quad A \rightarrow a, \quad A \rightarrow \epsilon$$

where A and B are nonterminals and a is a terminal.

The language generated by a type- i grammar is called a type- i language, $i = 0, 1, 2, 3$. A type-1 language is also called a *context-sensitive language* and a type-2 language is also called a *context-free language*. It turns out that every type-3 language is in fact a regular language, that is, it is represented by some regular expression and vice versa. See the Section 8.4.3 for the proof of the equivalence of type-3 (right-linear) grammars and regular expressions.

The grammars G_1 and G_3 given in the last subsection are context-free and the grammar G_2 is context sensitive. Now we give some examples of unrestricted and right-linear grammars.

Example 8.10

Let $G_4 = (\{0, 1\}, \{S, A, O, I, T\}, S, P)$, where P contains

$$\begin{aligned} S &\rightarrow AT \\ A &\rightarrow 0AO \quad A \rightarrow 1AI \\ OO &\rightarrow 0O \quad OI \rightarrow 1O \\ IO &\rightarrow 0I \quad II \rightarrow 1I \\ OT &\rightarrow 0T \quad IT \rightarrow 1T \\ A &\rightarrow \epsilon \quad T \rightarrow \epsilon \end{aligned}$$

Then G_4 generates the set $\{xx \mid x \in \{0, 1\}^*\}$. For example, we can derive the word 0101 from S as follows:

$$S \Rightarrow \underline{A}T \Rightarrow 0\underline{A}OT \Rightarrow 01\underline{A}IOT \Rightarrow 01\underline{I}OT \Rightarrow 01\underline{I}0T \Rightarrow 010\underline{I}T \Rightarrow 0101\underline{T} \Rightarrow 0101$$

Example 8.11

We give a right-linear grammar G_5 to generate the language represented by the regular expression in Example 8.3, that is, the set of all nonempty binary strings beginning and ending with the same bit. Let $G_5 = (\{0, 1\}, \{S, O, I\}, S, P)$, where P contains

$$\begin{aligned} S &\rightarrow 0O \quad S \rightarrow 1I \\ S &\rightarrow 0 \quad S \rightarrow 1 \\ O &\rightarrow 0O \quad O \rightarrow 1O \\ I &\rightarrow 0I \quad I \rightarrow 1I \\ O &\rightarrow 0 \quad I \rightarrow 1 \end{aligned}$$

The following theorem is due to Chomsky (1956, 1963).

Theorem 8.2

For each $i = 0, 1, 2$, the class of type- i languages properly contains the class of type- $(i + 1)$ languages.

For example, one can prove by using a technique called *pumping* that the set $\{0^n 1^n \mid n \geq 1\}$ is context-free but not regular, and the sets $\{0^n 1^n 2^n \mid n \geq 0\}$ and $\{xx \mid x \in \{0, 1\}^*\}$ are context sensitive but not context-free (Hopcroft and Ullman 1979). It is, however, a bit involved to construct a language that is of type-0 but not context sensitive. See, for example, Hopcroft and Ullman (1979) for such a language.

The four classes of languages in the Chomsky hierarchy also have been completely characterized in terms of TMs and their restricted versions. We have already defined a TM in Section 8.2. Many restricted versions of it will be defined in the next section. It is known that type-0 languages are exactly those recognized by TMs, context-sensitive languages are those recognized by TMs running in linear space, context-free languages are those recognized by TMs whose work tapes operate as pushdown stacks [called *pushdown automata* (PDA)], and regular languages are those recognized by TMs without any work tapes (called *finite-state machine* or *finite automata*) (Hopcroft and Ullman 1979).

Remark 8.1

Recall our definition of a TM and the function it computes from Section 8.2. In the preceding paragraph, we refer to *a language recognized* by a TM. These are two seemingly different ideas, but they are essentially the same. The reason is that the function f , which maps the set of strings over a finite alphabet to $\{0, 1\}$, corresponds in a natural way to the language L_f over Σ defined as: $L_f = \{x \mid f(x) = 1\}$. Instead of saying that a TM computes the function f , we say equivalently that it recognizes L_f .

Because $\{xx \mid x \in \{0, 1\}^*\}$ is a pattern language, the preceding discussion implies that the class of pattern languages is not contained in the class of context-free languages. The next theorem shows that the class of pattern languages is contained in the class of context-sensitive languages.

Theorem 8.3

Every pattern language is context sensitive.

The theorem follows from the fact that every pattern language is recognized by a TM in linear space (Angluin 1980) and linear space-bounded TMs recognize exactly context-sensitive languages. To show the basic idea involved, let us construct a context-sensitive grammar for the pattern language $\{xx \mid x \in \{0, 1\}^*\}$. The grammar G_4 given in Example 8.10 for this language is almost context sensitive. We just have to get rid of the two ε -productions: $A \rightarrow \varepsilon$ and $T \rightarrow \varepsilon$. A careful modification of G_4 results in the following grammar: $G_6 = (\{0, 1\}, \{S, A_0, A_1, O, I, T_0, T_1\}, S, P)$, where P contains

$$\begin{array}{l}
 S \rightarrow \varepsilon \\
 S \rightarrow A_0 T_0 \quad S \rightarrow A_1 T_1 \\
 A_0 \rightarrow 0 A_0 O \quad A_0 \rightarrow 1 A_0 I \\
 A_1 \rightarrow 0 A_1 O \quad A_1 \rightarrow 1 A_1 I \\
 A_0 \rightarrow 0 \quad A_1 \rightarrow 1 \\
 O 0 \rightarrow 0 O \quad O 1 \rightarrow 1 O \\
 I 0 \rightarrow 0 I \quad I 1 \rightarrow 1 I \\
 O T_0 \rightarrow 0 T_0 \quad I T_0 \rightarrow 1 T_0 \\
 O T_1 \rightarrow 0 T_1 \quad I T_1 \rightarrow 1 T_1 \\
 T_0 \rightarrow 0 \quad T_1 \rightarrow 1,
 \end{array}$$

which is context sensitive and generates $\{xx \mid x \in \{0, 1\}^*\}$. For example, we can derive 011011 as

$$\begin{aligned} &\Rightarrow \underline{A}_1 T_1 \Rightarrow 0 \underline{A}_1 O T_1 \Rightarrow 01 \underline{A}_1 I O T_1 \\ &\Rightarrow 011 \underline{I} O T_1 \Rightarrow 011 \underline{I} O T_1 \Rightarrow 0110 \underline{I} T_1 \Rightarrow 01101 \underline{T}_1 \Rightarrow 011011 \end{aligned}$$

For a class of languages, we are often interested in the so-called *closure properties* of the class.

Definition 8.17

A class of languages (e.g., regular languages) is said to be *closed* under a particular operation (e.g., union, intersection, complementation, concatenation, Kleene closure) if each application of the operation on language(s) of the class results in a language of the class.

These properties are often useful in constructing new languages from existing languages as well as proving many theoretical properties of languages and grammars. The closure properties of the four types of languages in the Chomsky hierarchy are now summarized (Gurari 1989, Harrison 1978, Hopcroft and Ullman 1979).

Theorem 8.4

1. The class of type-0 languages is closed under union, intersection, concatenation, and Kleene closure but not under complementation.
2. The class of context-free languages is closed under union, concatenation, and Kleene closure but not under intersection or complementation.
3. The classes of context-sensitive and regular languages are closed under all five of the operations.

For example, let $L_1 = \{0^m 1^n 2^p \mid m = n \text{ or } n = p\}$, $L_2 = \{0^m 1^n 2^p \mid m = n\}$, and $L_3 = \{0^m 1^n 2^p \mid n = p\}$. It is easy to see that all three are context-free languages. (In fact, $L_1 = L_2 \cup L_3$.) However, intersecting L_2 with L_3 gives the set $\{0^m 1^n 2^p \mid m = n = p\}$, which is not context-free.

We will look at context-free grammars more closely in the Section 8.4.3 and introduce the concept of *parsing* and ambiguity.

8.4.3 Context-Free Grammars and Parsing

From a practical point of view, for each grammar $G = (\Sigma, N, S, P)$ representing some language, the following two problems are important:

1. (Membership) Given a string over Σ , does it belong to $L(G)$?
2. (Parsing) Given a string in $L(G)$, how can it be derived from S ?

The importance of the membership problem is quite obvious: given an English sentence or computer program, we wish to know if it is grammatically correct or has the right format. Parsing is important because a derivation usually allows us to interpret the meaning of the string. For example, in the case of a Pascal program, a derivation of the program in Pascal grammar tells the compiler how the program should be executed. The following theorem illustrates the decidability of the membership problem for

the four classes of grammars in the Chomsky hierarchy. The proofs can be found in Chomsky (1963), Harrison (1978), and Hopcroft and Ullman (1979).

Theorem 8.5

The membership problem for type-0 grammars is undecidable in general and is decidable for any context-sensitive grammar (and thus for any context-free or right-linear grammars).

Because context-free grammars play a very important role in describing computer programming languages, we discuss the membership and parsing problems for context-free grammars in more detail. First, let us look at another example of context-free grammar. For convenience, let us abbreviate a set of productions with the same left-hand side nonterminal

$$A \rightarrow \alpha_1, \dots, A \rightarrow \alpha_n$$

as

$$A \rightarrow \alpha_1 \mid \dots \mid \alpha_n$$

Example 8.12

We construct a context-free grammar for the set of all valid Pascal real values. In general, a real constant in Pascal has one of the following forms:

$$m.n, \quad meq, \quad m.neq,$$

where m and q are signed or unsigned integers and n is an unsigned integer. Let $\Sigma = \{0, 1, 2, 3, 4, 5, 6, 7, 8, 9, e, +, -, .\}$, $N = \{S, M, N, D\}$, and the set P of the productions contain

$$\begin{aligned} S &\rightarrow M.N \mid MeM \mid M.NeM \\ M &\rightarrow N \mid +N \mid -N \\ N &\rightarrow DN \mid D \\ D &\rightarrow 0 \mid 1 \mid 2 \mid 3 \mid 4 \mid 5 \mid 7 \mid 8 \mid 9 \end{aligned}$$

Then the grammar generates all valid Pascal real values (including some absurd ones like 001.200e000). The value $12.3e-4$ can be derived as

$$\begin{aligned} S &\Rightarrow \underline{M}.NeM \Rightarrow \underline{N}.NeM \Rightarrow \underline{DN}.NeM \Rightarrow 1\underline{N}.NeM \Rightarrow 1\underline{D}.NeM \\ &\Rightarrow 12.\underline{N}eM \Rightarrow 12.\underline{D}eM \Rightarrow 12.3e\underline{M} \Rightarrow 12.3e\underline{-N} \Rightarrow 12.3e\underline{-D} \Rightarrow 12.3e-4 \end{aligned}$$

Perhaps the most natural representation of derivations for a context-free grammar is a *derivation tree* or a *parse tree*. Each *internal node* of such a tree corresponds to a nonterminal and each *leaf* corresponds to a terminal. If A is an internal node with children B_1, \dots, B_n ordered from left to right, then $A \rightarrow B_1 \dots B_n$ must be a production. The concatenation of all leaves from left to right yields the string being derived. For example, the derivation tree corresponding to the preceding derivation of $12.3e-4$ is given in Figure 8.3. Such a tree also makes possible the extraction of the parts 12, 3, and -4 , which are useful in the storage of the real value in a computer memory.

FIGURE 8.3 The derivation tree for 12.3e – 4.

Definition 8.18

A context-free grammar G is *ambiguous* if there is a string $x \in L(G)$, which has two distinct derivation trees. Otherwise G is *unambiguous*.

Unambiguity is a very desirable property to have as it allows a unique interpretation of each sentence in the language. It is not hard to see that the preceding grammar for Pascal real values and the grammar G_1 defined in Example 8.7 are all unambiguous. The following example shows an ambiguous grammar.

Example 8.13

Consider a grammar G_7 for all valid arithmetic expressions that are composed of unsigned positive integers and symbols $+$, $*$, $(,)$. For convenience, let us use the symbol n to denote any unsigned positive integer.

This grammar has the productions

$$S \rightarrow T + S \mid S + T \mid T$$

$$T \rightarrow F * T \mid T * F \mid F$$

$$F \rightarrow n \mid (S)$$

Two possible different derivation trees for the expression $1 + 2 * 3 + 4$ are shown in Figure 8.4. Thus, G_7 is ambiguous. The left tree means that the first addition should be done before the second addition and the right tree says the opposite.

Although in the preceding example different derivations/interpretations of any expression always result in the same value because the operations addition and multiplication are associative, there are situations where the difference in the derivation can affect the final outcome. Actually, the grammar G_7 can be made unambiguous by removing some (redundant) productions, for example, $S \rightarrow T + S$ and $T \rightarrow F * T$.

This corresponds to the convention that a sequence of consecutive additions (or multiplications) is always evaluated from left to right and will not change the language generated by G_7 . It is worth noting that there are context-free languages that cannot be generated by any

FIGURE 8.4 Different derivation trees for the expression $1 + 2 * 3 + 4$.

unambiguous context-free grammar (Hopcroft and Ullman 1979). Such languages are said to be *inherently ambiguous*. An example of inherently ambiguous languages is the set

$$\{0^m 1^n 2^n 3^n \mid m, n > 0\} \cup \{0^m 1^n 2^m 3^n \mid m, n > 0\}$$

We end this section by presenting an efficient algorithm for the membership problem for context-free grammars. The algorithm is due to Cocke, Younger, and Kasami (Hopcroft and Ullman 1979) and is often called the CYK algorithm. Let $G = (\Sigma, N, S, P)$ be a context-free grammar. For simplicity, let us assume that G does not generate the empty string ϵ and that G is in the so-called *Chomsky normal form* (Chomsky 1963), that is, every production of G is either in the form $A \rightarrow BC$ where B and C are nonterminals, or in the form $A \rightarrow a$ where a is a terminal. An example of such a grammar is G_1 given in Example 8.7. This is not a restrictive assumption because there is a simple algorithm that can convert every context-free grammar that does not generate ϵ into one in the Chomsky normal form.

Suppose that $x = a_1 \dots a_n$ is a string of n terminals. The basic idea of the CYK algorithm, which decides if $x \in L(G)$, is *dynamic programming*. For each pair i, j , where $1 \leq i \leq j \leq n$, define a set $X_{i,j} \subseteq N$ as

$$X_{i,j} = \{A \mid A \xrightarrow{*} a_i \dots a_j\}$$

Thus, $x \in L(G)$ if and only if $S \in X_{1,n}$. The sets $X_{i,j}$ can be computed inductively in the ascending order of $j - i$. It is easy to figure out $X_{i,i}$ for each i because $X_{i,i} = \{A \mid A \rightarrow a_i \in P\}$. Suppose that we have computed all $X_{i,j}$ where $j - i < d$ for some $d > 0$. To compute a set $X_{i,j}$ where $j - i = d$, we just have to find all of the nonterminals A such that there exist some nonterminals B and C satisfying $A \rightarrow BC \in P$ and for some k , $i \leq k < j$, $B \in X_{i,k}$ and $C \in X_{k+1,j}$. A rigorous description of the algorithm in a Pascal-style pseudocode is given as follows.

Algorithm CYK($x = a_1 \dots a_n$):

1. for $i \leftarrow 1$ to n do
2. $X_{i,i} \leftarrow \{A \mid A \rightarrow a_i \in P\}$
3. for $d \leftarrow 1$ to $n - 1$ do
4. for $i \leftarrow 1$ to $n - d$ do
5. $X_{i,i+d} \leftarrow \emptyset$
6. for $t \leftarrow 0$ to $d - 1$ do
7. $X_{i,i+d} \leftarrow X_{i,i+d} \cup \{A \mid A \rightarrow BC \in P \text{ for some } B \in X_{i,i+t} \text{ and } C \in X_{t+1,i+d}\}$

Table 8.2 shows the sets $X_{i,j}$ for the grammar G_1 and the string $x = 000111$. It just so happens that every $X_{i,j}$ is either empty or a singleton. The computation proceeds from the main diagonal toward the upper-right corner.

8.5 Computational Models

In this section, we will present many restricted versions of TMs and address the question of what kinds of problems they can solve. Such a classification is a central goal of computation theory. We have already classified problems broadly into (totally) decidable, partially decidable, and totally undecidable. Because the decidable problems are the ones of most practical interest, we can consider further classification of decidable problems by placing two types of restrictions on a TM. The first one is to restrict its structure. This way we obtain many machines of which a finite automaton and a pushdown automaton are the most important. The other way to restrict a TM is to bound the amount of resources it uses, such as the number of time steps or the number of tape cells it can use. The resulting machines form the basis for *complexity theory*.

8.5.1 Finite Automata

The finite automaton (in its deterministic version) was first introduced by McCulloch and Pitts (1943) as a logical model for the behavior of neural systems. Rabin and Scott (1959) introduced the nondeterministic version of the finite automaton and showed the equivalence of the nondeterministic and deterministic versions. Chomsky and Miller (1958) proved that the set of languages that can be recognized by a finite automaton is precisely the regular languages introduced in Section 8.4. Kleene (1956) showed that the languages accepted by finite automata are characterized by regular expressions as defined in Section 8.4.

In addition to their original role in the study of neural nets, finite automata have enjoyed great success in many fields such as sequential circuit analysis in circuit design (Kohavi 1978), asynchronous circuits (Brzozowski and Seger 1994), lexical analysis in text processing (Lesk 1975), and compiler design. They also led to the design of more efficient algorithms. One excellent example is the development of linear-time string-matching algorithms, as described in Knuth et al. (1977). Other applications of finite automata can be found in computational biology (Searls 1993), natural language processing, and distributed computing.

A finite automaton, as in Figure 8.5, consists of an input tape that contains a (finite) sequence of input symbols such as *aabab ...*, as shown in the figure, and a finite-state control. The tape is read by the one-way *read-only* input head from left to right, one symbol at a time. Each time the input head reads an input symbol, the finite control changes its state according to the symbol and the current state of the machine. When the input head reaches the right end of the input tape, if the machine is in a final state, we say that the input is accepted; if the machine is not in a final state, we say that the input is rejected. The following is the formal definition.

FIGURE 8.5 A finite automaton.

Definition 8.19

A *nondeterministic finite automaton* (NFA) is a quintuple $(Q, \Sigma, \delta, q_0, F)$, where

- Q is a finite set of *states*
- Σ is a finite set of *input symbols*
- δ , the *state transition function*, is a mapping from $Q \times \Sigma$ to subsets of Q
- $q_0 \in Q$ is the *initial state* of the NFA
- $F \subseteq Q$ is the set of *final states*

If δ maps $Q \times \Sigma$ to singleton subsets of Q , then we call such a machine a *deterministic finite automaton* (DFA).

When an automaton, M , is nondeterministic, then from the current state and input symbol, it may go to one of several different states. One may imagine that the device goes to all such states in parallel. The DFA is just a special case of the NFA; it always follows a single deterministic path. The device M *accepts* an input string x if, starting with q_0 and the read head at the first symbol of x , one of these parallel paths reaches an accepting state when the read head reaches the end of x . Otherwise, we say M *rejects* x . A language, L , is accepted by M if M accepts all of the strings in L and nothing else, and we write $L = L(M)$. We will also allow the machine to make ϵ -*transitions*, that is, changing state without advancing the read head. This allows transition functions such as $\delta(s, \epsilon) = \{s^1\}$. It is easy to show that such a generalization does not add more power.

Remark 8.2

The concept of a nondeterministic automaton is rather confusing for a beginner. But there is a simple way to relate it to a concept that must be familiar to all of the readers. It is that of a solitaire game. Imagine a game like *Klondike*. The game starts with a certain arrangement of cards (the input) and there is a well-defined final position that results in success; there are also dead ends where a further move is not possible; you lose if you reach any of them. At each step, the precise rules of the game dictate how a new arrangement of cards can be reached from the current one. But the most important point is that there are many possible moves at each step. (Otherwise, the game would be no fun!) Now consider the following question: What starting positions are *winnable*? These are the starting positions for which *there is a winning move sequence*; of course, in a typical play, a player may not achieve it. But that is beside the point in the definition of what starting positions are winnable. The connection between such games and a nondeterministic automaton should be clear. The multiple choices at each step are what make it *nondeterministic*. Our definition of winnable positions is similar to the concept of acceptance of a string by a nondeterministic automaton. Thus, an NFA may be viewed as a formal model to define solitaire games.

FIGURE 8.6 An NFA accepting $0(0 + 1)^*1$.

FIGURE 8.7 A DFA accepting $0(0 + 1)^*1$.

Example 8.14

We design a DFA to accept the language represented by the regular expression $0(0 + 1)^*1$ as in Example 8.2, that is, the set of all strings in $\{0, 1\}$ that begin with a 0 and end with a 1. It is usually convenient to draw our solution as in Figure 8.6. As a convention, each circle represents a state; the state a, pointed at by the initial arrow, is the initial state. The darker circle represents the final states (state c). The transition function δ is represented by the labeled edges. For example, $\delta(a, 0) = \{b\}$. When a transition is missing, for example, on input 1 from a and on inputs 0 and 1 from c, it is assumed that all of these lead to an implicit nonaccepting trap state, which has transitions to itself on all inputs.

The machine in Figure 8.6 is nondeterministic because from b on input 1 the machine has two choices: stay at b or go to c.

Figure 8.7 gives an equivalent DFA, accepting the same language.

Example 8.15

The DFA in Figure 8.8 accepts the set of all strings in $\{0, 1\}^*$ with an even number of 1s. The corresponding regular expression is $(0^*10^*)^*0^*$.

Example 8.16

As a final example, consider the special case of the tiling problem that we discussed in Section 8.2. This version of the problem is as follows: Let k be a fixed positive integer. Given a set of unit tiles, we want to know if they can tile any $k \times n$ area for all n . We show how to deal with the case $k = 1$ and leave it as an exercise to generalize our method for larger values of k . Number the quarters

FIGURE 8.8 A DFA accepting $(0^*10^*)^*0^*$.

FIGURE 8.9 Numbering the quarters of a tile.

of each tile as in Figure 8.9. The given set of tiles will tile the area if we can find a sequence of the given tiles T_1, T_2, \dots, T_m such that (1) the third quarter of T_1 has the same color as the first quarter of T_2 and the third quarter of T_2 has the same color as the first quarter of T_3 , etc., and (2) the third quarter of T_m has the same color as T_1 . These conditions can be easily understood as follows. The first condition states that the tiles T_1, T_2 , etc., can be placed adjacent to each other along a row in that order. The second condition implies that the whole sequence $T_1 T_2 \dots T_m$ can be replicated any number of times. And a little thought reveals that this is all we need to answer yes on the input. But if we cannot find such a sequence, then the answer must be no. Also note that in the sequence no tile needs to be repeated and so the value of m is bounded by the number of tiles in the input. Thus, we have reduced the problem to searching a finite number of possibilities and we are done.

How is the preceding discussion related to finite automata? To see the connection, define an alphabet consisting of the unit tiles and define a language $L = \{T_1 T_2 \dots T_m \mid T_1 T_2 \dots T_m \text{ is a valid tiling, } m \geq 0\}$. We will now construct an NFA for the language L . It consists of states corresponding to *distinct* colors contained in the tiles plus two states, one of them the start state and another state called the dead state. The NFA makes transitions as follows: From the start state, there is an ϵ -transition to each color state, and all states except the dead state are accepting states. When in the state corresponding to color i , suppose it receives input tile T . If the first quarter of this tile has color i , then it moves to the color of the third quarter of T ; otherwise, it enters the dead state. The basic idea is to remember the only relevant piece of information after processing some input. In this case, it is the third quarter color of the last tile seen. Having constructed this NFA, the question we are asking is if the language accepted by this NFA is infinite. There is a simple algorithm for this problem (Hopcroft and Ullman 1979).

The next three theorems show a satisfying result that all the following language classes are identical:

- The class of languages accepted by DFAs
- The class of languages accepted by NFAs
- The class of languages generated by regular expressions, as in Definition 8.8
- The class of languages generated by the right-linear, or type-3, grammars, as in Definition 8.16

Recall that this class of languages is called the *regular languages* (see Section 8.4).

Theorem 8.6

For each NFA, there is an equivalent DFA.

Proof An NFA might look more powerful because it can carry out its computation in parallel with its nondeterministic branches.

FIGURE 8.10 An NFA accepting L_3 .

But because we are working with a *finite number* of states, we can simulate an NFA $M = (Q, \Sigma, \delta, q_0, F)$ by a DFA $M' = (Q', \Sigma, \delta', q'_0, F')$, where

- $Q' = \{[S] : S \subseteq Q\}$
- $q'_0 = [q_0]$
- $\delta'([S], a) = [S'] = [\cup_{q_i \in S} \delta(q_i, a)]$
- F' is the set of all subsets of Q containing a state in F

It can now be verified that $L(M) = L(M')$.

Example 8.17

Example 8.1 contains an NFA and an equivalent DFA accepting the same language. In fact, the proof provides an effective procedure for converting an NFA to a DFA. Although each NFA can be converted to an equivalent DFA, the resulting DFA might be exponentially large in terms of the number of states, as we can see from the previous procedure. This turns out to be the best thing one can do in the worst case. Consider the following language: $L_k = \{x : x \in \{0, 1\}^* \text{ and the } k\text{th letter from the right of } x \text{ is a } 1\}$. An NFA of $k + 1$ states (for $k = 3$) accepting L_k is given in Figure 8.10. A counting argument shows that any DFA accepting L_k must have at least 2^k states.

Theorem 8.7

L is generated by a right-linear grammar if it is accepted by an NFA.

Proof Let L be accepted by a right-linear grammar $G = (\Sigma, N, S, P)$. We design an NFA $M = (Q, \Sigma, \delta, q_0, F)$ where $Q = N \cup \{f\}$, $q_0 = S$, $F = \{f\}$. To define the δ function, we have $C \in \delta(A, b)$ if $A \rightarrow bC$. For rules $A \rightarrow b$, $\delta(A, b) = \{f\}$. Obviously, $L(M) = L(G)$.

Conversely, if L is accepted by an NFA $M = (Q, \Sigma, \delta, q_0, F)$, we define an equivalent right-linear grammar $G = (\Sigma, N, S, P)$, where $N = Q$, $S = q_0$, $q_i \rightarrow aq_j \in N$ if $q_j \in \delta(q_i, a)$, and $q_j \rightarrow \varepsilon$ if $q_j \in F$. Again it is easily seen that $L(M) = L(G)$.

Theorem 8.8

L is generated by a regular expression if it is accepted by an NFA.

Proof (Idea) Part 1. We inductively convert a regular expression to an NFA that accepts the language generated by the regular expression as follows:

- Regular expression ε converts to $(\{q\}, \Sigma, \emptyset, q, \{q\})$.
- Regular expression \emptyset converts to $(\{q\}, \Sigma, \emptyset, q, \emptyset)$.
- Regular expression a , for each $a \in \Sigma$ converts to $(\{q, f\}, \Sigma, \delta(q, a) = \{f\}, q, \{f\})$.
- If α and β are regular expressions, converting to NFAs M_α and M_β , respectively, then the regular expression $\alpha \cup \beta$ converts to an NFA M , which connects M_α and M_β in parallel: M has an

initial state q_0 and all of the states and transitions of M_α and M_β ; by ϵ -transitions, M goes from q_0 to the initial states of M_α and M_β .

- If α and β are regular expressions, converting to NFAs M_α and M_β , respectively, then the regular expression $\alpha \cup \beta$ converts to NFA M , which connects M_α and M_β sequentially: M has all of the states and transitions of M_α and M_β , with M_α 's initial state as M 's initial state, ϵ -transition from the final states of M_α to the initial state of M_β , and M_β 's final states as M 's final states.
- If α is a regular expression, converting to NFA M_α , then connecting all of the final states of M_α to its initial state with ϵ -transitions gives α^* . Union of this with the NFA for ϵ gives the NFA for α^* .

Part 2. We now show how to convert an NFA to an equivalent regular expression. The idea used here is based on Brzozowski and McCluskey (1963); see also Brzozowski and Seger (1994) and Wood (1987).

Given an NFA M , expand it to M' by adding two extra states i , the initial state of M' , and t , the only final state of M' , with ϵ -transitions from i to the initial state of M and from all final states of M to t . Clearly, $L(M) = L(M')$. In M' , remove states other than i and t one by one as follows. To remove state p , for each triple of states q, p, q' as shown in Figure 8.11a, add the transition as shown in Figure 8.11b. If p does not have a transition leading back to itself, then $\beta = \epsilon$. After we have considered all such triples, delete state p and transitions related to p . Finally, we obtain Figure 8.12 and $L(\alpha) = L(M)$.

Apparently, DFAs cannot serve as our model for a modern computer. Many extremely simple languages cannot be accepted by DFAs. For example, $L = \{xx : x \in \{0, 1\}^*\}$ cannot be accepted by a DFA. One can prove this by counting or using the so-called pumping lemmas; one can also prove this by arguing that x contains more information than a *finite*-state machine can *remember*. We refer the interested readers to textbooks such as Hopcroft and Ullmann (1979), Gurari (1989), Wood (1987), and Floyd and Beigel (1994) for traditional approaches and to Li and Vitányi (1993) for a nontraditional approach. One can try to generalize the DFA to allow the input head to be *two way* but still read only. But such machines are not more powerful; they can be simulated by normal DFAs. The next step is apparently to add *storage* space such that our machines can *write* information in.

8.5.2 Turing Machines

In this section, we will provide an alternative definition of a TM to make it compatible with our definitions of a DFA, PDA, etc. This also makes it easier to define a nondeterministic TM. But this formulation (at least the deterministic version) is essentially the same as the one presented in Section 8.2.

A TM, as in Figure 8.13, consists of a *finite control*, an infinite *tape* divided into cells, and a read/write *head* on the tape. We refer to the two directions on the tape as *left* and *right*. The finite control can be in any one of a finite set Q of states, and each tape cell can contain a 0, a 1, or a *blank* B . Time is

FIGURE 8.11 Converting an NFA to a regular expression.

FIGURE 8.12 The reduced NFA.

FIGURE 8.13 A Turing machine.

discrete and the time instants are ordered $0, 1, 2, \dots$ with 0 the time at which the machine starts its computation. At any time, the head is positioned over a particular cell, which it is said to *scan*. At time 0 , the head is situated on a distinguished cell on the tape called the *start cell*, and the finite control is in the initial state q_0 . At time 0 , all cells contain *B*s, except a contiguous finite sequence of cells, extending from the start cell to the right, which contain *0*s and *1*s. This binary sequence is called the *input*.

The device can perform the following basic operations:

1. It can write an element from the tape alphabet $\Sigma = \{0, 1, B\}$ in the cell it scans.
2. It can shift the head one cell left or right.

Also, the device executes these operations at the rate of one operation per time unit (a *step*). At the conclusion of each step, the finite control takes on a state in Q . The device operates according to a finite set P of *rules*.

The rules have format (p, s, a, q) with the meaning that if the device is in state p and s is the symbol under scan, then write a if $a \in \{0, 1, B\}$ or move the head according to a if $a \in \{L, R\}$ and the finite control changes to state q . At some point, if the device gets into a special *final* state q_f , the device stops and accepts the input.

If every pair of distinct quadruples differs in the first two elements, then the device is *deterministic*. Otherwise, the device is *nondeterministic*. Not every possible combination of the first two elements has to be in the set; in this way, we permit the device to perform *no* operation. In this case, we say the device *halts*. In this case, if the machine is not in a final state, we say that the machine *rejects* the input.

Definition 8.20

A TM is a quintuple $M = (Q, \Sigma, P, q_0, q_f)$, where each of the components has been described previously.

Given an input, a deterministic TM carries out a uniquely determined succession of operations, which may or may not terminate in a finite number of steps. If it terminates, then the nonblank symbols left on the tape are the output. Given an input, a *nondeterministic TM* behaves much like an NFA. One may imagine that it carries out its computation in parallel. Such a computation may be viewed as a (possibly infinite) tree. The root of the tree is the starting configuration of the machine. The children of each node are all possible configurations one step away from this node. If any of the branches terminates in the final state q_f , we say the machine accepts the input. The reader may want to test understanding this

new formulation of a TM by redoing the doubling program on a TM with states and transitions (rather than a GOTO program).

A TM *accepts* a language L if $L = \{w : M \text{ accepts } w\}$. Furthermore, if M halts on all inputs, then we say that L is *Turing decidable* or *recursive*. The connection between a recursive language and a decidable problem (function) should be clear. It is that function f is decidable if and only if L_f is recursive. (Readers who may have forgotten the connection between function f and the associated language L_f should review Remark 8.1.)

Theorem 8.9

All of the following generalizations of TMs can be simulated by a one-tape deterministic TM defined in Definition 8.20.

- Larger tape alphabet Σ
- More work tapes
- More access points, read/write heads, on each tape
- 2D or more dimensional tapes
- Nondeterminism

Although these generalizations do not make a TM compute more, they do make a TM more efficient and easier to program. Many more variants of TMs are studied and used in the literature. Of all simulations in Theorem 8.9, the last one needs some comments. A nondeterministic computation branches like a tree. When simulating such a computation for n steps, the obvious thing for a deterministic TM to do is to try all possibilities; thus, this requires up to c^n steps, where c is the maximum number of nondeterministic choices at each step.

Example 8.18

A DFA is an extremely simple TM. It just reads the input symbols from left to right. TMs naturally accept more languages than DFAs can. For example, a TM can accept

$L = \{xx : x \in \{0, 1\}^*\}$ as follows:

- Find the middle point first: It is trivial by using two heads; with one head, one can mark one symbol at the left and then mark another on the right and go back and forth to eventually find the middle point.
- Match the two parts: With two heads, this is again trivial; with one head, one can again use the marking method matching a pair of symbols each round; if the two parts match, accept the input by entering q_f .

There are types of storage media other than a tape:

- A *pushdown store* is a semi-infinite work tape with one head such that each time the head moves to the left, it erases the symbol scanned previously; this is a last-in first-out storage.
- A *queue* is a semi-infinite work tape with two heads that move only to the right, the leading head is write only and the trailing head is read only; this is a first-in first-out storage.
- A *counter* is a pushdown store with a single-letter alphabet (except its one end, which holds a special marker symbol). Thus, a counter can store a nonnegative integer and can perform three operations.

A queue machine can simulate a normal TM, but the other two types of machines are not powerful enough to simulate a TM.

Example 8.19

When the TM tape is replaced by a pushdown store, the machine is called a *pushdown automaton*. Pushdown automata have been thoroughly studied because they accept the class of context-free languages defined in Section 8.4. More precisely, it can be shown that if L is a context-free language, then it is accepted by a PDA, and if L is accepted by a PDA, then there is a CFG generating L . Various types of PDAs have fundamental applications in compiler design.

The PDA is more restricted than a TM. For example, $L = \{xx : x \in \{0, 1\}^*\}$ cannot be accepted by a PDA, but it can be accepted by a TM as in Example 8.18. But a PDA is more powerful than a DFA. For example, a PDA can accept the language $L' = \{0^k 1^k : k \geq 0\}$ easily. It can read the 0s and push them into the pushdown store; then, after it finishes the 0s, each time the PDA reads a 1, it removes a 0 from the pushdown store; at the end, it accepts if the pushdown store is empty (the number of 0s matches that of 1s). But a DFA cannot accept L' , because after it has read all of the 0s, it cannot remember k when k has higher information content than the DFA's finite control.

Two pushdown stores can be used to simulate a tape easily. For comparisons of powers of pushdown stores, queues, counters, and tapes, see van Emde Boas (1990) and Li and Vitányi (1993).

The idea of the universal algorithm was introduced in Section 8.2. Formally, a *universal TM*, U , takes an encoding of a pair of parameters (M, x) as input and simulates M on input x . U accepts (M, x) if M accepts x . The universal TMs have many applications. For example, the definition of the Kolmogorov complexity (Li and Vitányi 1993) fundamentally relies on them.

Example 8.20

Let $L_u = \{\langle M, w \rangle : M \text{ accepts } w\}$. Then, L_u can be accepted by a TM, but it is not Turing decidable. The proof is omitted.

If a language is Turing acceptable but not Turing decidable, we call such a language *recursively enumerable* (r.e.). Thus, L_u is r.e. but not recursive. It is easily seen that if both a language and its complement are r.e., then both of them are recursive. Thus, \bar{L}_u is not r.e.

8.5.2.1 Time and Space Complexity

With TMs, we can now formally define what we mean by *time and space complexities*. Such a formal investigation by Hartmanis and Stearns (1965) marked the beginning of the field of *computational complexity*. We refer the readers to Hartmanis' Turing Award lecture (Hartmanis 1994) for an interesting account of the history and the future of this field.

To define the space complexity properly (in the sublinear case), we need to slightly modify the TM of Figure 8.13. We will replace the tape containing the input by a read-only input tape and give the TM some extra work tapes.

Definition 8.21

Let M be a TM. If, for each n , for each input of length n , and for each sequence of choices of moves when M is nondeterministic M makes at most $T(n)$ moves, we say that M is of *time complexity* $T(n)$; similarly, if M uses at most $S(n)$ tape cells of the work tape, we say that M is of *space complexity* $S(n)$.

Theorem 8.10

Any TM using $s(n)$ space can be simulated by a TM, with just one work tape, using $s(n)$ space. If a language is accepted by a k -tape TM running in time $t(n)$ [space $s(n)$], then it also can be accepted by another k -tape TM running in time $ct(n)$ [space $cs(n)$], for any constant $c > 0$.

To avoid writing the constant c everywhere, we use the standard big- O notation: we say $f(n)$ is $O(g(n))$ if there is a constant c such that $f(n) \leq cg(n)$ for all but finitely many n . The preceding theorem is called the linear speedup theorem; it can be proved easily by using a larger tape alphabet to encode several cells into one and hence compress several steps into one. It leads to the following definitions.

Definition 8.22

$\text{DTIME}[t(n)]$ is the set of languages accepted by multitape deterministic TMs in time $O(t(n))$.
 $\text{NTIME}[t(n)]$ is the set of languages accepted by multitape nondeterministic TMs in time $O(t(n))$.
 $\text{DSPACE}[s(n)]$ is the set of languages accepted by multitape deterministic TMs in space $O(s(n))$.
 $\text{NSPACE}[s(n)]$ is the set of languages accepted by multitape nondeterministic TMs in space $O(s(n))$.
 P is the complexity class $\bigcup_{c \in \mathbb{N}} \text{DTIME}[n^c]$.
 NP is the complexity class $\bigcup_{c \in \mathbb{N}} \text{NTIME}[n^c]$.
 PSPACE is the complexity class $\bigcup_{c \in \mathbb{N}} \text{DSPACE}[n^c]$.

Example 8.21

We mentioned in Example 8.18 that $L = \{xx : x \in \{0, 1\}^*\}$ can be accepted by a TM. The procedure we have presented in Example 8.18 for a one-head one-tape TM takes $O(n^2)$ time because the single head must go back and forth marking and matching. With two heads, or two tapes, L can be easily accepted in $O(n)$ time.

It should be clear that any language that can be accepted by a DFA, an NFA, or a PDA can be accepted by a TM in $O(n)$ time. The type-1 grammar in Definition 8.16 can be accepted by a TM in $O(n)$ space. Languages in P , that is, languages acceptable by TMs in *polynomial* time, are considered as *feasibly* computable. It is important to point out that all generalizations of the TM, except the nondeterministic version, can all be simulated by the basic one-tape deterministic TM with at most polynomial slowdown. The class NP represents the class of languages accepted in polynomial time by a nondeterministic TM. The nondeterministic version of PSPACE turns out to be identical to PSPACE (Savitch 1970). The following relationships are true:

$$P \subseteq NP \subseteq \text{PSPACE}$$

Whether or not either of the inclusions is proper is one of the most fundamental open questions in computer science and mathematics. Research in computational complexity theory centers around these questions. To solve these problems, one can identify the hardest problems in NP or PSPACE . These topics will be discussed in Chapter 8. We refer the interested reader to Gurari (1989), Hopcroft and Ullman (1979), Wood (1987), and Floyd and Beigel (1994).

8.5.2.2 Other Computing Models

Over the years, many alternative computing models have been proposed. With reasonable complexity measures, they can all be simulated by TMs with at most a polynomial slowdown. The reference van Emde Boas (1990) provides a nice survey of various computing models other than TMs. Because of

limited space, we will discuss a few such alternatives very briefly and refer our readers to van Emde Boas (1990) for details and references.

Random Access Machines. The *random access machine* (RAM) (Cook and Reckhow 1973) consists of a finite control where a program is stored, with several arithmetic registers and an infinite collection of memory registers $R[1], R[2], \dots$. All registers have an unbounded word length. The basic instructions for the program are LOAD, ADD, MULT, STORE, GOTO, ACCEPT, REJECT, etc. Indirect addressing is also used. Apparently, compared to TMs, this is a closer but more complicated approximation of modern computers. There are two standard ways for measuring time complexity of the model:

- The *unit-cost RAM*: in this case, each instruction takes one unit of time, no matter how big the operands are. This measure is convenient for analyzing some algorithms such as sorting. But it is unrealistic or even meaningless for analyzing some other algorithms, such as integer multiplication.
- The *log-cost RAM*: each instruction is charged for the sum of the lengths of all data manipulated implicitly or explicitly by the instruction. This is a more realistic model but sometimes less convenient to use.

Log-cost RAMs and TMs can simulate each other with polynomial overheads. The unit-cost RAM might be exponentially (but unrealistically) faster when, for example, it uses its power of multiplying two large numbers in one step.

Pointer Machines. The pointer machines were introduced by Kolmogorov and Uspenskii (1958) (also known as the Kolmogorov–Uspenskii machine) and by Schönhage in 1980 (also known as the storage modification machine, see Schönhage [1980]). We informally describe the pointer machine here. A pointer machine is similar to a RAM but differs in its memory structure. A pointer machine operates on a storage structure called a Δ structure, where Δ is a finite alphabet of size greater than one. A Δ -structure S is a finite directed graph (the Kolmogorov–Uspenskii version is an undirected graph) in which each node has $k = |\Delta|$ outgoing edges, which are labeled by the k symbols in Δ . S has a distinguished node called the *center*, which acts as a starting point for addressing, with words over Δ , other nodes in the structure. The pointer machine has various instructions to redirect the pointers or edges and thus modify the storage structure. It should be clear that turning machines and pointer machines can simulate each other with at most polynomial delay if we use the log-cost model as with the RAMs. There are many interesting studies on the efficiency of the preceding simulations. We refer the reader to van Emde Boas (1990) for more pointers on the pointer machines.

Circuits and Nonuniform Models. A *Boolean circuit* is a finite, labeled, directed acyclic graph. Input nodes are nodes without ancestors; they are labeled with input variables x_1, \dots, x_n . The internal nodes are labeled with functions from a finite set of Boolean operations, for example, {and, or, not} or $\{\oplus\}$. The number of ancestors of an internal node is precisely the number of arguments of the Boolean function that the node is labeled with. A node without successors is an output node. The circuit is naturally evaluated from input to output: at each node, the function labeling the node is evaluated using the results of its ancestors as arguments. Two cost measures for the circuit model are the following:

- *Depth*: the length of a longest path from an input node to an output node
- *Size*: the number of nodes in the circuit

These measures are applied to a family of circuits $\{C_n : n \geq 1\}$ for a particular problem, where C_n solves the problem of size n . If C_n can be computed from n (in polynomial time), then this is a *uniform measure*. Such circuit families are equivalent to TMs. If C_n cannot be computed from n , then such measures are *nonuniform* measures, and such classes of circuits are more powerful than TMs because they simply can compute any function by encoding the solutions of all inputs for each n . See van Emde Boas (1990) for more details and pointers to the literature.

Key Terms

Algorithm: A finite sequence of instructions that is supposed to solve a particular problem.

Ambiguous context-free grammar: For some string of terminals, the grammar has two distinct derivation trees.

Chomsky normal form: Every rule of the context-free grammar has the form $A \rightarrow BC$ or $A \rightarrow a$, where A , B , and C are nonterminals and a is a terminal.

Computable or decidable function/problem: A function/problem that can be solved by an algorithm (or equivalently, a TM).

Context-free grammar: A grammar whose rules have the form $A \rightarrow B$, where A is a nonterminal and B is a string of nonterminals and terminals.

Context-free language: A language that can be described by some context-free grammar.

Context-sensitive grammar: A grammar whose rules have the form $\alpha \rightarrow \beta$, where α and β are strings of nonterminals and terminals and $|\alpha| \leq |\beta|$.

Context-sensitive language: A language that can be described by some context-sensitive grammar.

Derivation or parsing: An illustration of how a string of terminals is obtained from the start symbol by successively applying the rules of the grammar.

Finite automaton or finite-state machine: A restricted TM where the head is read only and shifts only from left to right.

(Formal) grammar: A description of some language typically consisting of a set of terminals, a set of nonterminals with a distinguished one called the start symbol, and a set of rules (or productions) of the form $\alpha \rightarrow \beta$, depicting what string α of terminals and nonterminals can be rewritten as another string β of terminals and nonterminals.

(Formal) language: A set of strings over some fixed alphabet.

Halting problem: The problem of deciding if a given program (or TM) halts on a given input.

Nondeterministic TM: A TM that can make any one of a prescribed set of moves on a given state and symbol read on the tape.

Partially decidable decision problem: There exists a program that always halts and outputs 1 for every input expecting a positive answer and either halts and outputs 0 or loops forever for every input expecting a negative answer.

Program: A sequence of instructions that is not required to terminate on every input.

Pushdown automaton: A restricted TM where the tape acts as a pushdown store (or a stack).

Reduction: A computable transformation of one problem into another.

Regular expression: A description of some language using operators union, concatenation, and Kleene closure.

Regular language: A language that can be described by some right-linear/regular grammar (or equivalently by some regular expression).

Right-linear or regular grammar: A grammar whose rules have the form $A \rightarrow aB$ or $A \rightarrow a$, where A , B are nonterminals and a is either a terminal or the null string.

Time/space complexity: A function describing the maximum time/space required by the machine on any input of length n .

Turing machine: A simplest formal model of computation consisting of a finite-state control and a semi-infinite sequential tape with a read/write head. Depending on the current state and symbol read on the tape, the machine can change its state and move the head to the left or right.

Uncomputable or undecidable function/problem: A function/problem that cannot be solved by any algorithm (or equivalently, any TM).

Universal algorithm: An algorithm that is capable of simulating any other algorithms if properly encoded.

We would like to thank John Tromp and the reviewers for reading the initial drafts and helping us to improve the presentation.

Further Information

The fundamentals of the theory of computation, automata theory, and formal languages can be found in many text books including Floyd and Beigel (1994), Gurari (1989), Harel (1992), Harrison (1978), Hopcroft and Ullman (1979), and Wood (1987). The central focus of research in this area is to understand the relationships between the different resource complexity classes. This work is motivated in part by some major open questions about the relationships between resources (such as time and space) and the role of control mechanisms (nondeterminism/randomness). At the same time, new computational models are being introduced and studied. One such recent model that has led to the resolution of a number of interesting problems is the interactive proof systems. They exploit the power of randomness and interaction. Among their applications are new ways to encrypt information as well as some unexpected results about the difficulty of solving some difficult problems even approximately. Another new model is the quantum computational model that incorporates quantum-mechanical effects into the basic move of a TM. There are also attempts to use molecular or cell-level interactions as the basic operations of a computer. Yet another research direction motivated in part by the advances in hardware technology is the study of neural networks, which model (albeit in a simplistic manner) the brain structure of mammals. The following chapters of this volume will present state-of-the-art information about many of these developments. The following annual conferences present the leading research work in computation theory: Association of Computer Machinery (ACM) *Annual Symposium on Theory of Computing*; Institute of Electrical and Electronics Engineers (IEEE) *Symposium on the Foundations of Computer Science*; IEEE *Conference on Structure in Complexity Theory*; *International Colloquium on Automata, Languages and Programming*; *Symposium on Theoretical Aspects of Computer Science*; *Mathematical Foundations of Computer Science*; and *Fundamentals of Computation Theory*. There are many related conferences such as *Computational Learning Theory* and *ACM Symposium on Principles of Distributed Computing*, where specialized computational models are studied for a specific application area. Concrete algorithms is another closely related area in which the focus is to develop algorithms for specific problems. A number of annual conferences are devoted to this field. We conclude with a list of major journals whose primary focus is in theory of computation: *The Journal of the Association of Computer Machinery*, *SIAM Journal on Computing*, *Journal of Computer and System Sciences*, *Information and Computation*, *Mathematical Systems Theory*, *Theoretical Computer Science*, *Computational Complexity*, *Journal of Complexity*, *Information Processing Letters*, *International Journal of Foundations of Computer Science*, and *ACTA Informatica*.

9.1 Introduction

Cryptography is a vast subject, addressing problems as diverse as e-cash, remote authentication, fault-tolerant distributed computing, and more. We cannot hope to give a comprehensive account of the field here. Instead, we will narrow our focus to those aspects of cryptography most relevant to the problem of *secure communication*. Broadly speaking, secure communication encompasses two complementary goals: the **secrecy** and **integrity** of communicated data. These terms can be illustrated using the simple example of a user A attempting to transmit a message m to a user B over a public channel. In the simplest sense, techniques for data secrecy ensure that an eavesdropping adversary (i.e., an adversary who sees all communication occurring on the channel) cannot learn any information about the underlying message m . Viewed in this way, such techniques protect against a *passive* adversary who listens to—but does not otherwise interfere with—the parties’ communication. Techniques for data integrity, on the other hand, protect against an *active* adversary who may arbitrarily modify the information sent over the channel or may inject new messages of his own. Security in this setting requires that any such modifications or insertions performed by the adversary will be detected by the receiving party.

In the cases of both secrecy and integrity, two different assumptions regarding the initial setup of the communicating parties can be considered. In the **private-key setting** (also known as the “shared-key,” “secret-key,” or “symmetric-key” setting), which was the setting used exclusively for cryptography until the mid-1970s, parties A and B are assumed to have shared some secret information—a **key**—in advance. This key, which is completely unknown to the adversary, is then used to secure their future communication. (We do not comment further on how such a key might be generated and shared; for

TABLE 9.1 Overview of the Topics Covered in This Survey

	Private-Key Setting	Public-Key Setting
Secrecy	Private-key encryption (Section 9.2)	Public-key encryption (Section 9.4)
Integrity	Message authentication codes (Section 9.3)	Digital signature schemes (Section 9.5)

our purposes, it is simply an assumption of the model.) Techniques for secrecy in this setting are called **private-key encryption** schemes, and those for data integrity are termed **message authentication codes** (MACs).

In the **public-key setting**, one (or both) of the parties generate a pair of keys: a *public key* that is widely disseminated, and an associated *private key* which is kept secret. The party generating these keys may now use them as a receiver to ensure message secrecy using a **public-key encryption** scheme, or as a sender to provide data integrity using a **digital signature scheme**. Table 9.1 gives an overview of these different cryptographic tools.

In addition to showcasing the above primitives, and explaining how they should be used and how they can be constructed, the treatment here will also introduce a bit of the methodology of modern (i.e., post-1980s) cryptography. This includes an emphasis on formal *definitions* of security that pin down exactly what goals a scheme is intended to achieve; precisely stated *assumptions* (if needed) regarding the hardness of certain mathematical problems; and rigorous *proofs* of security that a cryptographic construction meets some definition of security given a particular assumption. This approach to designing and analyzing cryptosystems is much preferred to the heuristic, “ad-hoc” approach used in the past.

We warn the reader in advance that it is not the intention of this survey to cover the precise details of schemes used in practice today, nor will the survey be comprehensive. Rather, the aim of the survey is to provide the reader with an appreciation for the problem of secure communication along with an explanation of the core techniques used to address it. The reader seeking further details is advised to consult the references listed at the end of this chapter.

9.2 Private-Key Setting and Private-Key Encryption

We begin by discussing the private-key setting, where two parties share a random, secret key k that will be used to secure their future communication. Let us jump right in by defining the syntax of private-key encryption. Formally, a private-key encryption scheme consists of a pair of algorithms (Enc , Dec). The encryption algorithm Enc takes as input a key k and a message m (sometimes also called the **plaintext**), and outputs an encrypted version of the message called the **ciphertext** that will be denoted by c . The decryption algorithm Dec takes as input a key and a ciphertext, and outputs a message. The basic correctness requirement is that for every key k and message m (in some allowed set of messages) we have $m = \text{Dec}_k(\text{Enc}_k(m))$. Since it will come up later, we mention here that Enc may be a *randomized* algorithm, so that multiple ciphertexts can potentially be output when encrypting a given message with some key, in which case the preceding correctness condition is required to hold with probability 1. Without loss of generality, we may assume Dec is deterministic.

A private-key encryption scheme is used in the following way. Let k be the key shared by two parties A and B . For A to send a message m to B , she first **encrypts** the message by computing $c \leftarrow \text{Enc}_k(m)$ (we use “ \leftarrow ” to explicitly indicate that Enc may be randomized); the ciphertext c is then transmitted over the public channel to B . Upon receiving this ciphertext, B **decrypts** the ciphertext to recover the message by computing $m := \text{Dec}_k(c)$.

A private-key encryption scheme can also be used by a single party A to encrypt data (say, on a hard drive) that will be accessed by A herself at a later point in time. Here, A encrypts the data using a key k that she stores securely somewhere else. When A later wants to read the data, she can recover it by decrypting using k . Here, the “channel” is the hard drive itself and, rather than being separated in *space*, encryption and decryption are now separated in *time*. Everything we say in what follows will apply to

either usage of private-key encryption. (Message authentication codes, discussed in Section 9.3, can also be used for either of these canonical applications.)

The above discussion says nothing about the security provided by the encryption scheme. We consider this aspect in the following sections.

9.2.1 Perfect Secrecy

The goal of a private-key encryption scheme is to ensure the secrecy of m from an eavesdropping adversary \mathcal{A} who views c , but does not know k . How should secrecy be defined formally?

A natural first attempt would be to say that an encryption scheme is secure if \mathcal{A} cannot recover the message m in its entirety (assuming, say, m is chosen uniformly). A little thought shows that such a definition is inadequate: What if the distribution of m is not uniform? And surely we would not consider secure a scheme that always leaks the first bit of the message (without revealing anything about the rest of m)!

A better definition, introduced by Shannon [38] and termed *perfect secrecy*, is that the ciphertext c should leak no information whatsoever about m , regardless of its distribution. This is formalized by requiring that the *a posteriori* distribution of m (after \mathcal{A} observes the ciphertext) should be equivalent to the *a priori* distribution of m (reflecting the adversary's prior knowledge about the distribution of the message). Namely, a scheme (Enc, Dec) is perfectly secret if for any distribution \mathcal{M} over the space of possible messages, any message m , and any ciphertext c , it holds that

$$\Pr[M = m \mid C = c] = \Pr[M = m],$$

where M (respectively, C) denotes the random variable taking the value of the actual message of the sender (respectively, actual ciphertext transmitted).

Before giving an example of a scheme satisfying the above definition, we stress that the adversary (implicit in the above) is assumed to know the full details of the encryption scheme being used by the honest parties. (This is called *Kerckhoffs's principle* [29].) It is a mistake to require the details of a cryptosystem scheme to be hidden in order for it to be secure, and modern schemes are designed to be secure even when the full details of all algorithms are publicly known. The only thing unknown to the adversary is the key itself. This highlights the necessity of choosing the key at random, and the importance of keeping it completely secret.

Perfect secrecy can be achieved by the **one-time pad** encryption scheme, which works as follows. Let ℓ be the length of the message to be transmitted, where the message is viewed as a binary string. (Note that all potential messages are assumed to have the same length.) The parties share in advance a uniformly distributed, ℓ -bit key $k \in \{0, 1\}^\ell$. To encrypt message m the sender computes $c := m \oplus k$, where \oplus represents bit-wise exclusive-or. Decryption is performed by setting $m := c \oplus k$. Clearly, decryption always recovers the original message.

To see that this scheme is perfectly secret, fix any initial distribution over messages and let K be the random variable denoting the key. For any message m and observed ciphertext c , we have

$$\Pr[M = m \mid C = c] = \frac{\Pr[C = c \mid M = m] \Pr[M = m]}{\Pr[C = c]} = \frac{\Pr[C = c \mid M = m] \Pr[M = m]}{\sum_{m'} \Pr[C = c \mid M = m'] \cdot \Pr[M = m']}, \quad (9.1)$$

where the summation is over all possible messages m' . Moreover, for any c , m' (including $m' = m$) we have

$$\Pr[C = c \mid M = m'] = \Pr[K = c \oplus m'] = 2^{-\ell},$$

since k is a uniform ℓ -bit string. Substituting into (9.1), we have $\Pr[M = m \mid C = c] = \Pr[M = m]$ as desired.

Although the one-time pad is perfectly secret, it is of limited value in practice. For one, *the length of the shared key is equal to the length of the message*. Thus, the scheme becomes impractical when long messages are to be sent. Second, it is easy to see that the scheme provides secrecy *only when a given key is used to encrypt a single message* (hence the name “one-time pad”). This will not do in typical scenarios where A and B wish to share a single key that they can use to send multiple messages. Unfortunately, it can be shown that both these limitations are inherent for schemes achieving perfect secrecy.

9.2.2 Computational Secrecy

At the end of the previous section, we observed some fundamental limitations of perfect secrecy. To obtain reasonable solutions, we thus need to (slightly) relax our definition of secrecy. This is not too bad, however, since perfect secrecy may be considered to be unnecessarily strong: it requires *absolutely no information* about m to be leaked, even to an *all-powerful* eavesdropper. Arguably, it would be sufficient to leak a *tiny amount of information* and to restrict attention to eavesdroppers having some *bounded amount of computing power*. To take some concrete numbers, we may be satisfied with an encryption scheme that leaks a most 2^{-60} bits of information (on average) to any eavesdropper that invests at most 100 years of computational effort (on a standard desktop PC, for instance). Definitions of this latter sort are termed **computational**, to distinguish them from notions (like perfect secrecy) that are **information-theoretic** in nature. As initiated in the work of [11,36,33,35,44,9,22] and others, computational security is now the default way security is defined for cryptographic primitives.

A drawback of computational notions of security is that, given the current state of our knowledge, proofs that a given scheme satisfies any such definition must necessarily rely on (unproven) assumptions regarding the computational hardness of certain problems. Our confidence in the security of a particular scheme can be no better than our confidence in the underlying assumption(s) it is based on.

We illustrate the above by introducing a basic definition of computational secrecy. Fix some $t, \epsilon \geq 0$. Private-key encryption scheme (Enc, Dec) is (t, ϵ) -*indistinguishable* if for every eavesdropper \mathcal{A} running in time at most t , and for all (equal-length) messages m_0, m_1 , we have

$$\left| \Pr[\mathcal{A}(\text{Enc}_k(m_b)) = b] - \frac{1}{2} \right| \leq \epsilon.$$

The probability above is taken over uniform choice of the key k and the bit b , as well as any randomness used by Enc . In words: we choose a random key k , encrypt one of m_0 or m_1 (each with equal probability), and give the resulting ciphertext to \mathcal{A} ; the scheme is indistinguishable if any \mathcal{A} running in time t cannot determine which message was encrypted with probability ϵ -better than a random guess.

Perfect secrecy can be shown to be equivalent to $(\infty, 0)$ -indistinguishability, and so the above is a natural relaxation of perfect secrecy. Taking t bounded and ϵ strictly positive exactly corresponds to our intuitive idea of relaxing perfect secrecy by placing a bound t on the running time of \mathcal{A} , and being content with possibly allowing a tiny amount ϵ of “information leakage.”

9.2.3 Security against Chosen-Plaintext Attacks

Rather than give a construction satisfying the above definition, we immediately introduce an even stronger definition that is better suited for practical applications. Thus far, our security definitions have been restricted to consideration of an adversary who eavesdrops on a *single* ciphertext and, as we have mentioned, this restriction is essential in the context of perfect secrecy. As noted earlier, however, the honest parties would prefer to encrypt multiple messages using the same shared key; we would like to guarantee secrecy in this setting as well. Moreover, it may be the case that the adversary already knows some of the messages being encrypted; in fact, the adversary might even be able to influence some of the messages the parties send. This latter scenario, where the adversary can cause the parties to encrypt

plaintexts of the adversary's choice, is termed a **chosen-plaintext attack**. The one-time pad is trivially insecure against a chosen-plaintext attack: given a ciphertext $c = k \oplus m$ for a known message m , the adversary can easily recover the key k .

To capture the above attack scenarios, we modify the previous definition by additionally giving \mathcal{A} access to an *encryption oracle* $\text{Enc}_k(\cdot)$. This oracle allows the adversary to obtain the encryption of any message(s) of its choice using the key k shared by the parties. This oracle is meant to model the real-world capabilities of an adversary who can control what messages get encrypted by the parties; of course, if the adversary has only partial control over what messages get encrypted, then this only makes the adversary weaker. We say that an encryption scheme (Enc, Dec) is (t, ϵ) -*indistinguishable against a chosen-plaintext attack* (or (t, ϵ) -CPA secure) if for every adversary \mathcal{A} running in time at most t

$$\left| \Pr[\mathcal{A}^{\text{Enc}_k(\cdot)}(\text{Enc}_k(m_b)) = b] - \frac{1}{2} \right| \leq \epsilon,$$

where the probability space is as before.

It is not entirely obvious that CPA-security implies security when multiple messages are encrypted, but this can be shown to be the case [27].

Any easy, but important, observation is that any CPA-secure encryption scheme must have randomized encryption. This is true even if only security for multiple encrypted messages is desired: if the encryption scheme is deterministic, then given any two ciphertexts the adversary can tell whether or not they are encryptions of the same message, an undesirable leakage of information.

9.2.4 Block Ciphers

As a step toward constructing a CPA-secure private-key encryption scheme, we first introduce an important primitive for this application. A *keyed function* $F : \{0, 1\}^n \times \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$ is an efficiently computable function that maps two inputs to a single output; we treat the first input to F as a key that will be chosen at random and then fixed, and define $F_k(x) = F(k, x)$. (We have assumed for simplicity that the input and output of F_k have the same length ℓ , but this is not essential.) We call n the *key length* and ℓ the *block length*. Informally, F is pseudorandom if the function F_k , for a randomly chosen k , is “indistinguishable” from a completely random function f with the same domain and range. That is, consider an adversary \mathcal{A} who can send inputs to and receive outputs from a box that contains either F_k (for a random $k \in \{0, 1\}^n$) or f (for a random function f); the keyed function F is pseudorandom if \mathcal{A} cannot tell which is the case with probability significantly better than random guessing. Formally, F is a (t, ϵ) -**pseudorandom function** [20] if for any adversary \mathcal{A} running in time t

$$\left| \Pr[\mathcal{A}^{F_k(\cdot)} = 1] - \Pr[\mathcal{A}^{f(\cdot)} = 1] \right| \leq \epsilon,$$

where in the first case k is chosen uniformly from $\{0, 1\}^n$ and in the second case f is a completely random function.

If, for all k , the function F_k is a permutation (i.e., bijection) over $\{0, 1\}^\ell$ and moreover the inverse F_k^{-1} can be computed efficiently (given the key k), then F is called a *keyed permutation*. A pseudorandom function that is also a keyed permutation is called a *pseudorandom permutation* or a **block cipher**. (Technically, in this case F_k should be indistinguishable from a random permutation, but for large enough ℓ this is equivalent to being indistinguishable from a random function.)

A long sequence of theoretical results culminating in [20,24,31] shows that pseudorandom functions and block ciphers can be constructed from rather minimal cryptographic assumptions, and thus in particular from the cryptographic assumptions we will introduce in Section 9.4. Such constructions are

rather inefficient. In practice, dedicated and highly efficient block ciphers are used instead; although the security of these block ciphers cannot be cleanly reduced to a concise mathematical assumption, several design principles used in their construction can be given theoretical justification. More importantly, such block ciphers have been subjected to intense scrutiny by the cryptographic community for several years, and thus it is not unreasonable to view the assumption that these block ciphers are secure as being on par with other assumptions used in cryptography.

The most popular block cipher today is the Advanced Encryption Standard (AES) [10], which was standardized by NIST in 2001 after a multi-year, public competition. AES supports 128-, 192-, or 256-bit keys, and has a 128-bit block length. It superseded the Data Encryption Standard (DES) [13], which had been standardized by the US government in 1977. DES is still in wide use, but is considered insecure due to its relatively short key length (56 bits) and block length (64 bits). Further details and additional block ciphers are discussed in [30].

9.2.5 A CPA-Secure Scheme

Given any pseudorandom function $F : \{0, 1\}^n \times \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$ with ℓ sufficiently long, it is possible to construct a private-key encryption scheme (Enc, Dec) that is CPA-secure [21]. To encrypt a message $m \in \{0, 1\}^\ell$ using a key k , first choose a random string $r \in \{0, 1\}^\ell$; then output the ciphertext $\langle r, F_k(r) \oplus m \rangle$. Note that encryption here is randomized, and there are many possible ciphertexts associated with a given key and message. Decryption of a ciphertext $c = \langle c_1, c_2 \rangle$ using key k is performed by computing $m := c_2 \oplus F_k(c_1)$. It can be verified that correctness holds.

Intuitively, the sender and receiver are using $F_k(r)$ as a “one-time pad” to encrypt m . Although $F_k(r)$ is not random, it *is* pseudorandom and one can show that this is enough for security to hold. In a bit more detail: say the sender encrypts multiple messages m_1, m_2, \dots, m_q using random strings r_1, r_2, \dots, r_q , respectively. The facts that F is a pseudorandom function and k is unknown to the adversary imply that $F_k(r_1), F_k(r_2), \dots, F_k(r_q)$ are indistinguishable from independent, uniform strings of length ℓ unless $r_i = r_j$ for some $i \neq j$ (in which case, $F_k(r_i)$ and $F_k(r_j)$ are, of course, equal). Assuming this does not occur, then, usage of the encryption scheme is equivalent to using the one-time pad encryption scheme with q independent keys, and is thus secure. The probability that there exist distinct i, j with $r_i = r_j$ can be bounded by $q^2/2^\ell$, which is small for typical values of q, ℓ . A full proof can be found in [27, Chapter 3].

The scheme described above can be applied to messages of arbitrary length by encrypting in a block-by-block fashion. This results in a ciphertext whose length is twice that of the original plaintext. More efficient **modes of encryption** [14,27] are used in practice to encrypt long messages. As an example, counter mode (CTR-mode) encryption of a message $m = \langle m_1, \dots, m_t \rangle$ (with $m_i \in \{0, 1\}^\ell$) using a key k is done by choosing a random r as above, and then computing the ciphertext

$$\langle r, F_k(r+1) \oplus m_1, F_k(r+2) \oplus m_2, \dots, F_k(r+t) \oplus m_t \rangle.$$

(A proof of security for this scheme follows along similar lines as above.) The ciphertext is now only a single block longer than the plaintext.

9.2.6 Stronger Security Notions

Even the notion of CPA security considers only a passive adversary who eavesdrops on the public channel, but not an active adversary who interferes with the communication between the parties. (Although we will treat active attacks in the next section, there our concern will primarily be integrity rather than secrecy.) Encryption schemes providing security against an active adversary are available; see Section 9.3.2 and Section 9.3.7 [27] for further discussion.

9.3 Message Authentication Codes

The preceding section discussed how to achieve *secrecy*; we now discuss techniques for ensuring *integrity* (sometimes also called *authenticity*). Here, the problem is as follows: parties A and B share a key k in advance, and then communicate over a channel that is under the complete control of an adversary. When B receives a message, he wants to ensure that this message indeed originated from A and was not, for example, injected by the adversary, or generated by modifying the real message sent by A .

Secrecy and integrity are incomparable goals, and it is possible to achieve either one without the other. In particular, the one-time pad—which achieves perfect secrecy—provides no integrity whatsoever since *any* ciphertext c of the appropriate length decrypts to some valid message. Even worse, if c represents the encryption of some (possibly unknown) message m , then flipping the first bit of c has the predictable effect of flipping the first bit of the resulting decrypted message. This illustrates that *integrity is not implied by secrecy, and if integrity is required then specific techniques to achieve it must be used*.

In the private-key setting, the right tool in this context is a MAC. We first define the syntax. A MAC consists of two algorithms $(\text{Mac}, \text{VrfY})$. The *tag-generation algorithm* Mac takes as input a key k and a message m , and outputs a tag tag ; although it is possible for this algorithm to be randomized, there is not much loss of generality in assuming that it is deterministic, and so we write this as $\text{tag} := \text{Mac}_k(m)$. The *verification algorithm* VrfY takes as input a key, a message, and a tag; it outputs a single bit b with the intention that $b = 1$ denotes “validity” and $b = 0$ indicates “invalidity.” (If $\text{VrfY}_k(m, \text{tag}) = 1$, then we say that tag is a *valid tag* for message m with respect to key k .) An honestly generated tag on a message m should be accepted as valid, and so correctness requires that for any key k and message m , we have $\text{VrfY}_k(m, \text{Mac}_k(m)) = 1$.

Defining security for MACs is relatively simple, and there is only one widely accepted definition [3,23]. At a high level, the goal is to prevent an adversary from generating a valid tag on a message that was never previously authenticated by one of the honest parties. This should hold even if the adversary observes valid tags on several other messages of its choice. Formally, consider an adversary \mathcal{A} who is given access to an oracle $\text{Mac}_k(\cdot)$; the adversary can submit messages of its choice to this oracle and obtain the corresponding valid tags. \mathcal{A} succeeds if it can then output (m, tag) such that (1) m was not one of the messages m_1, \dots that \mathcal{A} had previously submitted to its oracle, and (2) tag is a valid tag for m ; that is, $\text{VrfY}_k(m, \text{tag}) = 1$. A MAC is (t, ϵ) -secure if for all \mathcal{A} running in time at most t , the probability with which \mathcal{A} succeeds in this experiment (where the probability is taken over random choice of k) is at most ϵ . This security notion is also called *existential unforgeability under adaptive chosen-message attack*.

One attack not addressed in the above discussion is a *replay attack*, whereby an adversary resends an honestly generated message m along with its valid tag. The receiver, in general, has no way of knowing whether the legitimate sender has simply sent m again, or whether this second instance of m was injected by the adversary. MACs, as defined, are stateless and so are unable to prevent such an attack. This is by choice: since repeated messages may be legitimate in some contexts, any handling of replay attacks must be taken care of at a higher level.

We now show a simple construction of a secure MAC based on any pseudorandom function/block cipher $F: \{0, 1\}^n \times \{0, 1\}^\ell \rightarrow \{0, 1\}^\ell$ with ℓ sufficiently long [21]. To generate a tag on a message $m \in \{0, 1\}^\ell$ using key k , simply compute $\text{tag} := F_k(m)$. Verification is done in the obvious way: $\text{VrfY}_k(m, \text{tag})$ outputs 1 if and only if $\text{tag} = F_k(m)$. We sketch the proof of security for this construction. Let m_1, \dots denote those messages for which adversary \mathcal{A} has requested a tag. Since F is a pseudorandom function, $\text{Mac}_k(m) = F_k(m)$ “looks random” for any $m \notin \{m_1, \dots\}$, the probability with which \mathcal{A} can correctly predict the value of $F_k(m)$, then, is roughly $2^{-\ell}$. For ℓ large enough, the probability of a successful forgery is very small.

9.3.1 MACs for Long Messages

The construction in the previous section assumed that messages to be authenticated had length ℓ , the block length of the underlying pseudorandom function. Practical block ciphers have relatively short

block length (e.g., $\ell \approx 128$ bits), which means that only very short messages can be authenticated by this construction. In this section, we explore two approaches for doing better.

The first approach is a specific construction called the *cipher-block chaining MAC* (CBC-MAC), which can be based on any pseudorandom function/block cipher F as before. Here, we assume that the length of the messages to be authenticated is some *fixed* multiple of the block length ℓ . The tag on a message $M = \langle m_1, m_2, \dots, m_L \rangle$ (with $m_i \in \{0, 1\}^\ell$) using key k is computed as follows:

```

tag0 = 0ℓ
For i = 1 to L:
  tagi = Fk(mi ⊕ tagi-1)
Output tagL

```

Verification of a tag tag on a message $M = \langle m_1, \dots, m_L \rangle$ is done by recomputing tag_L as above and outputting 1 if and only if $\text{tag} = \text{tag}_L$.

CBC-MAC is known to be secure if F is a pseudorandom function [3]. This is true only as long as fixed-length messages (i.e., when the number of message blocks L is fixed) are authenticated, and there are several known attacks on the basic CBC-MAC presented above when this is not the case. Subsequent work has shown how to extend basic CBC-MAC to allow authentication of arbitrary-length messages [8,25,34].

A second approach to authenticating arbitrary-length messages is generic, in that it gives a way to modify *any* MAC for short messages so as to handle longer messages. As we will present it here, however, this approach requires an additional cryptographic primitive called a **collision-resistant hash function**. Although hash functions play an important role in cryptography, our discussion will be brief and informal since they are used sparingly in the remainder of this survey.

A **hash function** H is a function that *compresses* an arbitrary-length input to a short, fixed-length string. Hash functions are widely used in many areas of computer science, but cryptographic hash functions have some special requirements that are typically not needed for other applications. The most important such requirement, and the only one we will discuss, is *collision resistance*. Informally, H is collision resistant if it is infeasible for an efficient adversary to find a *collision* in H , where a collision is a pair of distinct inputs x, x' with $H(x) = H(x')$. If H is collision resistant, then the hash of a long message serves as a “secure digest” of that message, in the following sense: for any value y (whether produced by an adversary or not), an adversary can come up with at most one x such that $H(x) = y$. The output length of a hash function fixes an upper bound on the computational difficulty of finding a collision: if H has output length ℓ , then a collision can always be found in $\mathcal{O}(2^{\ell/2})$ steps (see [27]).

As in the case of block ciphers, collision-resistant hash functions can be constructed from number-theoretic assumptions but such constructions are inefficient. (Interestingly, the precise assumptions needed to construct collision-resistant hash functions appear to be stronger than what is necessary to construct block ciphers.) Several dedicated, efficient constructions of hash functions are known; the most popular ones are currently given by the SHA family of hash functions [15], which have output lengths ranging from 160 to 512 bits. As of the time of this writing, however, NIST is running a public competition to choose a replacement (see <http://www.nist.gov/hash-competition>).

Returning to our discussion of MACs, let $H: \{0, 1\}^* \rightarrow \{0, 1\}^\ell$ be a collision-resistant hash function, and let $(\text{Mac}, \forall r f y)$ be a secure MAC for messages of length ℓ . Then we can construct a message authentication code $(\text{Mac}', \forall r f y')$ for arbitrary-length messages as follows. To authenticate m , first hash it to an ℓ -bit digest, and then authenticate the digest using the original MAC, that is, $\text{Mac}'_k(m) \stackrel{\text{def}}{=} \text{Mac}_k(H(m))$. Verification is done in the natural way, with $\forall r f y'_k(m, \text{tag}) \stackrel{\text{def}}{=} \forall r f y_k(H(m), \text{tag})$. It is not difficult to show that this construction is secure. The standardized HMAC message authentication code [2,17] can be viewed as following the above paradigm.

9.3.2 Joint Secrecy and Integrity

When communicating over a public channel, it is usually the case that both secrecy and integrity are required. Schemes achieving both these properties are called **authenticated encryption schemes** [4,28]. The natural way to achieve both these properties is to combine a private-key encryption scheme with a MAC; there are a number of subtleties in doing so, and the reader is referred elsewhere for a more in-depth treatment [4,27]. More efficient constructions of authenticated encryption schemes are also known.

9.4 Public-Key Setting and Public-Key Encryption

The private-key setting we have been considering until now requires the honest parties to share a secret key in advance in order to secure their communication. Historically, the private-key setting was the only one considered in cryptography. In the mid-1970s [11,33,35,36], however, the field of cryptography was revolutionized by the development of *public-key cryptography* which can enable secure communication between parties who share no secret information in advance and carry out all their communication over a public channel. The only requirement is that there is a way for one party to reliably send a copy of their public key to the other.

In the setting of public-key cryptography, any party A generates a pair of keys (pk, sk) on its own; the private key sk is held privately by A , while the public key pk must be obtained by any other party B who wishes to communicate with A . The first party can either send a copy of its public key directly to B , if an authenticated (but not necessarily private!) channel is available between A and B ; alternately, A can place a copy of its public key in a public directory (or on her webpage) and B can then obtain pk when needed. Regardless of which method is used, when we analyze security of public-key cryptosystems we simply assume that parties are able to obtain authentic copies of each others' public keys. (In practice, certification authorities and a public-key infrastructure are used to reliably distribute public keys; a discussion is outside the scope of this chapter.) We assume the adversary also knows all parties' public keys; this makes sense since parties make no effort to keep their public keys secret.

Public-key cryptography has a number of advantages relative to private-key cryptography. As we have already discussed, the use of public-key cryptography can potentially simplify key distribution since a private channel between the communicating users is not needed (as it is in the private-key setting). Public-key cryptography can also simplify key management in large systems. For example, consider a company with N employees where each employee should be able to communicate securely with any other employee. Using a private-key solution would require each user to share a (unique) key with every other user, requiring each employee to store $N - 1$ secret keys. In contrast, with a public-key solution, each user would need to know their own private key and the $N - 1$ public keys of the other employees; these public keys, however, could be stored in a public directory or other nonprivate storage. Finally, public-key cryptography is more suitable for "open systems" such as the Internet where the parties who need to communicate securely may have no prior trust relationship, as is the case when a (new) customer wants to encrypt their credit card prior to sending it to an online merchant.

The primary disadvantage of public-key cryptography is that it is less efficient than private-key cryptography. An exact comparison depends on many factors, but as a rough estimate, when encrypting "short" messages (say, less than 10 kB) public-key cryptosystems are 500–1000 times slower than comparable private-key cryptosystems and use roughly a factor of 10 more bandwidth. The power consumption needed to use public-key cryptography can also be an issue when cryptography is used in low-power devices (sensors, RFID tags, etc.). Thus, when private-key cryptography is an option, it is preferable to use it.

Let us formalize the syntax of public-key encryption. A public-key encryption scheme is composed of three algorithms (Gen , Enc , Dec). The *key-generation algorithm* Gen is a randomized algorithm that outputs a pair of keys (pk, sk) as described earlier. The *encryption algorithm* Enc takes as input a

public key pk and a message m , and outputs a ciphertext c . The *decryption algorithm* Dec takes as input a private key sk and a ciphertext c , and outputs a message m . (We highlight here that the decryption algorithm and the encryption algorithm use *different* keys.) Correctness requires that for all (pk, sk) output by Gen , and any message m , we have $\text{Dec}_{sk}(\text{Enc}_{pk}(m)) = m$.

Our definition of security is patterned on the earlier definition given for private-key encryption schemes; in fact, the only difference is that the adversary is given the public key. That is, public-key encryption scheme $(\text{Gen}, \text{Enc}, \text{Dec})$ is (t, ϵ) -*indistinguishable* if for every (probabilistic) eavesdropper \mathcal{A} running in time at most t , and for all (equal-length) messages m_0, m_1 , we have

$$\left| \Pr[\mathcal{A}(pk, \text{Enc}_{pk}(m_b)) = b] - \frac{1}{2} \right| \leq \epsilon,$$

where the probability is taken over random generation of (pk, sk) by Gen , uniform choice of b , and any randomness used by the encryption algorithm itself.

Interestingly, in the public-key setting, the above definition implies security against chosen-plaintext attacks (and hence also security when multiple messages are encrypted) and for this reason we will also use the above as our definition of CPA-security; this is in contrast to the private-key setting where security against chosen-plaintext attacks is stronger than indistinguishability. A bit of reflection shows why: in the public-key setting access to an encryption oracle is superfluous, since an adversary who is given the public key can encrypt any messages it likes by itself. A consequence is that, in order to meet even a minimal notion of security in the public-key setting, encryption must be randomized.

In contrast to the private-key setting, public-key cryptography seems to inherently rely on number-theoretic techniques. The two most commonly used techniques are explored in the following two subsections. These sections assume some basic mathematical background on the part of the reader; the necessary background is covered in [27].

9.4.1 RSA Encryption

We discuss the general case of **RSA cryptography**, followed by its application to the particular case of public-key encryption.

Rivest et al. [36] introduced the concept of RSA-based cryptography in 1978. Security here is ultimately based on (though not equivalent to) the assumption that factoring large numbers is hard, even though multiplying large numbers is easy. This, in turn, gives rise to problems that are easy if the factorization of some modulus N is known, but that are believed to be hard when the factors of N are unknown. This asymmetry can be exploited to construct public-key cryptosystems.

Specifically, let $N = pq$ be the product of two large primes p and q . (For concreteness, one may take p and q to be 1000-bit integers.) Let \mathbb{Z}_N^* denote the set of integers between 1 and $N - 1$ that are invertible modulo N ; that is, $x \in \mathbb{Z}_N^*$ if there exists an integer x^{-1} such that $x \cdot x^{-1} = 1 \pmod N$. It is known that \mathbb{Z}_N^* consists precisely of those integers between 1 and $N - 1$ that are *relatively prime* to (i.e., have no factor in common with) N . Using this, one can show that

$$|\mathbb{Z}_N^*| = (p-1) \cdot (q-1).$$

Define $\varphi(N) \stackrel{\text{def}}{=} |\mathbb{Z}_N^*|$. Basic group theory implies that for any integers e, d with $ed = 1 \pmod{\varphi(N)}$ and any $x \in \mathbb{Z}_N^*$, it holds that

$$(x^e)^d = x \pmod N; \tag{9.2}$$

in particular, this means that the function $f_{N,e} : \mathbb{Z}_N^* \rightarrow \mathbb{Z}_N^*$ defined by

$$f_{N,e}(x) = x^e \bmod N$$

is a bijection. Anyone given N , e , and x can easily compute $f_{N,e}(x)$ using standard algorithms for efficient modular exponentiation. The *RSA problem* is the problem of inverting this function: namely, given N , e , y with $y \in \mathbb{Z}_N^*$, to find a value $x \in \mathbb{Z}_N^*$ such that $x^e = y \bmod N$.

If the factors of N are known, then it is easy to compute $\varphi(N)$ and hence for any e relatively prime to $\varphi(N)$ the value $d \stackrel{\text{def}}{=} e^{-1} \bmod \varphi(N)$ can be efficiently computed. This value d can then be used to invert $f_{N,e}$ using Equation 9.2, and so in this case the RSA problem is easily solved. On the other hand, there is no known efficient algorithm for inverting $f_{N,e}$ given only N and e (and, in particular, without the factorization of N). The *RSA assumption* formalizes the apparent computational difficulty of solving the RSA problem. Let RSAGen be a randomized algorithm that outputs (N, e, d) where N is a product of two random, large primes and $ed = 1 \bmod \varphi(N)$. (We do not discuss how such an algorithm can be constructed; suffice it to say that efficient algorithms with the required behavior are known.) We say *the RSA problem is (t, ϵ) -hard for RSAGen* if, for all algorithms \mathcal{A} running in time at most t ,

$$\Pr[\mathcal{A}(N, e, y) = x \text{ s.t. } x^e = y \bmod N] \leq \epsilon,$$

where the probability is taken over the randomness of RSAGen as well as uniform choice of $y \in \mathbb{Z}_N^*$. It is clear that if the RSA problem is hard for RSAGen , then factoring moduli N output by RSAGen must be hard; the converse is not known, but hardness of the RSA problem for moduli generated appropriately (i.e., the RSA assumption) is widely believed to hold.

The above discussion should naturally motivate our first candidate public-key encryption scheme that we call “textbook RSA encryption.” For this scheme, the key-generation algorithm runs RSAGen to obtain (N, e, d) ; the public key consists of (N, e) , while the private key contains (N, d) . To encrypt a message $m \in \mathbb{Z}_N^*$ using the public key (N, e) , the sender computes $c := m^e \bmod N$. Given a ciphertext c thus computed, the message can be recovered by using the corresponding private key to compute

$$c^d \bmod N = (m^e)^d = m \bmod N.$$

It follows directly from the RSA assumption that if m is chosen uniformly from \mathbb{Z}_N^* , then an adversary who observes the ciphertext c cannot compute m in its entirety. But this, alone, is not a very satisfying guarantee! For one thing, a real-life message is unlikely to be random; in particular, it may very well correspond to some structured text. Furthermore, even in the case that m is random, the textbook RSA scheme provides no assurance that an adversary cannot deduce some partial information about m (and in fact, recovering some partial information about m is known to be possible). Finally, this scheme does not have randomized encryption; textbook RSA encryption thus cannot possibly be CPA-secure.

Randomized variants of textbook RSA, however, are used extensively in practice. For simplicity, we describe here a variant that roughly corresponds to the RSA PKCS #1 v1.5 standard [37]. (This standard has since been superseded by a later version which should be used instead.) Here, the message is randomly padded during encryption. That is, if N is a 2000-bit modulus, then encryption of an 800-bit message m can be done by choosing a random 200-bit string r and then computing

$$c = (r \parallel m)^e \bmod N;$$

decryption is done in the natural way. It is conjectured that this scheme is CPA-secure, though no proof based on the RSA assumption is known.

9.4.2 El Gamal Encryption

A second class of problems that can be used for public-key cryptography is related to the presumed hardness of the *discrete logarithm problem* in certain groups. This idea was introduced, in somewhat different form, by Diffie and Hellman in 1976 [11]. Our treatment will be abstract, though after introducing the basic ideas we will discuss some concrete instantiations.

Let \mathbb{G} be a finite, cyclic group of large prime order q , and let $g \in \mathbb{G}$ be a generator of \mathbb{G} . The fact that g is a generator implies that for any element $h \in \mathbb{G}$ there exists an $x \in \{0, \dots, q-1\} = \mathbb{Z}_q$ such that $g^x = h$. By analogy with logarithms over the real numbers, in this case we write $x = \log_g h$. The *discrete logarithm problem in \mathbb{G}* is to compute $\log_g h$ given h . For many groups (see below), this problem appears to be computationally infeasible. We may formalize this, the *discrete logarithm assumption in \mathbb{G}* , as follows: the discrete logarithm problem in \mathbb{G} is (t, ϵ) -hard if for all algorithms \mathcal{A} running in time at most t it holds that

$$\Pr[\mathcal{A}(h) = x \text{ s.t. } g^x = h] \leq \epsilon,$$

where the probability is taken over uniform choice of $h \in \mathbb{G}$.

For cryptographic applications, a stronger assumption is often needed. The **decisional Diffie–Hellman** problem is to distinguish tuples of the form (g^x, g^y, g^{xy}) (where x, y are chosen uniformly from \mathbb{Z}_q) from tuples of the form (g^x, g^y, g^z) (where x, y, z are chosen uniformly from \mathbb{Z}_q). We say the *decisional Diffie–Hellman problem is (t, ϵ) -hard in \mathbb{G}* if for all algorithms \mathcal{A} running in time at most t we have

$$\left| \Pr[\mathcal{A}(g^x, g^y, g^{xy}) = 1] - \Pr[\mathcal{A}(g^x, g^y, g^z) = 1] \right| \leq \epsilon,$$

where the probability space in each case is as described earlier. One way to solve the decisional Diffie–Hellman problem given a candidate tuple (g_1, g_2, g_3) is to compute $x = \log_g g_1$ and then check whether $g_3 \stackrel{?}{=} g_2^x$. We thus see that the decisional Diffie–Hellman problem in some group \mathbb{G} is no harder than the discrete logarithm problem in the same group. The converse is not, in general, true as there are candidate groups in which the discrete logarithm problem is hard but the decisional Diffie–Hellman problem is not. Nevertheless, for the groups discussed below, the stronger decisional Diffie–Hellman problem is widely believed to hold.

A classical example of a class of groups for which the above assumptions are believed to hold is given by large prime-order subgroups of \mathbb{Z}_p^* for p prime. As one concrete example, let $p = 2q + 1$, where both p and q are prime. Then the set of *quadratic residues* modulo p (namely, elements of \mathbb{Z}_p^* that can be written as squares of other elements) constitutes a subgroup $\mathbb{G} = \mathbb{Z}_p^{*\star}$ of order q . Another important example is given by the group of points over certain elliptic curves [43].

In their initial paper [11], Diffie and Hellman suggested a key-exchange protocol based on (what would later come to be called) the decisional Diffie–Hellman problem. This protocol was later adapted [12] to give the *El Gamal encryption scheme* that we describe now. Fix a group \mathbb{G} of prime order q , and generator $g \in \mathbb{G}$ as above. The key-generation algorithm simply chooses a random $x \in \mathbb{Z}_q$ which will be the private key; the public key is $h = g^x$. To encrypt a message $m \in \mathbb{G}$ with respect to the public key h , the sender chooses a random $y \in \mathbb{Z}_q$ and outputs the ciphertext $\langle g^y, h^y \cdot m \rangle$. Decryption of a ciphertext $\langle c_1, c_2 \rangle$ using the private key x is done by computing c_2/c_1^x . This recovers the correct result since

$$\frac{c_2}{c_1^x} = \frac{h^y \cdot m}{(g^y)^x} = \frac{(g^x)^y \cdot m}{g^{yx}} = \frac{g^{xy} \cdot m}{g^{yx}} = m.$$

It can be shown that the El Gamal encryption scheme is CPA-secure if the decisional Diffie–Hellman problem is hard in the underlying group \mathbb{G} .

9.4.3 Hybrid Encryption

In contrast to private-key encryption, which can be based on highly efficient block ciphers, current public-key encryption schemes involve arithmetic operations with “very large” integers. (Appropriate choice of parameters depends on numerous factors; the reader can think of operations on ≈ 1000 -bit numbers though that need not always be the case.) As a consequence, naive public-key encryption is orders of magnitude slower than private-key encryption.

When encrypting very long messages, however, *hybrid encryption* can be used to obtain the functionality of public-key encryption with the (asymptotic) efficiency of private-key encryption. Let Enc denote the encryption algorithm for some public-key scheme, and let Enc' denote the encryption algorithm for a private-key scheme using keys of length n . Hybrid encryption works as follows: to encrypt a (long) message m , the sender first chooses a random secret key $k \in \{0, 1\}^n$, encrypts k using Enc and the public key pk , and then encrypts m using Enc' and the key k . That is, the entire ciphertext is $\langle \text{Enc}_{pk}(k), \text{Enc}'_k(m) \rangle$. Decryption is done in the natural way, by recovering k from the first component of the ciphertext and then using k to decrypt the second part of the ciphertext. Note that the public-key scheme Enc is used only to encrypt a short key, while the bulk of the work is done using the more efficient private-key scheme.

One can show that hybrid encryption is CPA-secure if (1) the underlying public-key encryption scheme is CPA-secure and (2) the underlying private-key encryption scheme is indistinguishable. (CPA-security of the private-key encryption scheme is not necessary; intuitively, this is because the key k is generated freshly at random each time encryption is done, so any particular key is used only once.)

9.4.4 Stronger Security Notions

Our treatment of public-key encryption has only focused on security against passive attacks. As in the case of private-key encryption, however, in many scenarios security against an active adversary is also required. In fact, active attacks are arguably an even greater concern in the public-key setting where a recipient uses the same public key pk to communicate with multiple senders, some of whom may be malicious. (We refer to [27] for examples of some potential attacks.) To defend against this possibility, public-key encryption schemes satisfying stronger notions of security should be used; see [27] for details.

9.5 Digital Signature Schemes

As public-key encryption is to private-key encryption, so are digital signature schemes to MACs. That is, signature schemes allow a *signer* who has established a public key to “sign” messages in a way which is verifiable to anyone who knows the signer’s public key. Furthermore (by analogy with MACs), no adversary can forge a valid signature on any message that was not explicitly authenticated (i.e., signed) by the legitimate signer.

Formally, a signature scheme is comprised of three algorithms (Gen , Sign , Verify). The *key-generation algorithm* Gen is a probabilistic algorithm that outputs a pair of public and private keys (pk, sk) exactly as in the case of public-key encryption. The *signing algorithm* Sign takes as input a private key sk and a message m , and outputs a *signature* σ ; we denote this by $\sigma := \text{Sign}_{sk}(m)$. (One may assume this algorithm is deterministic without loss of generality.) Finally, the *verification algorithm* Verify takes as input a public key, a message, and a signature and outputs 0 or 1. If $\text{Verify}_{pk}(m, \sigma) = 1$, then we say that σ is a *valid signature* on m (with respect to pk). Analogous to the case of MACs, the correctness requirement is that for every (pk, sk) output by Gen , and for any message m , an honestly generated signature $\text{Sign}_{sk}(m)$ is always a valid signature on m .

A signature scheme can be used in the following way. User A locally generates (pk, sk) and widely publicizes her public key pk . She can then authenticate any desired message m by computing $\sigma := \text{Sign}_{sk}(m)$. Any other user B who has obtained a legitimate copy of A ’s public key can then verify that this message

was indeed certified by A by checking that $\text{Verf}_{Y_{pk}}(m, \sigma) \stackrel{?}{=} 1$. Note that in this case, in contrast to the case of public-key encryption, the owner of the public key acts as the sender rather than as the receiver.

Security for digital signature schemes is defined in a manner completely analogous to that of MACs. As there, we consider an adversary \mathcal{A} who is given access to an oracle $\text{Sig}_{sk}(\cdot)$; the adversary can submit messages of its choice to this oracle and obtain the corresponding valid signatures. In addition, here the adversary is also given the public key pk . Adversary \mathcal{A} succeeds if it can then output (m, σ) such that (1) m was not one of the messages m_1, \dots that \mathcal{A} had previously submitted to its oracle, and (2) σ is a valid signature on m ; that is, $\text{Verf}_{Y_{pk}}(m, \sigma) = 1$. A signature scheme is (t, ϵ) -secure if for all \mathcal{A} running in time at most t , the probability with which \mathcal{A} succeeds in this experiment (where the probability is taken over generation of (pk, sk)) is at most ϵ . This security notion is also called *existential unforgeability under adaptive chosen-message attack* [23].

Signature schemes offer several advantages relative to MACs. A basic advantage is that, once a signer's public key is widely distributed, that signer's signatures can be verified by *anyone*. (Contrast this to MACs, where a tag can only be verified by the party who shares the key with the sender.) As a result, signature schemes are suitable when "one-to-many" communication is required, with a canonical example being a software company releasing signed updates of its software. The very fact that signatures are publicly verifiable also implies their usefulness for *nonrepudiation*. That is, once a signer has issued a signature on a message, a recipient can prove that fact to someone else (a judge, say) by simply showing them the signature. (This makes digital signatures a potential replacement for handwritten signatures on legally binding documents.) On the other hand, for authenticating "short" messages, a signature scheme may be orders of magnitude less efficient than a MAC.

In the following sections, we briefly discuss two signature schemes in wide use today. Other schemes, some with better theoretical properties than those discussed here, can be found in [26]. Note that it suffices to construct a signature scheme for "short" messages; collision-resistant hashing can then be used, as in Section 9.3.1, to extend any such scheme for signing arbitrary-length messages.

9.5.1 RSA Signatures

We can use the RSA assumption introduced in Section 9.4.1 to construct signature schemes. We begin with a simple scheme that is insecure, and then discuss how to adapt it so as to make it resistant to attack.

At an intuitive level, signing a message must involve some operation that is "easy" for the signer who knows the private key corresponding to its own public key, but "difficult" for anyone who does *not* know the signer's private key. At the same time, the signature thus computed must be easy to verify for anyone knowing only the signer's public key. The RSA problem discussed earlier provides exactly this. Key generation is exactly the same as for RSA public-key encryption; that is, the algorithm runs `RSAGen` to obtain (N, e, d) , and outputs (N, e) and the public key, and (N, d) as the private key. To sign a message $m \in \mathbb{Z}_N^*$ using its private key, the signer computes $\sigma := m^d \bmod N$. Verification of a purported signature σ on a message m with respect to a public key (N, e) is done by checking whether $\sigma^e \stackrel{?}{=} m \bmod N$. Correctness holds for an honestly generated signature since

$$\sigma^e = (m^d)^e = m \bmod N.$$

Hardness of the RSA problem implies that it is infeasible for an adversary who knows only the signer's public key to generate a valid signature on a random message $m \in \mathbb{Z}_N^*$. But this is insufficient for security! In fact, the "textbook RSA" signature scheme just described is not secure. Here are two attacks:

1. An adversary knowing only the public key can easily construct a forgery by choosing an arbitrary $\sigma \in \mathbb{Z}_N^*$ and outputting this as the signature on the message $m = \sigma^e \bmod N$. Although m computed in this way may not be "meaningful," this attack is already enough to violate the

security definition. (In fact, the definition of what constitutes a “meaningful” message is context-dependent and so such an attack may be problematic in practice. Moreover, by repeatedly choosing random σ and following the same steps, the adversary may end up hitting upon a meaningful message.)

- Perhaps even worse, an adversary can forge a valid signature on an arbitrary message \hat{m} if it can get the signer to sign a single (different) message of the adversary’s choice. This attack begins by first having the adversary compute (m, σ) as above. Assume the adversary can then obtain a signature σ' (from the legitimate signer) on the message $m' = (\hat{m}/m) \bmod N$. The adversary then computes the signature $\hat{\sigma} = \sigma \cdot \sigma' \bmod N$ on \hat{m} . Note that $\hat{\sigma}$ is a valid signature on \hat{m} since

$$\hat{\sigma}^e = (\sigma \cdot \sigma')^e = \sigma^e \cdot (\sigma')^e = m \cdot m' = \hat{m} \bmod N.$$

The above shows that textbook RSA signatures are not secure. Fortunately, a simple modification prevents the above attacks: *hash* the message before signing it. That is, the signature on a message $m \in \{0, 1\}^*$ is now

$$\sigma = H(m)^d \bmod N,$$

where H is a hash function mapping arbitrary-length inputs to \mathbb{Z}_N^* . Verification is done in the natural way. It can be shown [6] that this scheme is secure if the RSA problem is hard and if, in addition, H “acts like a random function” in a sense we do not define here; see [5,27] for further discussion.

9.5.2 The Digital Signature Standard

The Digital Signature Algorithm (DSA), included as part of the Digital Signature Standard (DSS) [1,16], is another widely used signature scheme. Its security is related (though not known to be equivalent) to the hardness of computing discrete logarithms in a specific group \mathbb{G} . Specifically, \mathbb{G} is taken to be a subgroup of \mathbb{Z}_p^* of order q where both p and q are large primes. Let g be a generator of \mathbb{G} , and let H be a cryptographic hash function that, for simplicity, we view as mapping arbitrary-length inputs to \mathbb{Z}_q . (As will be clear, for security to hold H must at least be collision resistant.) Key generation works by choosing a random $x \in \mathbb{Z}_q$ and setting $y = g^x \bmod p$; the public key is y and the private key is x . To sign a message $m \in \{0, 1\}^*$, the signer generates a random $k \in \mathbb{Z}_q$ and computes

$$\begin{aligned} r &= (g^k \bmod p) \bmod q \\ s &= (H(m) + xr) \cdot k^{-1} \bmod q; \end{aligned}$$

the signature is (r, s) . Verification of signature (r, s) on message m with respect to public key y is done by checking that $r, s \in \mathbb{Z}_q^*$ and

$$r \stackrel{?}{=} (g^{H(m)s^{-1}} \cdot y^{rs^{-1}} \bmod p) \bmod q.$$

No proof of security for DSA is known; we refer the reader to a survey article by Vaudenay [42] for further discussion. See [26] and references therein for other signature schemes whose security can be proved equivalent to the discrete logarithm or Diffie–Hellman problems.

Key Terms

Block cipher: An efficient instantiation of a pseudorandom function that has the additional property of being efficiently invertible.

Chosen-plaintext attack: An attack on an encryption scheme in which an adversary causes the sender to encrypt messages of the adversary's choice.

Ciphertext: The result of encrypting a message.

Collision-resistant hash function: A hash function for which it is infeasible to find two different inputs mapping to the same output.

Computational security: Provides security against computationally bounded adversaries, assuming the computational hardness of some problem.

Data integrity: Ensuring that modifications to a communicated message are detected.

Data secrecy: Hiding the contents of a communicated message.

Decrypt: To recover the original message from the ciphertext.

Digital signature scheme: A method for providing data integrity in the public-key setting.

Encrypt: To apply an encryption scheme to a plaintext message.

Hash function: A cryptographic function mapping arbitrary-length inputs to fixed-length outputs.

Information-theoretic security: Provides security even against computationally unbounded adversaries.

Key: The secret shared by parties in the private-key setting. Also used for the public and private values generated by a party in the public-key setting.

Message authentication code: A method for providing data integrity in the private-key setting.

Mode of encryption: A method for using a block cipher to encrypt arbitrary-length messages.

One-time pad: A private-key encryption scheme achieving perfect secrecy.

Plaintext: The communicated data, or message.

Private-key encryption: Technique for ensuring data secrecy in the private-key setting.

Private-key setting: Setting in which communicating parties share a secret in advance of their communication.

Pseudorandom function: A keyed function which is indistinguishable from a truly random function.

Public-key encryption: Technique for ensuring data secrecy in the public-key setting.

Public-key setting: Setting in which parties generate public/private keys and widely disseminate their public key.

RSA cryptography: Cryptography based on the hardness of computing e th roots modulo a number N that is the product of two large primes.

Further Information

The textbook by this author and Yehuda Lindell [27] covers the material of this survey, and more, in extensive detail. The online notes of Bellare and Rogaway [7] are also quite useful. The books by Smart [39] and Stinson [41] give slightly different perspectives on the material. Readers looking for a more advanced treatment may consult the texts by Goldreich [18,19]. More applied aspects of cryptography can be found in the book by Stallings [40] or the comprehensive (though now somewhat outdated) *Handbook of Applied Cryptography* [32].

The International Association for Cryptologic Research (IACR) sponsors the *Journal of Cryptology* along with a number of conferences, with Crypto and Eurocrypt being the best known. Proceedings of these conferences (dating, in some cases, to the early 1980s) are published as part of Springer-Verlag's *Lecture Notes in Computer Science*. Research in theoretical cryptography often appears at the ACM Symposium on Theory of Computing, the IEEE Symposium on Foundations of Computer Science, and elsewhere; more applied aspects of cryptography are frequently published in security conferences including the ACM Conference on Computer and Communications Security. Articles on cryptography also appear in the *Journal of Computer and System Sciences*, the *Journal of the ACM*, and the *SIAM Journal on Computing*.

10.1 Introduction

Algebraic algorithms deal with numbers, vectors, matrices, polynomials, formal power series, exponential and differential polynomials, rational functions, algebraic sets, curves, and surfaces. In this vast area, manipulation with matrices and polynomials is fundamental for modern computations in sciences and engineering. The list of the respective computational problems includes the solution of a polynomial equation and linear and polynomial systems of equations, univariate and multivariate polynomial evaluation, interpolation, factorization and decompositions, rational interpolation, computing matrix factorization and decompositions (which in turn include various triangular and orthogonal factorizations such as LU, PLU, QR, QRP, QLP, CS, LR, Cholesky factorizations, and eigenvalue and singular value decompositions), computation of the matrix characteristic and minimal polynomials, determinants, Smith and Frobenius normal forms, ranks, and (generalized) inverses, univariate and

Tsigaridas). Sections 10.3.5, 10.5, and “Further information” have been written jointly by all authors, Section 10.4 has been contributed essentially by the first author, the other sections by the second author.

multivariate polynomial resultants, Newton's polytopes, greatest common divisors (GCDS), and least common multiples as well as manipulation with truncated series and algebraic sets.

Such problems can be solved by using the error-free symbolic computations with infinite precision. Computer algebra systems such as Maple and Mathematica compute the solutions based on various non-trivial computational techniques such as modular computations, the Euclidean algorithm and continuous fraction approximation, Hensel's and Newton's lifting, Chinese remainder algorithm, elimination and resultant methods, and Gröbner bases computation. The price to achieve perfect accuracy is the substantial memory space and computer time required to support the computations.

The alternative numerical methods rely on operations with binary or decimal numbers truncated or rounded to a fixed precision. Operating with the IEEE standard floating point numbers represented with single or double precision enables much faster computations using much smaller memory but requires theoretical and/or experimental study of the impact of rounding errors on the output. The study involves forward and backward error analysis, linear and nonlinear operators, and advanced techniques from approximation and perturbation theories. Solution of some problems involves more costly computations with extended precision. The resulting algorithms support high performance libraries and packages of subroutines such as those in Matlab, NAG SMP, LAPACK, ScaLAPACK, ARPACK, PARPACK, MPSolve, and EigenSolve.

In this chapter, we cover both approaches, whose combination frequently increases their power and enables more effective computations. We focus on the algebraic algorithms in the large, popular, and highly important fields of matrix computations and root-finding for univariate polynomials and systems of multivariate polynomials. We cover part of these huge subjects and include basic bibliography for further study. To meet space limitation we cite books, surveys, and comprehensive articles with pointers to further references, rather than including all the original technical papers. Our expositions in Sections 10.2 and 10.3 follow the line of the first surveys in this area in [163,168,173–175].

We state the complexity bounds under the RAM (random access machine) model of computation [1,96]. In most cases we assume the *arithmetic* model, that is we assign a unit cost to addition, subtraction, multiplication, and division of real numbers, as well as to reading or writing them into a memory location. This model is realistic for computations with a fixed (e.g., the IEEE standard single or double) precision, which fits the size of a computer word, and then the arithmetic model turns into the *word* model [96]. In other cases we allow working with extended precision and assume the *Boolean* or *bit* model, assigning a unit cost to every Boolean or bitwise operation. This accounts for both arithmetic operations and the length (precision) of the operands. We denote the bounds for this complexity by $\tilde{O}_B(\cdot)$. We explicitly specify whether we use the arithmetic, word, or Boolean model unless this is clear from the context.

We write *ops* for “arithmetic operations,” “log” for “ \log_2 ” unless specified otherwise, and $\tilde{O}_B(\cdot)$ to show that we are ignoring logarithmic factors.

10.2 Matrix Computations

Matrix computations are the most popular and a highly important area of scientific and engineering computing. Most frequently they are performed numerically, with values represented using the IEEE standard single or double precision. In the chapter of this size we must omit or just barely touch on many important subjects of this field. The reader can find further material and bibliography in the surveys [163,168] and the books [6,8,21,56,62,64,103,110,178,222,227,239] and for more specific subject areas in [6,103,222,227,237,239] on eigendecomposition and SVD, [8,56,62,103,110,222,227] on other numerical matrix factorizations, [23,130] on the over- and underdetermined linear systems, their least-squares solution, and various other numerical computations with singular matrices, [106] on randomized matrix computations, [114,178] on structured matrix computations, [21,103,172,210] on parallel matrix algorithms, and [43,47,66,67,96,97,115,116,169,172,183,202,226,238] on “Error-free Rational Matrix Computations,” including computations over finite fields, rings, and semirings that produce

solutions to linear systems of equations, matrix inverses, ranks, determinants, characteristic and minimal polynomials, and Smith and Frobenius normal forms.

10.2.1 Dense, Sparse, and Structured Matrices: Their Storage and Multiplication by Vectors

An $m \times n$ matrix $A = [a_{i,j}, i = 1, \dots, m; j = 1, \dots, n]$ is also denoted $[a_{i,j}]_{i,j=1}^{m,n}$ and $[\mathbf{A}_1 \mid \dots \mid \mathbf{A}_m]$; it is a two-dimensional array with the (i, j) th entry $[A]_{i,j} = a_{i,j}$ and the j th column \mathbf{A}_j . A^T is the transpose of A . Matrix A is a column vector if $n = 1$ and a row vector if $m = 1$. Vector $\mathbf{v} = [v_i]_{i=1}^n$ is an n th dimensional column vector. The straightforward algorithm computes the product $\mathbf{A}\mathbf{v}$ by performing $(2n - 1)m$ ops; this is optimal for general (dense unstructured) $m \times n$ matrices, represented with their entries, but numerous applications involve structured matrices represented with much fewer than mn scalar values. A matrix is singular if its product by some vectors vanish; they form its *null space*.

An $m \times n$ matrix is *sparse* if it is filled mostly with zeros, having only $\phi = o(mn)$ nonzero entries. An important class is the matrices associated with graphs that have *families of small separators* [102,134]. This includes *banded* matrices $[b_{i,j}]_{i,j}$ with small *bandwidth* $2w + 1$ such that $b_{i,j} = 0$ unless $|i - j| \leq w$. A sparse matrix can be stored economically by using appropriate data structures and can be multiplied by a vector fast, in $2\phi - m$ ops. Sparse matrices arise in many important applications, for example, to solving ordinary and partial differential equations (ODEs and PDEs) and graph computations.

Dense structured $n \times n$ matrices are usually defined by $O(n)$ parameters, and one can apply FFT to multiply such matrix by a vector by using $O(n \log n)$ or $O(n \log^2 n)$ ops [178]. Such matrices are omnipresent in applications in signal and image processing, coding, ODEs, PDEs, particle simulation, and Markov chains. Most popular among them are the *Toeplitz matrices* $T = [t_{i,j}]_{i,j=1}^{m,n}$ and the *Hankel matrices* $H = [h_{i,j}]_{i,j=1}^{m,n}$ where $t_{i,j} = t_{i+1,j+1}$ and $h_{i,j} = h_{i+1,j-1}$ for all i and j in the range of their definition. Each such matrix is defined by $m + n - 1$ entries of its first row and first or last column. Products $T\mathbf{v}$ and $H\mathbf{v}$ can be equivalently written as polynomial products or vector convolutions; their FFT-based computation takes $O((m + n) \log(m + n))$ ops per product [1,21,178]. Many other fundamental computations with Toeplitz and other structured matrices can be linked to polynomial computations enabling acceleration in both areas of computing [17–21,24,81,85,150–152,168,172,178,187,207,208]. Similar properties hold for Vandermonde matrices $V = [v_i^j]_{i,j=0}^{m-1,n-1}$ and Cauchy matrices $C = \left[\frac{1}{s_i - t_j} \right]_{i,j=1}^{m,n}$ where s_i and t_j denote $m + n$ distinct scalars.

One can extend the structures of *Hankel*, *Bézout*, *Sylvester*, *Frobenius (companion)*, *Vandermonde*, and *Cauchy* matrices to more general classes of matrices by associating linear displacement operators. (See [21,178] for the details and the bibliography.) The important classes of *semiseparable*, *quasiseparable*, and other *rank structured* $m \times n$ matrices generalize banded matrices and their inverses; they are expressed by $O(m + n)$ parameters and can be multiplied by vectors by performing $O(m + n)$ ops [68, 231].

10.2.2 Matrix Multiplication, Factorization, and Randomization

The straightforward algorithm computes the $m \times p$ product AB of $m \times n$ by $n \times p$ matrices by using $2mnp - mp$ ops, which is $2n^3 - n^2$ if $m = n = p$. This upper bound is not sharp. Strassen decreased it to $O(n^{2.81})$ ops in 1969. His result was first improved in [162] and 10 times afterward, most recently by Coppersmith and Winograd in [48], Stothers in [224], and Vasilevska Williams in [233], who use Cn^ω ops for $\omega < 2.376$, $\omega < 2.374$, and $\omega < 2.3727$, respectively. Due to the huge overhead constants C , however, we have that $Cn^\omega < 2n^3$ only for enormous values n . The well-recognized group-theoretic techniques [44] enable a distinct description of the known matrix multiplication algorithms, but so far have only supported the same upper bounds on the complexity as the preceding works. References [224,233] extend the algorithms given in Reference [48], which in turn combines arithmetic progression technique with the previous advanced techniques. Each technique, however, contributes to a dramatic increase of the overhead constant that makes the resulting algorithms practically noncompetitive.

The only exception is the *trilinear aggregating* technique of [161] (cf. [163]), which alone supports the exponent 2.7753 [128] and together with the any precision approximation techniques of [163] was an indispensable ingredient of all algorithms that have beaten Strassen’s exponent 2.81 of 1969. The triple product property, which is the basis of [44], may very well have a natural link to trilinear aggregating, although the descriptions available for the two approaches are distinct. For matrices of realistic sizes the numerical algorithms in [118], relying on trilinear aggregating, use about as many ops as the algorithms of Strassen 1969 and Winograd 1971 but need substantially less memory space and are more stable numerically.

The exponent ω of matrix multiplication is fundamental for the theory of computing because $O(n^\omega)$ or $O(n^\omega \log n)$ bounds the complexity of many important matrix computations such as the computation of $\det A$, the *determinant* of an $n \times n$ matrix A ; its *inverse* A^{-1} (where $\det A \neq 0$); its *characteristic polynomial* $c_A(x) = \det(xI - A)$ and *minimal polynomial* $m_A(x)$, for a scalar variable x ; the Smith and Frobenius normal forms; the *rank*, $\text{rank } A$; a submatrix of A having the maximal rank, the solution vector $\mathbf{x} = A^{-1} \mathbf{v}$ to a nonsingular *linear system of equations* $A \mathbf{x} = \mathbf{v}$, and various *orthogonal* and *triangular factorizations* of the matrix A , as well as various *computations with singular matrices* and seemingly unrelated combinatorial and graph computations, for example, pattern recognition or computing all pair shortest distances in a graph [21, p. 222] or its transitive closure [1]. Consequently, all these operations use $O(n^\omega)$ ops where theoretically $\omega < 2.3727$ [1, Chapter 6], [21, Chapter 2]. In practice, however, the solution of all these problems takes order of n^3 ops, because of the huge overhead constant C of all known algorithms that multiply $n \times n$ matrices in Cn^ω ops for $\omega < 2.775$, the overhead of the reduction to a matrix multiplication problem, the memory space requirements, and numerical stability problems [103].

Moreover, the straightforward algorithm for matrix multiplication remains the users’ choice because it is highly effective on parallel and pipeline architectures [103,210]; on many computers it supersedes even the so-called “superfast” algorithms, which multiply a pair of $n \times n$ structured matrices in nearby linear arithmetic time, namely, by using $O(n \log n)$ or $O(n \log^2 n)$ ops, where both input and output matrices are represented with their short generator matrices having $O(n)$ entries [178].

Numerous important practical problems have been reduced to matrix multiplication because it is so effective. This has also motivated the development of block matrix algorithms (called *level-three BLAS*, which is the acronym for Basic Linear Algebra Subprograms).

Devising asymptotically fast matrix multipliers, however, had independent technical interest. For example, trilinear aggregating was a nontrivial decomposition of the three-dimensional tensor associated with matrix multiplication, and [161] was the first of now numerous examples where nontrivial tensor decompositions enable dramatic acceleration of important matrix computations [124,137,160].

The two basic techniques below extend matrix multiplication. Hereafter O denotes matrices filled with zeros; I is the square identity matrices, with ones on the diagonal and zeros elsewhere.

Suppose we seek the *Krylov sequence* or *Krylov matrix* $[B^i \mathbf{v}]_{i=0}^{k-1}$ for an $n \times n$ matrix B and an n -dimensional vector \mathbf{v} [103,104,238]; in block Krylov computations the vector \mathbf{v} is replaced by a matrix. The straightforward algorithm uses $(2n - 1)n(k - 1)$ ops, that is about $2n^3$ for $k = n$. An alternative algorithm first computes the matrix powers

$$B^2, B^4, B^8, \dots, B^{2^s}, \quad s = \lceil \log k \rceil - 1$$

and then the products of $n \times n$ matrices B^{2^i} by $n \times 2^i$ matrices, for $i = 0, 1, \dots, s$:

$$\begin{aligned} B & \quad \mathbf{v}, \\ B^2 & \quad [\mathbf{v}, B\mathbf{v}] = [B^2\mathbf{v}, B^3\mathbf{v}], \\ B^4 & \quad [\mathbf{v}, B\mathbf{v}, B^2\mathbf{v}, B^3\mathbf{v}] = [B^4\mathbf{v}, B^5\mathbf{v}, B^6\mathbf{v}, B^7\mathbf{v}] \\ & \quad \vdots \end{aligned}$$

The last step completes the evaluation of the Krylov sequence in $2s + 1$ matrix multiplications, by using $O(n^w \log k)$ ops overall.

Special techniques for parallel computation of Krylov sequences for sparse and/or structured matrices A can be found in [170]. According to these techniques, Krylov sequence is recovered from the solution to the associated linear system $(I - A) \mathbf{x} = \mathbf{v}$, which is solved fast in the case of a special matrix A .

Another basic idea of matrix algorithms is to represent the input matrix A as a block matrix and to operate with its blocks rather than with its entries. For example, one can compute $\det A$ and A^{-1} by first factorizing A as a 2×2 block matrix,

$$A = \begin{bmatrix} I & O \\ A_{1,0}A_{0,0}^{-1} & I \end{bmatrix} \begin{bmatrix} A_{0,0} & O \\ O & S \end{bmatrix} \begin{bmatrix} I & A_{0,0}^{-1}A_{0,1} \\ O & I \end{bmatrix} \quad (10.1)$$

where $S = A_{1,1} - A_{1,0}A_{0,0}^{-1}A_{0,1}$. The 2×2 block triangular factors are readily invertible, $\det A = (\det A_{0,0})\det S$ and $(BCD)^{-1} = D^{-1}C^{-1}B^{-1}$, and so the cited tasks for the input A are reduced to the same tasks for the half-size matrices $A_{0,0}$ and S . It remains to factorize them recursively. The northwestern blocks (such as $A_{0,0}$), called leading principal submatrices, must be nonsingular throughout the recursive process, but this property holds for the highly important class of *symmetric positive definite* matrices $A = C^TC$, $\det C \neq 0$, and can be also achieved by means of symmetrization, pivoting, or randomization [1, Chapter 6], [21, Chapter 2], [178, Sections 5.5 and 5.6]). Recursive application of (10.1) should produce the LDU factorization $A = LDU$ where the matrices L and U^T are lower triangular and D diagonal. Having this factorization computed, we can readily solve linear systems $A\mathbf{x}_i = \mathbf{b}_i$ for various vectors \mathbf{b}_i , by using about $2n^2$ ops for each i , rather than $\frac{2}{3}n^3 + O(n^2)$ in Gaussian elimination.

Factorizations (including PLU, QR, QRP, QLP, CS, LR, Cholesky factorizations, and eigenvalue and singular value decompositions) are the most basic tool of matrix computations (see, e.g., [222]), recently made even more powerful with *randomization* (see [106,186,188,193–196,198], and the bibliography therein). It is well known that random matrices tend to be nonsingular and well conditioned (see, e.g., [217]), that is they lie far from singular matrices and therefore [103,110,222] are not sensitive to rounding errors and are suitable for numerical computations. The solution $\mathbf{x} = A^{-1}\mathbf{b}$ of a nonsingular linear system $A\mathbf{x} = \mathbf{b}$ of n equations can be obtained with a precision p_{out} in $O_B(n^3p + n^2p_{\text{out}})$ Boolean time for a fixed low precision p provided the matrix A is well conditioned; that accelerates Gaussian elimination by an order of magnitude for large $n + p_{\text{out}}$. Recent randomization techniques in [106,186,188,193–196,198] extend this property to much larger class of linear systems and enhance the power of various other matrix computations with singular or ill-conditioned matrices, for example, their approximation by low-rank matrices, computing a basis for the null space of a singular matrix, and approximating such bases for nearly singular matrices. Similar results have been proved for rectangular and Toeplitz matrices.

We refer the reader to [99,106,217] on impressive progress achieved in many other areas of matrix computations by means of randomization techniques.

10.2.3 Solution of Linear Systems of Equations

The solution of a linear system of n equations, $A\mathbf{x} = \mathbf{b}$, is the most frequent operation in scientific and engineering computations and is highly important theoretically. Gaussian elimination solves such a system by applying $(2/3)n^3 + O(n^2)$ ops.

Both Gaussian elimination and (*Block*) *Cyclic Reduction* use $O(nw^2)$ ops for banded linear systems with bandwidth $O(w)$. One can solve rank structured linear systems in $O(n)$ ops [68,231]; generalized nested dissection uses $O(n^{1.5})$ flops for the inputs associated with small separator families [134,169,202].

Likewise, we can dramatically accelerate Gaussian elimination for dense structured input matrices represented with their short generators, defined by the associated *displacement operators*.

This includes Toeplitz, Hankel, Vandermonde, and Cauchy matrices as well as matrices with similar structures. The MBA divide-and-conquer “superfast” algorithm (due to Morf 1974/1980 and Bitmead and Anderson 1980) solves nonsingular structured linear systems of n equations in $O(n \log^2 n)$ ops by applying the recursive 2×2 block factorization (10.1) and preserving matrix structure [21,178,191,205]. In the presence of rounding errors, however, Gaussian elimination, the MBA and Cyclic Reduction algorithms easily fail unless one applies pivoting, that is interchanges the equations (and sometimes unknowns) to avoid divisions by absolutely small numbers. A by-product is the factorization $A = PLU$ or $A = PLUP'$, for lower triangular matrices L and U^T and permutation matrices P and P' .

Pivoting, however, takes its toll. It “usually degrades the performance” [103, p. 119] by interrupting the string of arithmetic computations with the foreign operations of comparisons, is not friendly to block matrix algorithms and updating input matrices, hinders parallel processing and pipelining, and tends to destroy structure and sparseness, except for the inputs that have Cauchy-like and Vandermonde-like structure. The latter exceptional classes have been extended to the inputs with structures of Toeplitz/Hankel type by means of *displacement transformation* [167,178]. The users welcome this numerical stabilization, even though it slows down the MBA algorithm by a factor of $n/\log^2 n$, that is from “superfast” to “fast,” which is still by a factor of n faster than the solution for general unstructured inputs, which takes order n^3 ops.

Can we avoid pivoting in numerical algorithms with rounding for general, sparse and structured linear systems to achieve both numerical stability and superfast performance? Yes, for the important classes where the input matrices $A = (a_{ij})_{i,j}$ are diagonally dominant, that is $|a_{ii}| > \sum_{i \neq j} |a_{ij}|$ or $|a_{ii}| > \sum_{j \neq i} |a_{ij}|$ for all i , or symmetric positive definite, that is $A = C^T C$ for a nonsingular matrix C . To these input classes Gaussian elimination, cyclic reduction, and the MBA algorithm can be safely applied with rounding and with no pivoting. For some other classes of sparse and positive definite linear systems, pivoting has been modified into nested dissection, Markowitz heuristic rule, and other techniques that preserve sparseness during the elimination yielding faster solution without causing numerical problems [62,101,134,169,202]. Can we extend these benefits to other input matrix classes?

Every nonsingular linear system $A\mathbf{x} = \mathbf{b}$ is equivalent to the symmetric positive definite ones $A^T A\mathbf{x} = A^T \mathbf{b}$ and $A A^T \mathbf{y} = \mathbf{b}$ where $\mathbf{x} = A\mathbf{y}$, but great caution is recommended in such symmetrizations because the condition number $\kappa(A) = \|A\|_2 \|A^{-1}\|_2 \geq 1$ is squared in the transition to the matrices $A^T A$ and $A A^T$, which means growing propagation and magnification of rounding errors.

There are two superior directions. The algorithms of [195,196,199] avoid pivoting for general and structured linear systems by applying randomization. These techniques are recent, proposed in [186, Section 12.2], but their effectiveness has formal and experimental support.

A popular classical alternative to Gaussian elimination is the iterative solution, for example, by means of the conjugate gradient and GMRES algorithms [10,103,104,232]. They compute sufficiently long Krylov sequences (defined in the previous section) and then approximate the solution with linear combinations $\sum_i c_i A^i \mathbf{b}$ or $\sum_i c_i (A^T A)^i A^T \mathbf{b}$ for proper coefficients c_i . The cost of computing the product of the matrix A or $A^T A$ by a vector is dominant, but it is small for structured and sparse matrices A . One can even call a matrix sparse or structured if and only if it can be multiplied by a vector fast.

Fast convergence to the solution is critical. It is not generally guaranteed but proved for some important classes of input matrices. The major challenges are the extension of these classes and the design of powerful methods for special input classes, notably *multilevel methods* (based on the *algebraic multigrid*) [140,149,201] and tensor decompositions [124,160], highly effective for many linear systems arising in discretization of ODEs, PDEs, and integral equations.

Preconditioning of the input matrices at a low computational cost accelerates convergence of iterations for many important classes of sparse and structured linear systems [10,104], and more recently, based on randomized preconditioning, for quite general as well as structured linear systems [186,188,193–196,198].

One can iteratively approximate the inverse or pseudoinverse of a matrix [103, Section 5.5.4] by means of Newton's iteration $X_{i+1} = 2X_i - X_i M X_i$, $i = 0, 1, \dots$. We have $I - M X_{i+1} = (I - M X_i)^2 = (I - M X_0)^{2^{i+1}}$; therefore, the residual norm $\|I - M X_i\|$ is squared in every iteration step, $\|I - M X_i\| \leq \|I - M X_0\|^{2^i}$ for $i = 1, 2, \dots$, and so convergence is very fast unless $\|I - M X_0\| \geq 1$ or is near 1. The cost of two matrix multiplications is dominant per an iteration step; this makes the computation fast on multiprocessors as well as in the case of structured matrices M and X_i . See more on Newton's iteration, including the study of its initialization, convergence, and preserving displacement matrix structure, in [178, Chapters 4 and 6], [182,185,189,200,203,204].

10.2.4 Symbolic Matrix Computations

Rational matrix computations for a rational or integer input (such as the solution of a linear system and computing the determinant of a matrix) can be performed with no errors. To decrease the computational cost, one should control the growth of the precision of computing. Some special techniques achieve this in rational Gaussian elimination [7,97]. As a more fundamental tool one can reduce the computations modulo a sufficiently large integer m to obtain the rational or integer output values $z = p/q$ (e.g., the solution vector for a linear system) modulo m . Then we can recover z from two integers m and $z \bmod m$ by applying the continued fraction approximation algorithm, in other contexts called Euclidean algorithm [96,236]. Instead we can readily obtain $z = z \bmod m$ if $z \bmod m < r$ or $z = -m + z \bmod m$ if $z \bmod m < r$ otherwise, provided we know that the integer z lies in the range $[-r, r]$ and if $m > 2r$.

Computing the determinant of an integer matrix, we can choose the modulus m based on Hadamard's bound. A nonsingular linear system $A\mathbf{x} = \mathbf{v}$ can become singular after the reduction modulo a prime p but only with a low probability for a random choice of a prime p in a fixed sufficiently large interval as well as for a reasonably large power of two and a random integer matrix [205].

One can choose $m = m_1 m_2 \cdots m_k$ for pairwise relatively prime integers m_1, m_2, \dots, m_k (we call them *coprimes*), then compute z modulo all these coprimes, and finally recover z by applying the Chinese remainder algorithm [1,96]. The error-free computations modulo m_i require the precision of $\log m_i$ bits; the cost of computing the values $z \bmod m_i$ for $i = 1, \dots, k$ dominates the cost of the subsequent recovery of the value $z \bmod m$.

Alternatively one can apply *p-adic (Newton–Hensel) lifting* [96]. For solving linear systems of equations and matrix inversion they can be viewed as the symbolic counterparts to iterative refinement and Newton's iteration of the previous section, both well known in numerical linear algebra [183].

Newton's lifting begins with a prime p , a larger integer k , an integer matrix M , and its inverse $Q = M^{-1} \bmod p$, such that $I - QM \bmod p = 0$. Then, one writes $X_0 = Q$, recursively computes the matrices $X_j = 2X_{j-1} - X_{j-1} M X_{j-1} \bmod (p^{2^j})$, notes that $I - X_j M = 0 \bmod (p^{2^j})$ for $j = 1, 2, \dots, k$, and finally recovers the inverse matrix M^{-1} from $X_k = M^{-1} \bmod p^{2^k}$.

Hensel's lifting begins with the same input complemented with an integer vector \mathbf{b} . Then one writes $\mathbf{r}^{(0)} = \mathbf{b}$, recursively computes the vectors

$$\mathbf{u}^{(i)} = Q\mathbf{r}^{(i)} \bmod p, \quad \mathbf{r}^{(i+1)} = (\mathbf{r}^{(i)} - M\mathbf{u}^{(i)})/p, \quad i = 0, 1, \dots, k-1$$

and $\mathbf{x}^{(k)} = \sum_{i=0}^{k-1} \mathbf{u}^{(i)} p^i$ such that $M\mathbf{x}^{(k)} = \mathbf{b} \bmod (p^k)$, and finally recovers the solution \mathbf{x} to the linear system $M\mathbf{x} = \mathbf{b}$ from the vector $\mathbf{x}^{(k)} = \mathbf{x} \bmod (p^k)$.

Newton's and Hensel's lifting are particularly powerful where the input matrices M and M^{-1} are sparse and/or structured, for example, Toeplitz, Hankel, Vandermonde, Cauchy. Hensel's lifting enables the solution in nearly optimal time under both Boolean and word models [183]. We can choose p being a power of two and use computations in the binary mode. Reference [69] discusses lifting for sparse linear systems.

10.2.5 Computing the Sign and the Value of a Determinant

The value or just the sign of $\det A$, the determinant of a square matrix A , is required in some fundamental geometric and algebraic/geometric computations such as the computation of convex hulls, Voronoi diagrams, algebraic curves and surfaces, multivariate and univariate resultants, and Newton's polytopes. Faster numerical methods are preferred as long as the correctness of the output can be certified. In the customary *arithmetic filtering* approach, one applies fast numerical methods as long as they work and, in the rare cases when they fail, shifts to the slower symbolic methods. For fast numerical computation of $\det A$ one can employ factorizations $A = PLUP'$ (see Section 10.2.2) or $A = QR$ [45,103], precondition the matrix A [186], and then certify the output sign [206].

If A is a rational or integer matrix, then the Chinese remainder algorithm of the previous subsection is highly effective, particularly using heuristics for working modulo m for m much smaller than Hadamard's bound on $|\det A|$ [26].

Alternatively [70,165,166], one can solve linear systems $Ay(i) = \mathbf{b}(i)$ for random vectors $\mathbf{b}(i)$ and then apply Hensel's lifting to recover $\det A$ as a least common denominator of the rational components of all $y(i)$.

Storjohann in [223] advanced randomized Newton's lifting to yield $\det A$ more directly in the optimal asymptotic Boolean time $\tilde{O}_B(n^{\omega+1})$ for $\omega < 2.3727$. Wiedemann in 1986, Coppersmith in 1994, and a number of their successors compute $\det A$ by extending the Lanczos and block Lanczos classical algorithms. This is particularly effective for sparse or structured matrices A and in further extension to multivariate determinants and resultants (cf. [85,86,117,180]).

10.3 Polynomial Root-Finding and Factorization

10.3.1 Computational Complexity Issues

Approximate solution of an n th degree polynomial equation,

$$p(x) = \sum_{i=0}^n p_i x^i = p_n \prod_{j=1}^n (x - z_j) = 0, \quad p_n \neq 0 \quad (10.2)$$

that is the approximation of the roots z_1, \dots, z_n for given coefficients p_0, \dots, p_n , is a classical problem that has greatly influenced the development of mathematics and computational mathematics throughout four millennia, since the Sumerian times [173,174]. The problem remains highly important for the theory and practice of the present day algebraic and algebraic/geometric computation, and new root-finding algorithms appear every year [141–144].

To approximate even a single root of a monic polynomial $p(x)$ within error bound 2^{-b} we must process at least $(n+1)nb/2$ bits of the input coefficients p_0, \dots, p_{n-1} . Indeed perturb the x -free coefficient of the polynomial $(x - 6/7)^n$ by 2^{-bn} . Then the root $x = 6/7$ jumps by 2^{-b} , and similarly if we perturb the coefficients p_i by $2^{(i-n)b}$ for $i = 1, \dots, n-1$. Thus to ensure the output precision of b bits, we need an input precision of at least $(n-i)b$ bits for each coefficient p_i , $i = 0, 1, \dots, n-1$. We need at least $[(n+1)nb/4]$ bitwise operations to process these bits, each operation having at most two input bits.

It can be surprising, but we can approximate all n roots within 2^{-b} by using bn^2 Boolean (bit) operations up to a polylogarithmic factor for b of order $n \log n$ or higher, that is we can approximate all roots about as fast as we write down the input. We achieve this by applying the *divide-and-conquer algorithms* in [171,173,179] (see [123,157,218] on the related works). The algorithms first compute a sufficiently wide root-free annulus A on the complex plane, whose exterior and interior contain comparable numbers of the roots, that is the same numbers up to a fixed constant factor. Then the two factors of $p(x)$ are numerically computed, that is $F(x)$, having all its roots in the interior of the annulus, and $G(x) = p(x)/F(x)$, having no roots there. Then the polynomials $F(x)$ and $G(x)$ are recursively factorized until factorization

of $p(x)$ into the product of linear factors is computed numerically. From this factorization, approximations to all roots of $p(x)$ are obtained. For approximation of a single root see the competitive algorithms of [177].

It is interesting that, up to polylog factors, both lower and upper bounds on the Boolean time decrease to bn [179] if we only seek the factorization of $p(x)$, that is, if instead of the roots z_j , we compute scalars a_j and b_j such that

$$\|p(x) - \prod_{j=1}^n (a_j x - c_j)\| < 2^{-b} \|p(x)\| \quad (10.3)$$

for the polynomial norm $\|\sum_i q_i x^i\| = \sum_i |q_i|$.

The *isolation of the zeros* of a polynomial $p(x)$ of (10.2) having integer coefficients and simple zeros is the computation of n disjoint discs, each containing exactly one root of $p(x)$. This can be a bottleneck stage of root approximation because one can contract such discs by performing a few subdivisions and then apply numerical iterations (such as Newton's) that would very rapidly approximate the isolated zeros within a required tolerance. Reference [184] yields even faster refinement by extending the techniques of [171,173,179].

Based on the classical gap theorem (recently advanced in [84]), Schönhage in [218, Section 20] the isolation problem has been reduced to computing factorization (10.3) for $b = \lceil (2n+1)(l+1+\log(n+1)) \rceil$ where l is the maximal coefficient length, that is the minimum integer such that $|\Re(p_j)| < 2^l$ and $|\Im(p_j)| < 2^l$ for $j = 0, 1, \dots, n$. Combining the cited algorithms of [171,173,179] with this reduction yields

Theorem 10.1

Let polynomial $p(x)$ of (10.2) have n distinct simple zeros and integer coefficients in the range $[-2^\tau, 2^\tau]$. Then one can isolate the n zeros of $p(x)$ from each other at the Boolean cost $\tilde{O}_B(n^2\tau)$.

The algorithms of [171,173,179] incorporate the techniques of [157,218], but advance them and support substantially smaller upper bounds on the computational complexity. In particular these algorithms decrease by a factor of n the estimates of [218, Theorems 2.1, 19.2 and 20.1] on the Boolean complexity of polynomial factorization, root approximation, and root isolation.

10.3.2 Root-Finding via Functional Iterations

About the same record complexity estimates for root-finding would be also supported by some *functional iteration* algorithms if one assumes their convergence rate defined by ample empirical evidence, although never proved formally. The users accept such an evidence instead of the proof and prefer the latter algorithms because they are easy to program and have been carefully implemented; like the algorithms of [171,173,177,179] they allow tuning the precision of computing to the precision required for every output root, which is higher for clustered and multiple roots than for single isolated roots.

For approximating a single root z , the current practical champions are modifications of *Newton's iteration*, $z(i+1) = z(i) - a(i)p(z(i))/p'(z(i))$, $a(i)$ being the step-size parameter [136], *Laguerre's method* [94,107], and the *Jenkins-Traub algorithm* [112]. One can deflate the input polynomial via its numerical division by $x - z$ to extend these algorithms to approximating a small number of other roots. If one deflates many roots, the coefficients of the remaining factor can grow large as, for example, in the divisor of the polynomial $p(x) = x^{1000} + 1$ that has degree 498 and shares with $p(x)$ all its roots having positive real parts.

For the approximation of all roots, a good option is the Weierstrass–Durand–Kerner’s (hereafter *WDK*) algorithm, defined by the recurrence

$$z_j(l+1) = z_j(l) - \frac{p(z_j(l))}{p_n \prod_{i \neq j} (z_j(l) - z_i(l))}, \quad j = 1, \dots, n, \quad l = 0, 1, \dots \quad (10.4)$$

It has excellent empirical global convergence. Reference [208] links it to polynomial factorization and adjusts it to approximating a single root in $O(n)$ ops per step.

A customary choice of n initial approximations $z_j(0)$ to the n roots of the polynomial $p(x)$ (see [16] for a heuristic alternative) is given by $z_j(0) = r t \exp(2\pi\sqrt{-1}/n)$, $j = 1, \dots, n$. Here, $t > 1$ is a fixed scalar and r is an upper bound on the root radius, such that all roots z_j lie in the disc $\{x : |x| = r\}$ on the complex plane. This holds, for example, for

$$r = 2 \max_{i < n} |p_i/p_n|^{\frac{1}{n-i}} \quad (10.5)$$

For a fixed l and for all j the computation in (10.4) uses $O(n^2)$ ops. We can use just $O(n \log^2 n)$ ops if we apply fast multipoint polynomial evaluation algorithms based on fast FFT-based polynomial division [1,21,25,178,190], but then we would face numerical stability problems.

As with Newton’s, Laguerre’s, Jenkins–Traub’s algorithms and the inverse power iteration in [17,207], one can employ this variant of the *WDK* to approximate many or all roots of $p(x)$ without deflation. Toward this goal, one can concurrently apply the algorithm at sufficiently many distinct initial points $z_j(0) = r t \exp(2\pi\sqrt{-1}/N)$, $j = 1, \dots, N \geq n$ (on a large circle for large t) or according to [16]. The work can be distributed among processors that do not need to interact with each other until they compute the roots.

See [141–144,173] and references therein on this and other effective functional iteration algorithms. Reference [16] covers *MPSolve*, the most effective current root-finding subroutines, based on Ehrlich–Aberth’s algorithm.

10.3.3 Matrix Methods for Polynomial Root-Finding

By cautiously avoiding numerical problems [103, Section 7.4.6], one can approximate the roots of $p(x)$ as the eigenvalues of the associated (generalized) companion matrices, that is matrices having characteristic polynomial $p(x)$. Then one can employ numerically stable methods and the excellent software available for matrix computations, such as the QR celebrated algorithm. For example, Matlab’s subroutine *roots* applies it to the companion matrix of a polynomial. Malek and Vaillancourt (1995), and Fortune [93] and in his root-finding package *EigenSolve*, apply it to other generalized companion matrices and update them when the approximations to the roots are improved.

The algorithms of [15,17–19,181,197,207,230] exploit the structure of (generalized) companion matrices, for example, where they are diagonal plus rank-one (hereafter *DPR1*) matrices, to accelerate the eigenvalue computations. The papers [17,207] apply and extend the inverse power method [103, Section 7.6.1]; they exploit matrix structure, simplify the customary use of Rayleigh quotients for updating approximate eigenvalues, and apply special preprocessing techniques. For both companion and *DPR1* inputs the resulting algorithms use linear space and linear arithmetic time per iteration step, enable dramatic parallel acceleration, and deflate the input in $O(n)$ ops; for *DPR1* matrices repeated deflation can produce all n roots with no numerical problems.

The algorithms of [15,18,19,230] employ the QR algorithm but decrease the arithmetic time per iteration step from quadratic to linear by exploiting the rank matrix structure of companion matrices.

Substantial further refinement of these techniques is required to make them competitive with MPSolve. See [243] on recent progress.

The papers [181,197] advance Cardinal's polynomial root-finders of 1996, based on repeated squaring. Each squaring is reduced to performing a small number of FFTs and thus uses order $n \log n$ ops. One can weigh potential advantage of convergence to nonlinear factors of $p(x)$, representing multiple roots or root clusters, at the price of increasing the time per step by a factor of $\log n$ versus the inverse power method, advanced for root-finding in [17,207].

10.3.4 Extension to Approximate Polynomial GCDs

Reference [176] combines polynomial root-finders with algorithms for bipartite matching to compute approximate univariate polynomial GCD of two polynomials, that is, the GCD of the maximum degree for two polynomials of the same or smaller degrees lying in the ϵ -neighborhood of the input polynomials for a fixed positive ϵ . Approximate GCDs are required in computer vision, algebraic geometry, computer modeling, and control. For a single example, GCD defines the intersection of two algebraic curves defined by the two input polynomials, and approximate GCD does this under input perturbations of small norms. See [14] in the bibliography on approximate GCDs, but see [167,178,195] on the structured matrix algorithms involved.

10.3.5 Univariate Real Root Isolation and Approximation

In some algebraic and geometric computations, the input polynomial $p(x)$ has real coefficients, and only its real roots must be approximated. One of the fastest real root-finders in the current practice is still MPSolve, which uses almost the same running time for real roots as for all complex roots. This can be quite vexing, because very frequently the real roots make up only a small fraction of all roots [77]. Recently, however, the challenge was taken in the papers [197,207], whose numerical iterations are directed to converge to real and nearly real roots. This promises acceleration by a factor of d/r where the input polynomial has d roots, of which r roots are real or nearly real. In the rest of this section we cover an alternative direction, that is real root-finding by means of isolation of the real roots of a polynomial.

We write $p(x) = a_d x^d + \dots + a_1 x + a_0$, assume integral coefficients with the maximum bit size $\tau = 1 + \max_{i \leq d} \{\lg |a_i|\}$, and seek isolation of real roots, that is seek real line intervals with rational endpoints, each containing exactly one real root. We may seek also the root's multiplicity. We assume rational algorithms, that is, error-free algorithms that operate with rational numbers.

If all roots of $p(x)$ are simple, then the minimal distance between them, the *separation bound*, is at most $b = d^{-(d+2)/2} (d+1)^{(1-d)/2} 2^{\tau(1-d)}$, or roughly $2^{-O(d\tau)}$ (e.g., [147]), and we isolate real roots as soon as we approximate them within less than $b/2$. Effective solution algorithms rely on continued fractions (see the following text), having highly competitive implementation in SYNAPS [109,153] and its descendant REALROOT, a package of MATHEMAGIX, on the Descartes' rule of signs, and the Sturm or Sturm-Habicht sequences.

Theorem 10.2

The rational algorithms discussed in the sequel isolate all r real roots of $p(x)$ in $\tilde{O}_B(d^4\tau^2)$ bitwise ops. Under certain probability distributions for the coefficients, they are expected to use $\tilde{O}_B(d^3\tau)$ or $\tilde{O}_B(rd^2\tau)$.

The bounds exceed those of Theorem 10.1, has changed this, by closing the gap. Moreover rational solvers are heavily in use [245], have long and respected history, and are of independent technical interest. Most popular are the subdivision algorithms, such as STURM, DESCARTES, and BERNSTEIN.

By mimicking binary search, they repeatedly subdivide an initial interval that contains all real roots until every tested interval contains at most one real root. They differ in the way of counting the real roots in an interval.

The algorithm `STURM` (due to Sturm 1835) is the closest to binary search; it produces isolating intervals and root multiplicities at the cost $\tilde{O}_B(d^4\tau^2)$ [63,83]; see [77] on the decrease of the expected cost to $\tilde{O}_B(rd^2\tau)$.

The complexity of both algorithms `DESCARTES` and `BERNSTEIN` is $\tilde{O}_B(d^4\tau^2)$ [72,83]. Both rely on Descartes' rule of sign, but the `BERNSTEIN` algorithm also employs the Bernstein basis polynomial representation. See [2,234] on the theory and history of `DESCARTES`, [46,71,146,215,216] on its modern versions, and [83,156] and the references therein on the `BERNSTEIN` algorithm.

The continued fraction algorithm, `CF`, computes the continued fraction expansions of the real roots of the polynomial. The first formulation of the algorithm is due to Vincent. By Vincent's theorem repeated transforms $x \mapsto c + \frac{1}{x}$ eventually yield a polynomial with zero or one sign variation and thus (by Descartes' rule) with zero or resp. one real root in $(0, \infty)$. In the latter case the inverse transformation computes an isolating interval. Moreover, the c 's in the transform correspond to the partial quotients of the continued fraction expansion of the real root. Variants differ in the way they compute the partial quotients.

Recent algorithms control the growth of coefficient bit-size and decrease the bit-complexity from exponential (of Vincent) to $\tilde{O}_B(d^3\tau)$ expected and $\tilde{O}_B(d^4\tau^2)$ worst-case bit complexity. See [145,219,228,229] and the references therein on these results, history, and variants of `CP` algorithms.

10.4 Systems of Nonlinear Equations

Given a system $\{p_1(x_1, \dots, x_n), \dots, p_r(x_1, \dots, x_n)\}$ of nonlinear polynomials with rational coefficients, the n -tuple of complex numbers (a_1, \dots, a_n) is a solution of the system if $p_i(a_1, \dots, a_n) = 0$, $1 \leq i \leq r$. Each $p_i(x_1, \dots, x_n)$ is said to be an element of $\mathbf{Q}[x_1, \dots, x_n]$, the ring of polynomials in x_1, \dots, x_n over the field of rational numbers. In this section, we explore the problem of solving a well-constrained system of nonlinear equations, namely when $r = n$, which is the typical case in applications. We also indicate how an initial phase of exact algebraic computation leads to certain numerical methods that can approximate all solutions; the interaction of symbolic and numeric computation is currently an active domain of research, for example [22,82,125]. We provide an overview and cite references to different symbolic techniques used for solving systems of algebraic (polynomial) equations. In particular, we describe methods involving *resultant* and *Gröbner basis* computations.

Resultants, as explained in the following text, formally express the solvability of algebraic systems with $r = n + 1$; solving a well-constrained system reduces to a resultant computation as illustrated in the sequel. The *Sylvester resultant method* is the technique most frequently utilized for determining a common root of two polynomial equations in one variable. However, using the Sylvester method successively to solve a system of multivariate polynomials proves to be inefficient.

It is more efficient to eliminate n variables together from $n + 1$ polynomials, thus, leading to the notion of the *multivariate resultant*. The three most commonly used multivariate resultant matrix formulations are those named after *Sylvester or Macaulay* [36,38,135], those named after *Bézout or Dixon* [33,60,121], or the *hybrid formulation* [57,113,122]. Extending the Sylvester–Macaulay type, we shall emphasize also *sparse resultant* formulations [37,98,225]. For a unified treatment, see [81].

The theory of Gröbner bases provides powerful tools for performing computations in multivariate polynomial rings. Formulating the problem of solving systems of polynomial equations in terms of polynomial ideals, we will see that a Gröbner basis can be computed from the input polynomial set, thus, allowing for a form of back substitution in order to compute the common roots.

Although not discussed, it should be noted that the *characteristic set algorithm* can be utilized for solving polynomial systems. Although introduced for studying algebraic differential equations [213], the method was converted to ordinary polynomial rings when developing an effective method for automatic

theorem proving [241]. Given a polynomial system P , the characteristic set algorithm computes a new system in triangular form, such that the set of common roots of P is equivalent to the set of roots of the triangular system [120]. *Triangular systems* have k_1 polynomials in a specific variable, k_2 polynomials in this and one more variable, k_3 polynomials in these two and one more variable, and so on, for a total number of $k_1 + \dots + k_n$ polynomials.

10.4.1 Resultant of Univariate Systems

The question of whether two polynomials $f(x), g(x) \in \mathbf{Q}[x]$,

$$f(x) = f_n x^n + f_{n-1} x^{n-1} + \dots + f_1 x + f_0$$

$$g(x) = g_m x^m + g_{m-1} x^{m-1} + \dots + g_1 x + g_0$$

have a common root leads to a condition that has to be satisfied by the coefficients of f, g . Using a derivation of this condition due to Euler, the *Sylvester matrix* of f, g (which is of dimension $m + n$) can be formulated. The vanishing of the determinant of the Sylvester matrix, known as the *Sylvester resultant*, is a necessary and sufficient condition for f, g to have common roots in the algebraic closure of the coefficient ring.

As a running example, let us consider the following bivariate system [131]:

$$f = x^2 + xy + 2x \quad + y - 1 = 0$$

$$g = x^2 \quad + 3x - y^2 + 2y - 1 = 0$$

Without loss of generality, the roots of the Sylvester resultant of f and g treated as polynomials in y , whose coefficients are polynomials in x , are the x -coordinates of the common roots of f, g . More specifically, the Sylvester resultant with respect to y is given by the following determinant:

$$\det \begin{bmatrix} x+1 & x^2+2x-1 & 0 \\ 0 & x+1 & x^2+2x-1 \\ -1 & 2 & x^2+3x-1 \end{bmatrix} = -x^3 - 2x^2 + 3x$$

An alternative matrix of order $\max\{m, n\}$, named after Bézout, yields the same determinant.

The roots of the Sylvester determinant are $\{-3, 0, 1\}$. For each x value, one can substitute the x value back into the original polynomials yielding the solutions $(-3, 1), (0, 1), (1, -1)$. More practically, one can use the Sylvester matrix to reduce system solving to the computation of eigenvalues and eigenvectors as explained in Section 10.4.3.

The Sylvester formulations have led to a *subresultant theory*, which produced an efficient algorithm for computing the GCD of univariate polynomials and their resultant, while controlling intermediate expression swell [133,212]. Subresultant theory has been generalized to several variables, for example [32,53].

10.4.2 Resultants of Multivariate Systems

The solvability of a set of nonlinear multivariate polynomials is determined by the vanishing of a generalization of the resultant of two univariate polynomials. We examine two generalizations: the classical and the sparse resultants. Both generalize the determinant of $n + 1$ linear polynomials in n variables.

The *classical resultant* of a system of $n + 1$ polynomials with symbolic coefficients in n variables vanishes exactly when there exists a common solution in the *projective space* over the algebraic closure

of the coefficient ring [50]. The *sparse (or toric) resultant* characterizes solvability of the same overconstrained system over a smaller space, which coincides with affine space under certain genericity conditions [51,98,225]. The main algorithmic question is to construct a matrix whose determinant is the resultant or a nontrivial multiple of it.

Cayley, and later Dixon, generalized Bézout’s method to a set

$$\{p_1(x_1, \dots, x_n), \dots, p_{n+1}(x_1, \dots, x_n)\}$$

of $n + 1$ polynomials in n variables. The vanishing of the determinant of the Bézout–Dixon matrix is a necessary and sufficient condition for the polynomials to have a nontrivial projective common root and also a necessary condition for the existence of an affine common root [33,60,81,121]. A nontrivial resultant multiple, known as the *projection operator*, can be extracted via a method discussed in [41, Theorem 3.3.4]. This article, along with [73], explains the correlation between residue theory and the Bézout–Dixon matrix; the former leads to an alternative approach for studying and approximating all common solutions.

Macaulay [135] constructed a matrix whose determinant is a multiple of the classical resultant; he stated his approach for a well-constrained system of n homogeneous polynomials in n variables. The Macaulay matrix simultaneously generalizes the Sylvester matrix and the coefficient matrix of a system of linear equations. Like the Dixon formulation, the Macaulay determinant is a multiple of the resultant. Macaulay, however, proved that a certain minor of his matrix divides the matrix determinant to yield the exact resultant in the case of generic coefficients. To address arbitrary coefficients, Canny [36] proposed a general method that perturbs any polynomial system and extracts a nontrivial projection operator from Macaulay’s construction.

By exploiting the structure of polynomial systems by means of sparse elimination theory, a matrix formula for computing the sparse resultant of $n + 1$ polynomials in n variables was given in [37] and consequently improved in [40,76]. Like the Macaulay and Dixon matrices, the determinant of the sparse resultant matrix, also known as Newton matrix, only yields a projection operation. However, in certain cases of bivariate and multihomogeneous systems, determinantal formulae for the sparse resultant have been derived [57,80,122]. To address degeneracy issues, Canny’s perturbation has been extended in the sparse context [54]. D’Andrea [52] extended Macaulay’s rational formula for the resultant to the sparse setting, thus defining the sparse resultant as the quotient of two determinants; see [79] for a simplified algorithm in certain cases.

Here, sparsity means that only certain monomials in each of the $n + 1$ polynomials have nonzero coefficients. Sparsity is measured in geometric terms, namely, by the **Newton polytope** of the polynomial, which is the convex hull of the exponent vectors corresponding to nonzero coefficients. The **mixed volume** of the Newton polytopes of n polynomials in n variables is defined as an integer-valued function that bounds the number of toric common roots of these polynomials [13]. This remarkable bound is the cornerstone of sparse elimination theory. The mixed volume bound is significantly smaller than the classical Bézout bound for polynomials with small Newton polytopes but they coincide for polynomials whose Newton polytope is the unit simplex multiplied by the polynomial’s total degree. Since these bounds also determine the degree of the sparse and classical resultants, respectively, the latter has larger degree for sparse polynomials. Last, but not least, the classical resultant can identically vanish over sparse systems, whereas the sparse resultant can still yield the desired information about their common roots [51].

10.4.3 Polynomial System Solving by Using Resultants

Suppose we are asked to find the common roots of a set of n polynomials in n variables $\{p_1(x_1, \dots, x_n), \dots, p_n(x_1, \dots, x_n)\}$. By augmenting this set by a generic linear polynomial [36,51], we construct the *u-resultant*

of a given system of polynomials. The u-resultant is named after the indeterminates u , traditionally used to represent the generic coefficients of the additional linear polynomial. The u-resultant factors into linear factors over the complex numbers, providing the common roots of the given polynomials equations. The method relies on the properties of the multivariate resultant, and hence, can be constructed using either Macaulay's, Dixon's, or sparse formulations. An alternative approach is to *hide* a variable in the coefficient field [74,81,138].

Consider the previous example augmented by a generic linear form:

$$\begin{aligned}
 p_1 &= x^2 + xy + 2x + y - 1 = 0 \\
 p_2 &= x^2 + 3x - y^2 + 2y - 1 = 0 \\
 p_l &= ux + vy + w = 0
 \end{aligned}$$

As described in [38], the following (transposed) Macaulay matrix M corresponds to the u-resultant of the above system of polynomials:

$$M = \begin{bmatrix}
 1 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
 1 & 1 & 0 & 0 & 1 & 0 & u & 0 & 0 & 0 \\
 2 & 0 & 1 & 3 & 0 & 1 & 0 & u & 0 & 0 \\
 0 & 1 & 0 & -1 & 0 & 0 & v & 0 & 0 & 0 \\
 1 & 2 & 1 & 2 & 3 & 0 & w & v & u & 0 \\
 -1 & 0 & 2 & -1 & 0 & 3 & 0 & w & 0 & u \\
 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\
 0 & 1 & 0 & 0 & 2 & -1 & 0 & 0 & v & 0 \\
 0 & -1 & 1 & 0 & -1 & 2 & 0 & 0 & w & v \\
 0 & 0 & -1 & 0 & 0 & -1 & 0 & 0 & 0 & w
 \end{bmatrix}$$

It should be noted that

$$\det(M) = (u - v + w)(-3u + v + w)(v + w)(u - v)$$

corresponds to the affine solutions (1, -1), (-3, 1), (0, 1), whereas one solution at infinity corresponds to the last factor.

Resultant matrices can also reduce polynomial system solving to a regular or generalized eigenproblem (cf. "Matrix Eigenvalues and Singular Values Problems"), thus, transforming the nonlinear question to a problem in linear algebra. This is a classical technique that enables us to numerically approximate all solutions [4,39,41,74,81]. For demonstration, consider the previous system and its resultant matrix M . The matrix rows are indexed by the following row vector of monomials in the eliminated variables:

$$\mathbf{v} = [x^3, x^2y, x^2, xy^2, xy, x, y^3, y^2, y, 1]$$

Vector $\mathbf{v}M$ expresses the polynomials indexing the columns of M , which are multiples of the three input polynomials by various monomials. Let us specialize variables u and v to random values. Then, M contains a single variable w and is denoted $M(w)$. Solving the linear system $\mathbf{v}M(w) = \mathbf{0}$ in vector \mathbf{v} and in

scalar w is a generalized eigenproblem, since $M(w)$ can be represented as $M_0 + wM_1$, where M_0 and M_1 have numeric entries. If, moreover, M_1 is invertible, we arrive at the following eigenproblem:

$$\mathbf{v}(M_0 + wM_1) = \mathbf{0} \Leftrightarrow \mathbf{v}(-M_1^{-1}M_0 - wI) = \mathbf{0} \Leftrightarrow \mathbf{v}(-M_1^{-1}M_0) = w\mathbf{v}$$

For every solution (a, b) of the original system, there is a vector \mathbf{v} among the computed eigenvectors, which we evaluate at $x = a$, $y = b$ and from which the solution can be recovered by division [74]. As for the eigenvalues, they correspond to the values of w at the solutions; see [75] on numerical issues and an implementation.

An alternative method for approximating or isolating all real roots of the system is to use the so-called rational univariate representation (RUR) of algebraic numbers [35,214]. This allows us to express each root coordinate as the value of a univariate polynomial, evaluated over an algebraic number, which is specified as a solution of a single polynomial equation. All polynomials involved in this approach are derived from the resultant.

The resultant matrices are sparse and have quasi Toeplitz/Hankel structure (also called multilevel Toeplitz/Hankel structure), which enables their fast multiplication by vectors. By combining the latter property with various advanced nontrivial methods of multivariate polynomial root-finding, substantial acceleration of the construction and computation of the resultant matrices and approximation of the system's solutions was achieved in [24,85,86,150–152].

A comparison of the resultant formulations can be found, for example, in [81,120,138]. The multivariate resultant formulations have been used for diverse applications such as *algebraic and geometric reasoning* [41,59,138], including separation bounds for the isolated roots of arbitrary polynomial systems [84], *robot kinematics* [55,138,211], and *nonlinear computational geometry, computer-aided geometric design and, in particular, implicitization* [32,42,78,87,111].

10.4.4 Gröbner Bases

Solving systems of nonlinear equations can be formulated in terms of polynomial ideals [50,105,127]. The *ideal* generated by a system of polynomials p_1, \dots, p_r over $\mathbf{Q}[x_1, \dots, x_n]$ is the set of all linear combinations

$$(p_1, \dots, p_r) = \{h_1 p_1 + \dots + h_r p_r \mid h_1, \dots, h_r \in \mathbf{Q}[x_1, \dots, x_n]\}$$

The algebraic variety of $p_1, \dots, p_r \in \mathbf{Q}[x_1, \dots, x_n]$ is the set of their common roots,

$$V(p_1, \dots, p_r) = \{(a_1, \dots, a_n) \in \mathbf{C}^n \mid p_1(a_1, \dots, a_n) = \dots = p_r(a_1, \dots, a_n) = 0\}$$

A version of the *Hilbert Nullstellensatz* states that

$$V(p_1, \dots, p_r) = \text{the empty set } \emptyset \Leftrightarrow 1 \in (p_1, \dots, p_r) \text{ over } \mathbf{Q}[x_1, \dots, x_n]$$

which relates the solvability of polynomial systems to the ideal membership problem.

A term $t = x_1^{e_1} x_2^{e_2} \dots x_n^{e_n}$ of a polynomial is a product of powers with $\deg(t) = e_1 + \dots + e_n$. In order to add needed structure to the polynomial ring we will require that the terms in a polynomial be ordered in an admissible fashion [50,97]. Two of the most common admissible orderings are the **lexicographic order** ($<_l$), where terms are ordered as in a dictionary, and the **degree order** ($<_d$), where terms are first compared by their degrees with equal degree terms compared lexicographically. A variation to the lexicographic order is the *reverse lexicographic order*, where the lexicographic order is reversed.

Much like a polynomial remainder process, the process of polynomial reduction involves subtracting a multiple of one polynomial from another to obtain a smaller degree result [50,105,127]. A polynomial g is said to be reducible with respect to a set $P = \{p_1, \dots, p_r\}$ of polynomials if it can be reduced by one or more polynomials in P . When g is no longer reducible by the polynomials in P , we say that g is *reduced* or is a *normal form* with respect to P .

For an arbitrary set of basis polynomials, it is possible that different reduction sequences applied to a given polynomial g could reduce to different normal forms. A basis $G \subseteq \mathbf{Q}[x_1, \dots, x_n]$ is a *Gröbner basis* if and only if every polynomial in $\mathbf{Q}[x_1, \dots, x_n]$ has a unique normal form with respect to G . Buchberger [27–29] showed that every basis for an ideal (p_1, \dots, p_r) in $\mathbf{Q}[x_1, \dots, x_n]$ can be converted into a Gröbner basis $\{p_1^*, \dots, p_s^*\} = GB(p_1, \dots, p_r)$, concomitantly designing an algorithm that transforms an arbitrary ideal basis into a Gröbner basis. Another characteristic of Gröbner bases is that by using the abovementioned reduction process we have

$$g \in (p_1, \dots, p_r) \Leftrightarrow g \bmod (p_1^*, \dots, p_s^*) = 0$$

Further, by using the Nullstellensatz it can be shown that p_1, \dots, p_r viewed as a system of algebraic equations is solvable if and only if $1 \notin GB(p_1, \dots, p_r)$.

Depending on which admissible term ordering is used in the Gröbner bases construction, an ideal can have different Gröbner bases. However, an ideal cannot have different (reduced) Gröbner bases for the same term ordering. Any system of polynomial equations can be solved using a lexicographic Gröbner basis for the ideal generated by the given polynomials. It has been observed, however, that Gröbner bases, more specifically lexicographic Gröbner bases, are hard to compute [139]. In the case of zero-dimensional ideals, those whose varieties have only isolated points, a change of basis algorithm was outlined in [90], which can be utilized for solving: one computes a Gröbner basis for the ideal generated by a system of polynomials under a degree ordering. The so-called *change of basis algorithm* can then be applied to the degree ordered Gröbner basis to obtain a Gröbner basis under a lexicographic ordering. Significant progress has been achieved in the algorithmic realm by Faugère [88,89].

Another way to finding all common real roots is by means of RUR; see the previous section. All polynomials involved in this approach can be derived from the Gröbner basis. A rather recent development concerns the generalization of Gröbner bases to *border bases*, which contain all information required for system solving but can be computed faster and seem to be numerically more stable [127,154,155,221].

Turning to Lazard’s example in form of a polynomial basis,

$$\begin{array}{rcccccc} p_1 & = & x^2 & +xy & +2x & & +y & -1 \\ p_2 & = & x^2 & & +3x & -y^2 & +2y & -1 \end{array}$$

one obtains (under lexicographical ordering with $x <_y$) a Gröbner basis in which the variables are triangulated such that the finitely many solutions can be computed via back substitution:

$$\begin{array}{rcccccc} p_1^* & = & x^2 & & +3x & & +2y & -2 \\ p_2^* & = & & xy & -x & & -y & +1 \\ p_3^* & = & & & & y^2 & & -1 \end{array}$$

The final univariate polynomial has minimal degree, whereas the polynomials used in the back substitution have total degree no larger than the number of roots. As an example, x^2y^2 is reduced with respect to the previously computed Gröbner basis $\{p_1^*, p_2^*, p_3^*\} = GB(p_1, p_2)$ along two distinct reduction paths, both yielding $-3x - 2y + 2$ as the normal form.

There is a strong connection between lexicographic Gröbner bases and the previously mentioned resultant techniques. For some types of input polynomials, the computation of a reduced system via resultants might be much faster than the computation of a lexicographic Gröbner basis.

Gröbner bases can be used for many polynomial ideal theoretic operations [29,49]. Other applications include computer-aided geometric design [111], polynomial interpolation [129], coding and cryptography [92], and robotics [91].

10.5 Research Issues and Summary

Algebraic algorithms deal with numbers, vectors, matrices, polynomials, formal power series, exponential and differential polynomials, rational functions, algebraic sets, curves, and surfaces. In this vast area, manipulations with matrices and polynomials, in particular the solution of a polynomial equation and linear and polynomial systems of equations, are most fundamental in modern computations in sciences, engineering, and signal and image processing. We reviewed the state of the art for the solution of these three tasks and gave pointers to the extensive bibliography.

Among numerous interesting and important research directions of the topics in Sections 10.2 and 10.3, we wish to cite computations with structured matrices, including their applications to polynomial root-finding, currently of growing interest, and new techniques for randomized preprocessing for matrix computations, evaluation of resultants and polynomial root-finding.

Section 10.4 of this chapter has briefly reviewed polynomial system solving based on resultant matrices as well as Gröbner bases. Both approaches are currently active. This includes practical applications to small and medium-size systems. Efficient implementations that handle the nongeneric cases, including multiple roots and nonisolated solutions, are probably the most crucial issues today in relation to resultants. The latter are also studied in relation to a more general object, namely the discriminant of a well-constrained system, which characterizes the existence of multiple roots. Another interesting current direction is algorithmic improvement by exploiting the structure of the polynomial systems, including sparsity, or the structure of the encountered matrices, for both resultants and Gröbner bases.

Key Terms

Characteristic polynomial: Shift an input matrix A by subtracting the identity matrix xI scaled by variable x . The determinant of the resulting matrix is the characteristic polynomial of the matrix A . Its roots coincide with the eigenvalues of the shifted matrix $A - xI$.

Condition number of a matrix is a scalar κ which grows large as the matrix approaches a singular matrix; then numeric inversion becomes an ill-conditioned problem. $\kappa \text{ OUTPUT ERROR NORM} \approx \text{INPUT ERROR NORM}$.

Degree order: An order on the terms in a multivariate polynomial; for two variables x and y with $x < y$ the ascending chain of terms is $1 < x < y < x^2 < xy < y^2 \dots$

Determinant: A polynomial in the entries of a square matrix whose value is invariant in adding to a row (resp. column) any linear combination of other rows (resp. columns). $\det(AB) = \det A \cdot \det B$ for a pair of square matrices A and B , $\det B = -\det A$ if the matrix B is obtained by interchanging a pair of adjacent rows or columns of a matrix A , $\det A \neq 0$ if and only if a matrix A is invertible. Determinant of a block diagonal or block triangular matrix is the product of the diagonal blocks, and so $\det A = (\det A_{0,0}) \det S$ under (10.1). One can compute a determinant by using these properties and matrix factorizations, for example, recursive factorization (10.1).

Gröbner basis: Given a term ordering, the Gröbner basis of a polynomial ideal is a generating set of this ideal, such that the (multivariate) division of any polynomial by the basis has a unique remainder.

Lexicographic order: An order on the terms in a multivariate polynomial; for two variables x and y with $x < y$ the ascending chain of terms is $1 < x < x^2 < \dots < y < xy < x^2y \dots < y^2 < xy^2 \dots$

Matrix eigenvector: A column vector \mathbf{v} such that $A\mathbf{v} = \lambda\mathbf{v}$, for a square matrix A and the associated eigenvalue λ . A generalized eigenvector \mathbf{v} satisfies the equation $A\mathbf{v} = \lambda B\mathbf{v}$ for two square matrices A and B and the associated eigenvalue λ . Both definitions extend to row vectors that pre-multiply the associated matrices.

Mixed volume: An integer-valued function of n convex polytopes in n -dimensional Euclidean space. Under proper scaling, this function bounds the number of toric complex roots of a well-constrained polynomial system, where the convex polytopes are defined to be the Newton polytopes of the given polynomials.

Newton polytope: The convex hull of the exponent vectors corresponding to terms with nonzero coefficients in a given multivariate polynomial.

Ops: Arithmetic operations, that is, additions, subtractions, multiplications, or divisions; as in **flops**, that is, floating point operations.

Resultant: A polynomial in the coefficients of a system of n polynomials with $n + 1$ variables, whose vanishing is the minimal necessary and sufficient condition for the existence of a solution of the system.

Separation bound: The minimum distance between two (complex) roots of a univariate polynomial.

Singularity: a square matrix is singular if its product with some nonzero matrix is the zero matrix. Singular matrices do not have inverses.

Sparse matrix: a matrix whose zero entries are much more numerous than its nonzero entries.

Structured matrix: A matrix whose every entry can be derived by a formula depending on a smaller number of parameters, typically on $O(m + n)$ parameters for an $m \times n$ matrix, as opposed to its mn entries. For instance, an $m \times n$ Cauchy matrix has $\frac{1}{s_i - t_j}$ as the entry in row i and column j and is defined by $m + n$ parameters s_i and t_j , $i = 1, \dots, m$; $j = 1, \dots, n$. Typically a structured matrix can be multiplied by a vector in nearly linear arithmetic time.

Further Information

The books and special issues of journals [1,5,21,25,31,58,82,97,178,221,244] provide a broader introduction to the general subject and further bibliography.

There are well-known libraries and packages of subroutines for the most popular numerical matrix computations, in particular, [61] for solving linear systems of equations, [95,220], ARPACK, and PARPACK for approximating matrix eigenvalues, and [3] for both of the two latter computational problems. Comprehensive treatment of numerical matrix computations and extensive bibliography can be found in [103,222], and there are many more specialized books on them [6,8,62,100,104,110,209,227,239] as well as many survey articles [108,159,168] and thousands of research articles. Further applications to the graph and combinatorial computations related to linear algebra are cited in “Some Computations Related to Matrix Multiplication” and [169].

On parallel matrix computations, see [101,103,115,116,192] assuming general input matrices, [101,108,169,202] assuming sparse inputs, [62] assuming banded inputs, and [21,172,178] assuming dense structured inputs. On Symbolic-Numeric algorithms, see the books [21,178,235], surveys [168,173,175], special issues [22,82,125,126], and the bibliography therein. For the general area of exact computation and the theory behind algebraic algorithms and computer algebra, see [9,30,50,51,58,96,97,147,148,240,242,244].

There is a lot of generic software packages for exact computation, SYNAPS [253], a C++ open source library devoted to symbolic and numeric computations with polynomials, algebraic numbers, and polynomial systems, which has been evolving into the REALROOT package of the open source computer algebra system MATHEMAGIX; NTL a high-performance C++ library providing data structures and algorithms for vectors, matrices, and polynomials over the integers and finite fields, and EXACUS [11], a C++ library for curves and surfaces that provides exact methods for solving polynomial equations. A highly

efficient tool is FGB for Gröbner basis, and RS for the rational univariate representation, and real solutions of systems of polynomial equations and inequalities. Finally, LIN BOX [65] is a C++ library that provides exact high-performance implementations of linear algebra algorithms.

This chapter does not cover the area of polynomial factorization. We refer the interested reader to [96,132,158], and the bibliography therein.

The *SIAM Journal on Matrix Analysis and Applications* and *Linear Algebra and Its Applications* are specialized on Matrix Computations, *Mathematics of Computation* and *Numerische Mathematik* are leading among numerous other good journals on numerical computing.

The *Journal of Symbolic Computation* and the *Foundations of Computational Mathematics* specialize on topics in Computer Algebra, which are also covered in the *Journal of Computational Complexity*, the *Journal of Pure and Applied Algebra* and, less regularly, in the *Journal of Complexity*. *Mathematics for Computer Science* and *Applicable Algebra in Engineering, Communication and Computing* are currently dedicated to the subject of the chapter as well. *Theoretical Computer Science* has become more open to algebraic–numerical and algebraic–geometric subjects [22,34,82,125].

The annual *International Symposium on Symbolic and Algebraic Computation (ISSAC)* is the main conference in computer algebra; these topics are also presented at the bi-annual Conference *MEGA* and the newly founded SIAM conference on Applications of Algebraic Geometry. They also appear in the annual *ACM Conference on Computational Geometry*, as well as at various Computer Science conferences, including SODA, FOCS, and STOC.

Among many conferences on numerical computing, most comprehensive ones are organized under the auspices of SIAM and ICIAM. The International Workshop on Symbolic-Numeric Algorithms can be traced back to 1997 (SNAP in INRIA, Sophia Antipolis) and a special session in IMACS/ACA98 Conference in Prague, Czech Republic, in 1998 [175]. It restarted in Xi'an, China, 2005; Timishiora, Romania, 2006 (supported by IEEE), and London, Ontario, Canada, 2007 (supported by ACM). The topics of Symbolic-Numerical Computation are also represented at the conferences on the *Foundations of Computational Mathematics (FoCM)* (meets every 3 years) and quite often at ISSAC.

From an engineering standpoint, “randomness” sounds like a bad idea; when we build things, we want them to be predictable. It is therefore somewhat surprising how important randomness has become in the design of algorithms and data structures. A randomized algorithm or data structure is allowed to make random choices during its execution.*

The reason to allow randomness in the design is that it provides a larger trade-off space for qualities we may desire. Typically, when we talk about analyzing algorithms and data structures, we are concerned with the two basic measures we want to optimize: worst-case time and space. Allowing randomness allows us to consider other measures, including the following:

- *Expected time and space:* We might allow worst-case time or space to be large if they are not large very frequently.
- *Correctness:* We might allow our algorithm or data structure to occasionally give a wrong answer or otherwise fail, again if it does not happen frequently, in return for gains in average or worst-case time or space. While it may be counterintuitive to treat correctness as just another performance metric, this idea has proven quite powerful in both theory and practice.

* A closely related but different line of work addresses the probabilistic analysis of algorithms (and data structures), where one assumes the *input* is random according to some distribution, rather than allowing the *algorithm* to make random choices. In the setting of probabilistic analysis, there can still be bad but rare *inputs* to the algorithm; in studying randomized algorithms, we are concerned with bad but rare *random choices* made by the algorithm.

Finally, randomized algorithms and data structures often provide another less tangible benefit: simplicity. Simplicity can be useful not just for theoretical analysis; if we think of programmer time as a measurable and important resource, a simple randomized algorithm may be more useful than a more complex deterministic algorithm, even if it does not gain by other more standard metrics.

The field of randomized algorithms and data structure is so large, it would be impossible to consider summarizing the entire area in a short survey. There are entire books devoted to the subject, notably the general texts by Motwani and Raghavan [47] and Mitzenmacher and Upfal [43], and there are several texts that cover specialized subbranches of the area as well, such as [21,46,60,66].

In what follows, we provide some basic examples of how randomness is used in algorithms and data structures. We have chosen to emphasize approaches that have proven useful in practice. We assume that the reader has had an appropriate undergraduate-level training in algorithms, complexity, and probability theory.

Outline: Hashing is one of the most fundamental uses of randomness in computer science. In Section 11.1, we discuss several variations of hash tables. Tabulation hashing gives an efficient implementation of a hash function using a small amount of space with desirable theoretical and practical properties. We then explore the power of building hash tables with multiple hash functions for items to choose from and in particular examine cuckoo hashing, which allows items to move among its choices even after they were initially inserted to the table. Section 11.2 applies hashing to create a sketch of the data set; we consider two sketches, the Bloom filter and the count-min sketch. A further application of hashing is presented in Section 11.3, namely, the use of hash functions to create concise *fingerprints* of items. We demonstrate two applications of fingerprints in text analysis: the Karp–Rabin string matching algorithm and the shingling algorithm for identifying similar documents. Randomization is also an essential component of modern public-key cryptosystems. Section 11.4 demonstrates how randomness is utilized in the RSA cryptosystem and in a related algorithm for choosing large random prime numbers. We also present two practical applications of randomization that do not have (yet) a complete theoretical analysis: the naive Bayesian classifier (Section 11.5) and randomized greedy heuristics (Section 11.6).

11.1 Hashing

A hash function h maps a domain to a range so that the result “looks random.” Of course, any particular function is fully deterministic. In analyzing hashing, we assume that the hash function h is chosen at random from a family of hash functions \mathcal{H} . To simplify the analysis we often assume that the hash function is fully random, that is, chosen at random from the family of all functions, although in practice fully random hash functions are not possible. The number of random bits needed to represent a fully random hash function mapping $\{0, 1\}^n$ to $\{0, 1\}^m$ would be $2^n \times m$ bits, which is far too large for any reasonable n . In practice we use hash functions chosen from smaller families that have concise representation and are easy to compute. Constructing such families of functions that look sufficiently random is a major theoretical and practical research area, as we discuss in Section 11.1.1.

A common use for hashing is to build a hash table; the hash of an item—which is more commonly called a *key* in this context—provides a location, often called a bin or bucket, for where to find the key. If we have n keys and a hash table of n buckets, on average, each bucket will have a load of 1 key; however, even with a fully random hash function, the bucket with the most keys (or maximum load) will have $(1 + o(1))(\log n / \log \log n)$ keys with high probability [30].

We use this result as a baseline. To start, we consider one method for coming up with good hash functions using fewer random bits. It yields hash tables with a maximum load similar in size to fully random hash functions. Then, we show some useful ways to make better hash tables, with much smaller maximum load per bucket, by using multiple hash functions.

11.1.1 Tabulation Hashing

Tabulation hashing is a fairly old scheme based on lookup tables currently enjoying a renaissance based on new results regarding its performance. Variations (such as Zobrist hashing [67], which was used to hash positions in board games to bit strings) were known in the late 1960s; it was also considered by Carter and Wegman [10]. Our description is based primarily on recent work by Pătraşcu and Thorup [51,52].

We assume the keys are a fixed number of bits b . We view b as a vector of t characters, each of c bits, so that $b = ct$. Suppose that we want our output to consist of a bits; that is, we want a hash function $h: \{0, 1\}^b \rightarrow \{0, 1\}^a$. Our hash function is derived from a lookup table with $2^c \times t$ entries; each entry is initialized with an a -bit random value. Hence, the space required is $at2^c$ bits in total and our analysis assumes that the bits of the table are chosen uniformly at random from all 2^{at2^c} possibilities.

Let our lookup table T be such that $T[i, j]$ provides the a bits when the i th character takes on the value j , where $i \in [1, t]$ and $j \in [0, 2^c - 1]$. Let our key x be given by $x = x_1 \dots x_t$, where the x_k are the t characters constituting x . Then

$$h(x) = T[1, x_1] \oplus T[2, x_2] \dots \oplus T[t, x_t],$$

where \oplus is the bitwise exclusive-or operation. Naturally, a key advantage of tabulation hashing is that it is very fast, if one can choose the table parameters to fit into memory. For example, suppose one wants to hash 128 bit keys (such as IPv6 addresses) into 32 bits. Using $c = 8$ and $t = 16$, the table requires 2^{17} bits, small enough to fit into even fairly small caches, and only a small number of simple operations.

Figure 11.1 that follows shows how 32-bit keys can be hashed into 12-bit values using just 384 random bits.

Tabulation hashing seems weak under some standard measures of approximate independence of hash values. For example, it is three-wise independent but not four-wise independent. That is, for any three keys x, y , and z , we have that $h(x), h(y)$, and $h(z)$ are all mutually independent, but if we have four keys w, x, y , and z , the values $h(w), h(x), h(y)$, and $h(z)$ need not be mutually independent. For example, if w, x, y , and z are all the same except for the last two characters, so that for a prefix p we have $w = pc_1c_3, x = pc_2c_4, y = pc_1c_4$, and $z = pc_2c_3$, then $h(w) \oplus h(x) \oplus h(y) \oplus h(z) = 0$. More specifically the strings

FIGURE 11.1 The first several rows of a table for tabulation hashing. In the example, a 32-bit string is broken into 4 characters of 8 bits each. By looking at each character in the appropriate column—shown by the bold an italicized entries—we find the 12-bit strings that are XOR’ed together to form the final hash value.

But recent work shows tabulation hashing is much stronger than the earlier result suggests. For example, one standard question is how well a hash function distributes n keys into a hash table with m buckets. In this respect, tabulation hashing does quite well: when $m = O(n)$, the most loaded bucket in the table has $O(\log n / \log \log n)$ keys with high probability, matching the same bounds as perfect random hashing. This follows from the following theorem (taken from Theorem 1 in [51]), which shows that tabulation hashing yields useful Chernoff-like bounds:

Theorem 11.1

Consider hashing n keys into $m \geq n^{1-1/(2c)}$ buckets using tabulation hashing, where c is a constant and $a = \log m$. Let X denote the number of keys that hash into a specific bucket (e.g., bucket 1). Let $\mu = E[X] = n/m$. The following probability bounds hold for any constant γ :

$$\forall \delta \leq 1: \Pr[|X - \mu| \geq \delta\mu] \leq 2e^{-\Omega(\delta^2\mu)} + m^{-\gamma};$$

$$\forall \delta = \Omega(1): \Pr[X \geq (1 + \delta)\mu] \leq (1 + \delta)^{-\Omega((1+\delta)\mu)} + m^{-\gamma}.$$

The result follows by taking $m = O(n)$ and using a union bound.

Other known methods for generating hash values have not been shown to have (and often do not have) this useful property. The simplicity and small space usage of tabulation hashing, combined with performance guarantees such as this one, make it a strong contender for many practical applications. Indeed, tabulation hashing is stronger than standard pairwise-independent hashing, where any pair of items appear to be hashed independently even though larger collections of items may have dependencies, but very competitive in terms of computation. The tabulation hashing paper [51] as well as other works [62,63] provide useful insights regarding implementing both tabulation hashing and other universal hashing schemes, including comparisons.

11.1.2 Hashing with Choices

One way to break the $O(\log n / \log \log n)$ maximum load for hashing when n keys are hashed into n buckets is to give each key being hashed more than one location to be placed—that is, give the keys a choice. The main result behind multiple-choice hashing was presented in a seminal work by Azar et al. [4], who showed the following: suppose that n keys are hashed sequentially into n buckets by hashing each key d times to obtain d choices of a bucket for each key and placing each key in the choice with the smallest current number of keys (or *load*). As we have noted, when $d = 1$, which is standard hashing, then the maximum load grows like $(1 + o(1))(\log n / \log \log n)$ with high probability [30]; the result of [4] is that when $d \geq 2$, the maximum load grows like $\log \log n / \log d + O(1)$ with high probability, which even for two choices gives a maximum load of 5 in most practical scenarios. Notice that the gap in going from one to two choices is a different type of behavior; going from two to three choices just changes a constant factor. The upshot is that by giving keys just a small amount of choice in where they are placed, the maximum load can be greatly reduced; the cost is that now d locations have to be checked when trying to look up the key, which is usually a small price to pay in systems where the d locations can be looked up in parallel.

The intuition behind the proof is very easy (although the probabilistic formalism is somewhat more complicated). Suppose that we know that the fraction of buckets with load at least i after hashing all n keys is given by p_i . Then, at any time in the process, the probability that a key hashes to d locations that all have load at least i is at most $(p_i)^d$. Hence, the expected number of keys that cause a bucket to have load at least $i + 1$ is at most $n(p_i)^d$, so the fraction p_{i+1} of buckets with load at least $i + 1$ should satisfy $p_{i+1} \leq (p_i)^d$.

TABLE 11.1 Results for the Basic d -Choice Scheme (S) vs. Vöcking's Scheme (V)

i	$d = 2$		$d = 3$		$d = 4$	
	S	V	S	V	S	V
1	7.6×10^{-1}	7.7×10^{-1}	8.2×10^{-1}	8.4×10^{-1}	8.6×10^{-1}	8.8×10^{-1}
2	2.3×10^{-1}	2.2×10^{-1}	1.8×10^{-1}	1.6×10^{-1}	1.4×10^{-1}	1.2×10^{-1}
3	8.9×10^{-3}	4.4×10^{-3}	5.1×10^{-4}	1.1×10^{-5}	2.3×10^{-5}	7.8×10^{-11}
4	6.0×10^{-6}	5.2×10^{-8}	3.9×10^{-12}	4.5×10^{-31}	4.0×10^{-21}	2.3×10^{-141}

Note: Numbers represent the fraction of buckets of each load under fluid limit model, when n keys are placed in n buckets. These numbers are very accurate even for moderate values of n (in the thousands).

Let us assume that this equation holds for all i . Now clearly $p_2 \leq 1/2$, since at most $1/2$ the buckets can have load at least 2, and by induction

$$p_k \leq 2^{-d^{k-2}}.$$

In particular, when $k > \log \log n / \log d + 2$, we have $p_k < 1/n$, so the expected number of buckets of this load is less than 1. The proof of [4] formalizes this argument more carefully, proving the maximum load in a bucket is $\log \log n / \log d + O(1)$ with high probability.

One interesting aspect of multiple-choice hashing in practice is that very precise estimates of the load distribution on the buckets can be obtained using fluid limit models, which give a simple family of differential equations that accurately describe the behavior of the hash table. Details appear in [41,45].

A variant later introduced by Vöcking [64] both gives slightly improved performance and is particularly amenable to parallelization. The hash table is split into d equal-sized subtables, which we think of as being ordered from left to right; when inserting a key, one bucket is chosen uniformly and independently from each subtable as a possible location; the key is placed in the least loaded bucket, breaking ties to the left. (The scheme is often called the d -left scheme.) This combination of splitting and tiebreaking reduces the maximum load to $\log \log n / (d\phi_d) + O(1)$, where ϕ_d is the asymptotic growth rate of the d th order Fibonacci numbers [64]. Again, very precise numerical estimates can be found using fluid limit models [45]. Table 11.1, for example, shows the fraction of buckets with loads from 1 to 4 for the basic d -choice scheme and for Vöcking's variation for $d = 2, 3$, and 4 in the asymptotic limit with n balls and n buckets. As can be seen, the loads with Vöcking's scheme fall even more quickly than the standard scheme. For example, under Vöcking's scheme with three choices, and practical sizes for n , we would never expect to see any bucket with load 4 or more; for the standard scheme, with three choices, a bucket with load 4 would be a rare but not outstandingly unusual event.

In practice, the size of the most loaded bucket is generally highly concentrated around a specific value. As noted for example in [7], this effectively means that d -left hash tables can provide an "almost perfect" hash table in many settings. That is, the hash table is highly loaded with little empty space, insertions and lookups are guaranteed to take constant time, and the probability of failure (such as some bucket becoming overloaded) is very small. Such hash tables can then be used to bootstrap further data structures. They are particularly important for fast lookups, a common need in network processing tasks.

Several other variations of this process have been considered, such as when items are both inserted and deleted, when a "stash" is used to handle items that overflow buckets, and when placements are done in parallel; some of these variations are covered in various surveys [34,42].

11.1.3 Cuckoo Hashing: Adding Moves

Cuckoo hashing [50] extends multiple-choice hashing schemes by allowing keys to move among their choices in order to avoid collisions. In the original description, a key can be placed in one of two possible

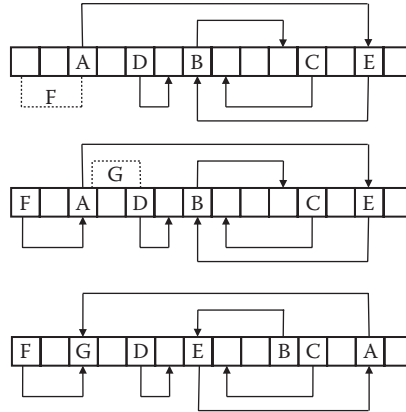

FIGURE 11.2 A cuckoo hash table example. When key F is inserted, it is placed in an empty bucket. When key G is inserted, it causes a sequence of moves in order to find a place.

buckets; each bucket can hold a single key. If both of the buckets already hold keys, we *move the key* in one of those buckets to the other of its two choices. If this other bucket is itself full, this move may in turn require the move of this other element, and so on until an empty spot for the current key is found. The name cuckoo hashing comes from the cuckoo bird in nature, which kicks other birds out of their nest, much like the hashing scheme recursively kicks keys out of their location as needed.

Figure 11.2 shows how one view of how a cuckoo hash table with two choices per key can be represented. An arrow represents the other choice for each key, so key A is placed in one bucket, but its other choice initially contains the key E. When key F is inserted, it is placed into an empty bucket. However, when key G is inserted, it takes the place of A, which then displaces E, which then displaces B to an empty bucket. It is unfortunately possible that a key cannot be placed, because the process of moving keys leads to a cycle; this is a cuckoo hash table failure.

In the case of two bucket choices per key, we can naturally view the process in the settings of random graphs. Let us assume that the two bucket choices for an element are always chosen to be distinct. Then we can think of the m buckets as vertices of a graph, and each of the n keys as being a random edge, with its two bucket choices being the endpoints of the edge. The question then becomes whether the edges of the graph can be *oriented* so each points to one of its two endpoints, in such a way that no endpoint is pointed to by two edges. Such an orientation would correspond to a successful placement of keys into buckets. Of course, beyond asking whether there *exists* a valid orientation, it is important to determine whether the cuckoo hashing algorithm outlined earlier can find it.

Hence, for two choices, we can consider the basic setting of random graphs, where there are very natural properties we can use.

Successfully placing an element corresponds to finding an augmenting path in the underlying graph where buckets are nodes and elements correspond to edges between nodes. When there are n keys to be placed in $2(1 + \epsilon)n$ buckets, that is, when the load of the table is less than $1/2$, all such augmenting paths are $O(\log n)$ in length with high probability. We therefore can declare that a failure occurs if a key cannot be placed after $c \log n$ steps for an appropriately chosen constant c .

Theorem 11.2

Consider a cuckoo hash table with $2(1 + \epsilon)n$ buckets and two choices per key for n keys. Then with probability $1 - O(1/n)$, when keys are placed sequentially, all keys are successfully placed, with each key taking at most $O(\log n)$ steps to be placed. The expected time to place each key is $O(1)$.

Cuckoo hashing can naturally be generalized to situations with more than two choices per bucket and more than one key per bucket [17,26]. The advantage of these generalizations is that much higher loads can be obtained. If everything can be placed successfully, then lookups take time $O(1)$ as long as the number of choices d is constant. For $d > 2$, there is a correspondence to random hypergraphs, and when a bucket can hold $k > 1$ keys, we seek orientations that allow at most k edges assigned to each vertex. While these settings are substantially more technically challenging, a great deal has been learned about such schemes in the last few years. For example, when $d = 3$ choices are used, a cuckoo hash table can handle (asymptotically) a load of over 91%; with $d = 4$ choices, a load of over 97% can be handled [16,27,28]. Also, the use of a small “stash” to hold keys that would not otherwise be able to be placed can dramatically reduce the probability of failure in practical settings [35].

Cuckoo hashing is a fairly new hashing method, but several applications of the idea have already been suggested, including for storage schemes using flash memory [13], hash tables for graphical processing units and associated graphics applications [3], scalable distributed directories [25], and in hardware caches [58].

11.2 Sketches

A large number of data structures have arisen that make use of hashing to create a *sketch* of a data set. A sketch can be seen as a useful small summary of a data set that allows specific operations on the data. Here we look at some simple sketches that provide a basic introduction to the general methodology.

11.2.1 Bloom Filters

Bloom filters are named after Burton Bloom, who first described them in a paper in 1970 [5]. A Bloom filter is a randomized data structure that succinctly represents a set and supports membership queries. For a set S , if $x \in S$, the Bloom filter will always return 1. If $x \notin S$, the Bloom filter will return 0 with probability close to 1.

We review the necessary background, based on the presentation of the survey [8], which covers more details and some basic applications of Bloom filters. A Bloom filter representing a set $S = \{x_1, x_2, \dots, x_n\}$ of n keys from a universe U consists of an array B of m bits, initially all set to 0. The filter uses k hash functions h_1, \dots, h_k with range $\{0, \dots, m - 1\}$. Here (and throughout in our applications unless otherwise stated), we assume that our hash functions are fully random, so that each hash value is uniform on the range and independent of other hash values. Technically, this is a strong assumption, but it proves both useful and generally accurate in practice. (See [44] for possible reasons for this.)

For each key $x \in S$, the bits $B[h_i(x)]$ are set to 1 for $1 \leq i \leq k$ in the array B . (A bit may be set to 1 multiple times.) To check if a key y is in S , we check whether all array bits $B[h_i(y)]$ are set to 1 for $1 \leq i \leq k$. If not, then clearly y is not a member of S . If all $h_i(y)$ are set to 1, we assume that y is in S . This may be incorrect; an element $y \notin S$ may hash to bits in the array that are set to 1 by elements of S . Hence, a Bloom filter may yield a *false-positive* error. Figure 11.3 shows further how Bloom filters function and how false-positives can occur.

The probability of a false-positive can be estimated in a straightforward fashion, under our assumption that the hash functions are fully random. Suppose that after all n keys of S are hashed into the Bloom filter, a fraction ρ of the bits is 0. Then by independence of our hash values, the probability that an element y gives a false-positive is just $(1 - \rho)^k$. What can we say about ρ ? The expected value of ρ is just the probability that any specific bit remains 0; a bit has to be missed by kn hashes for that to happen, and that occurs with probability

$$p' = \left(1 - \frac{1}{m}\right)^{kn} \approx e^{-kn/m}.$$

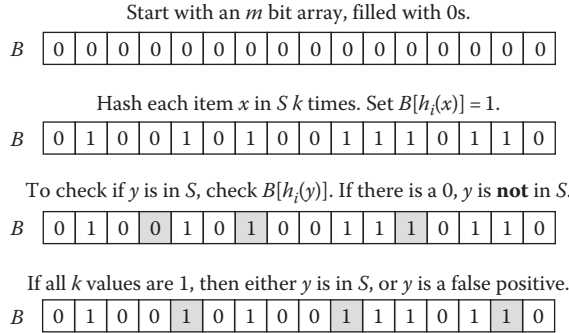

FIGURE 11.3 The basics of Bloom filters.

Now ρ can be shown (using various concentration methods) to be closely concentrated around its expectation p' . Hence, a clean formula that very closely approximates the false-positive probability f is

$$f \approx (1 - e^{-kn/m})^k.$$

What is the best choice for the number of hash functions? Using calculus, it is easy to show that f is minimized when $k = \ln 2 \cdot (m/n)$, in which case

$$f \approx (1 - e^{-kn/m})^k = \left(\frac{1}{2}\right)^k \approx (0.6185)^{m/n}.$$

Of course, in practice, k must be an integer.

The utility of Bloom filters stems from the fact that the false-positive probability falls exponentially in m/n , the number of bits per key. When m/n is 8, the false-positive probability is just over 2%; when m/n is 10, it falls below 1%. Hence, when elements are large, Bloom filters allow one to save significant space at the cost of some false-positives. For many applications, that trade-off is appealing. In particular, Bloom filters have been suggested for a number of network processing tasks, such as longest prefix matching, or matching of signature strings within packets [14,15,61]. In the case of packet signatures, we may read the packet byte by byte and in parallel consider strings of various lengths ending at that byte. The signatures might live in a slower memory hash table, one for each signature length, or other lookup structure. By using a smaller Bloom filter in faster memory to record the set of signature strings in each table, the number of lookups can be reduced; in the common case, no slower lookups will be required, and false-positives will only minimally affect performance if they are kept sufficiently small. This use of a Bloom filter as a method to filter out requests to a slower or otherwise more costly lookup structure when we expect most lookups to be unsuccessful provides a common application of Bloom filters in real systems. Another notable early use of Bloom filters in networking is to provide a sketch of the contents of a web cache, to allow cooperative caching [23,56]. Instead of passing around lists of URLs, machines can pass around more space-efficient Bloom filters. The effects of false-positives, which can make a machine look to a local neighbor for a document that is not actually stored before then going to the web for it, can be made suitably small to still allow for improved performance.

11.2.2 Count-Min Sketches

Bloom filters only provide information about set membership, but the same basic framework—hash keys into multiple buckets in a way that preserves information about the elements despite collisions—has

now been used for many other data structures. As one example, we present here the *count-min sketch* [12] of Cormode and Muthukrishnan.* The count-min sketch is designed for settings where elements have associated counts. For example, in a network, a source–destination pair might have an associated number of bytes sent between them. We might want to track these counts, approximately, with an eye toward finding the *heavy hitters*, which are the flows sending the largest number of bytes. Tracking byte counts for all flows within a router would be too expensive, so we seek a small data structure that allows for accurate detection. Such structures also provide a building block for many other types of queries and applications, in databases and in various data stream settings. For example, they can be used to effectively estimate inner products of vectors [12].

We use the following framework. The input is a stream of *updates* in the form of order pairs (i_t, c_t) , starting from $t = 1$, where each *key* i_t is a member of a universe $U = \{1, \dots, n\}$, and each *count* c_t is an integer. The state of the system at time T is given by a vector $\vec{a}(T) = (a_1(T), \dots, a_n(T))$, where $a_j(T)$ is the total count associated with key j at time T , or

$$a_j(T) = \sum_{t \leq T : i_t = j} c_t.$$

We will assume in what follows the typical case where we have the guarantee that counts are nonnegative, so $a_j(T) \geq 0$ for every j and T .

It is slightly more convenient for our analysis to split our structure into a 2D array **Count** with k rows and w columns, with each array entry being a counter. (There is essentially no difference in theory or practice if we just use a single array, but the argument is slightly harder.) As we did with Bloom filters, here we use k independent hash functions $h_1, \dots, h_k: \{1, \dots, n\} \rightarrow \{1, \dots, w\}$; there is one for each row. (Actually, it is enough to assume that the hash functions are universal—also called pairwise independent—as shown in [12]; our arguments also hold with this assumption.) Every entry of the array is initialized to 0.

When a pair (i, c) arrives, we add c to the counters **Count** $[1, h_1(i)], \dots, \mathbf{Count}[k, h_k(i)]$. As long as all counts are nonnegative, then each entry **Count** $[j, h_j(i)]$ will be a *lower bound* on $a_i(T)$. Intuitively, our hope is that, for at least one of these counters, no or at least very few other keys land in the same array counter. In that case, the minimum of the values **Count** $[j, h_j(i)]$ will actually be very close to the true count $a_i(T)$. That is, we use of $\hat{a}_i = \min_{j \in \{1, \dots, k\}} \mathbf{Count}[j, h_j(i)]$ as an estimate of $a_i(T)$.

We now show that \hat{a}_i is a good bound for $a_i(T)$, as long as $a_i(T)$ is reasonably large and we size our array of counters appropriately. For $j \in \{1, \dots, k\}$, let

$$X_{i,j} = \sum_{i' \neq i : h_j(i') = h_j(i)} a_{i'}(T).$$

Since the hash functions are fully random, $\mathbf{E}[X_{i,j}] \leq \|\vec{a}\|/w$, where $\|\vec{a}\| = \sum_{x \in [1,n]} a_x(T)$ (the L_1 norm of \vec{a} , again assuming all entries are nonnegative). Markov's inequality then implies that for any threshold value $\theta > 0$, we have $\Pr(X_{i,j} \geq \theta) \leq \|\vec{a}\|/(w\theta)$. By definition, our estimate satisfies $\hat{a}_i = a_i + \min_{j \in \{1, \dots, k\}} X_{i,j}$ and by independence of the h_j 's, we can conclude that

$$\Pr(\hat{a}_i \geq a_i + \theta) \leq \left(\frac{\|\vec{a}\|}{w\theta} \right)^k.$$

* Estan and Varghese introduced the same data structure at essentially the same time and used it for applications in network measurement [22]. They refer to the data structure as a *parallel multistage filter*.

In particular, if we fix some parameters $\varepsilon, \delta > 0$ and set $w = \lceil e/\varepsilon \rceil$, $d = \lceil \ln(1/\delta) \rceil$, and $\theta = \varepsilon \|\vec{a}\|$, then we obtain

$$\Pr(\hat{a}_i \geq a_i + \varepsilon \|\vec{a}\|) \leq \left(\frac{1}{e}\right)^{\ln(1/\delta)} = \delta.$$

In essence, we have that \hat{a}_i is likely to be a fairly good estimate of a_i —within ε times the total count over all keys. As long as a_i is not too small—for example, it is a constant fraction of the total count—this can be a useful estimate.

One practical improvement, which unfortunately has resisted much theoretical analysis, uses a technique called *conservative updating* [22]. Here, we need to assume that all increment values c_i are nonnegative. The basic idea is to never increment a counter more than is strictly necessary in order to guarantee that $\hat{a}_i \geq a_i(T)$. Formally, to process an update (i, c) , we let $c' = \min_{j \in \{1, \dots, k\}} \text{Count}[j, h_j(i)]$ and then set $\text{Count}[j, h_j(i)] = \max(c + c', \text{Count}[j, h_j(i)])$ for $j = 1, \dots, k$. Notice that a counter is not updated if it is already larger than the previous estimated count associated with the key, which is c' (the minimum over all the counters associated with i before the update), plus the update value c . It is easy to see that at every time step we still have $\hat{a}_i \geq a_i(T)$ using this conservative updating, but now the counters are not incremented as much. Intuitively, this technique further reduces the effects of keys colliding in our array of counters. In particular, keys with small count are much less likely to have any effect on estimates for large keys. Experiments show that the improvement can be substantial [22].

11.3 String Matching and Document Similarity

Hash functions can be used to create succinct *fingerprints* of keys, so that with high probability most keys have unique fingerprints. We present two applications of this tool in the context of text analysis.

11.3.1 Karp–Rabin String Matching Algorithm

Given a long string of n characters $X[1, n] = x_1, \dots, x_n$ and a shorter string of m characters $Y[1, m] = y_1, \dots, y_m$, we want to find all the occurrences of $Y[1, m]$ in $X[1, n]$, that is, all indices i_1, \dots, i_k , such that the m character substring $X[i_j, i_j + m - 1]$ is identical to $Y[1, m]$. The problem is easily solved in $O(mn)$ time. The randomized Karp–Rabin algorithm [33,29] always gives the correct answer and terminates in expected $O(n + km)$ time, where k is the number of occurrences of the string $Y[1, m]$ in $X[1, n]$. (In the worst case, the algorithm still takes only $\Omega(mn)$ time.)

Without loss of generality, we can assume that the characters in the strings are from the integer domain $\{0, \dots, b - 1\}$. Alternatively, we can view an m character string as a number written in radix b . The Karp–Rabin algorithm is based on two ideas:

1. The m character strings can be hashed into a small domain of integers to speed up the comparisons of two strings.
2. The hash value of the string $X[i + 1, i + m]$ can be computed with a constant number of operations from the hash value of the string $X[i, i + m - 1]$.

The second idea is key; if we simply hashed each m character substring of $X[1, m]$ in $O(m)$ time per hash, there would be no gain. An example of a hash function that satisfies the earlier requirements is the radix b representation of a string of m characters modulo a prime integer p :

$$h(X[i, i + m - 1]) = \left(\sum_{j=0}^{m-1} x_{i+j} b^{m-j-1} \right) \bmod p.$$

To see how to go from one hash value to the next, assume that we have computed $h(X[i, i + m - 1])$. Then

$$h(X[i + 1, i + m]) = \left(b \left(h(X[i, i + m - 1]) - x_i b^{m-1} \right) + x_{i+m} \right) \bmod p,$$

which requires only $O(1)$ operations modulo p for each new value.

The algorithm begins by computing

$$h(Y[1, m]) = \left(\sum_{j=1}^m y_j b^{m-j} \right) \bmod p$$

in $O(m)$ operations, and then for $i = 1, \dots, m - n + 1$ it computes and tests if

$$h(X[i, i + m - 1]) = h(Y[1, m]),$$

which requires a total of $O(n)$ operations overall.

If $h(X[i, i + m - 1]) \neq h(Y[1, m])$, then the two strings are not equal. If $h(X[i, i + m - 1]) = h(Y[1, m])$, the algorithm compares the m characters in the two string to verify the identity. Thus, the algorithm always gives the correct answer.

The expected run-time of the algorithm depends on the expected number of times in which $h(X[i, i + m - 1]) = h(Y[1, m])$, since in those cases the algorithm needs to individually check each of the m characters in the two strings. In particular, we are interested in minimizing the number of times in which the two hash values are equal but the two strings are not identical. In that case for some integer $r \neq 0$.

$$\sum_{j=0}^{m-1} x_{i+j} b^{m-j-1} - \sum_{j=1}^m y_j b^{m-j} = rp \neq 0. \quad (11.1)$$

Algorithm 11.1 Karp–Rabin Multiple Pattern Search

- 1: **input:** String $X[1, n]$; ℓ ; patterns $Y_1[1, m], \dots, Y_\ell[1, m]$, a random prime p and hash function h as defined in the text;
- 2: **for** $j = 0, \dots, p - 1$ **do**
- 3: $TABLE[j] = \phi$;
- 4: **end for**
- 5: Add 1 to the bucket $TABLE[h(X[1, m])]$;
- 6: **for** $i = 1, \dots, n - m + 1$ **do**
- 7: $h(X[i + 1, i + m]) = (b(h(X[i, i + m - 1]) - x_i b^{m-1}) + x_{i+m}) \bmod p$
- 8: Add $i + 1$ to the bucket $TABLE[h(X[i + 1, i + m])]$;
- 9: **end for**
- 10: **for** $j = 1, \dots, \ell$; **do**
- 11: **for** $k \in TABLE[h(Y_j[1, m])]$ **do**
- 12: **if** $X[k, k + m - 1] = Y_j[1, m]$ **then**
- 13: OUTPUT: "Pattern j appears in $X[k, k + m - 1]$ "
- 14: **end if**
- 15: **end for**
- 16: **end for**

For a given p , there are many sequences that satisfy (1). However, if we choose p at random from a sufficiently large collection of prime numbers, then the probability of satisfying (1) is small. Specifically, an integer n has no more than $\log n$ distinct prime factors, while there are asymptotically $n/\log n$ primes in the range $[1, n]$ (see, e.g., [48,59] [Theorem 5.14] or other references to the Prime Number Theorem). Since $\sum_{j=0}^{m-1} x_{i+j} b^{m-j-1} \leq b^m$, it is divisible by no more than $m \log b$ prime numbers. Thus, if we choose p uniformly at random from all the primes in the range $[0, nm^2 \log b \log(nm^2 \log b)]$, the expected number of false equalities in the running of the algorithm is bounded by

$$(n-m+1)(m \log b) \frac{\log(nm^2 \log b \log(nm^2 \log b))}{nm^2 \log b \log(nm^2 \log b)} = O\left(\frac{1}{m}\right).$$

In this case, the expected extra work from testing false identities is $O(1)$, and the expected run-time (except for verifying correct matches) is $O(n+m)$ steps.

The Karp–Rabin method is particularly useful to search for multiple patterns simultaneously (see Algorithm 11.1). Assume that we have ℓ equal-length patterns $Y_1[1, m], \dots, Y_\ell[1, m]$, and we want to find any occurrence of any of these patterns in a long string $X[1, n]$. Such searches are useful for plagiarism detection and DNA motif discovery [57]. (If the ℓ patterns do not have the same length, we can use prefixes of the longer patterns.) Comparing the hash value of each of the strings $X[i, i+m-1]$, $1 \leq i \leq n-m+1$ to the hash value of each of the ℓ patterns in the natural manner could require $\Omega(\ell n)$ time. However, suppose that we instead store the hash values of the strings in a hash table with an appropriate pointer back to the corresponding string location. For simplicity, we assume that the hash table has size p ; however, similar results can be proven for a table of $O(n)$ entries. We test for each of the ℓ patterns if its hash value coincides with any stored pointer in the table (an entry of the table can store a set of indices). The total work in populating the hash table is $O(n)$, and computing the hash values for the ℓ patterns takes $O(\ell m)$ time. If a substring matches the pattern hash, we need to verify the string matching by comparing the m characters. If we choose a prime p at random from an interval $[0, nm^2 \ell \log b \log(nm^2 \ell \log b)]$, the probability of a false identity is $O(1/m)$, and the expected run-time (except for verifying correct matches) is $O(n + \ell m)$. (To reduce the hash table size from modulo p to modulo n , we must keep both the string location and the corresponding original hash value modulo p ; we then only do the $O(m)$ work to check the pattern if the hash values modulo p match as well.)

11.3.2 Detecting Similar Documents

A major computational problem in indexing web pages for search engines is eliminating near-duplicate documents. A near-duplicate document is not an exact duplicate; exact duplicates are actually fairly easy to detect. For example, one could hash each document to a fingerprint of 128 bits and keep a sorted list of the fingerprints. To check for an exact duplicate, one could just search the fingerprint list; with a fingerprint of 128 bits, with high probability, two distinct documents should never obtain the same fingerprint hash value. In contrast, near-duplicate documents often differ in just a few locations, such as the date of last update. But even small differences will yield distinct fingerprints, so we cannot simply hash the pages as we can to check for exact duplicates.

It is estimated that about 40% of the pages on the web are duplicates or near-duplicates of other pages [38]. Eliminating near-duplicate documents increases the efficiency of the search engine and in general provides better results to the users. The *shingling technique* [9] provides an efficient and practical solution to this problem. Similar techniques are also used in other settings, such as plagiarism detectors [11].

Given a document, the process usually begins by putting it in a canonical form, by removing all punctuation, capitalization, stop words, and other extraneous information, so that the document is reduced to a sequence of terms (words). Then, given a document of n terms $X = X[1, n]$ and an integer

$k > 0$, a k -shingle in X is any subsequence of k consecutive terms $X[j, j + k - 1]$ in X . Let S_X be the collections of all k -shingles in X :

$$S_X = \{X[i, i + k - 1], 1 \leq i \leq n - k + 1\}.$$

We measure the similarity of two documents X and Y by the *Jaccard coefficient* [31] of their respective k -shingle sets, S_X and S_Y :

$$\text{Jaccard}(S_X, S_Y) = \frac{|S_X \cap S_Y|}{|S_X \cup S_Y|}.$$

The Jaccard coefficient has properties that make it a useful measure of similarity. In particular, the Jaccard coefficient is 1 for identical sets and 0 for disjoint sets. If $\text{Jaccard}(S_X, S_Y) \geq r$ for some predefined threshold r (say 0.9), we consider the two documents similar and remove one of them. The challenge is to implement this computation efficiently so that it can scale to the size of web search engines. This is achieved through two randomization steps.

We first map each shingle, using a hash function $h(\cdot)$, into a relatively large space of numbers (say 64 bits numbers). Let $h(s)$ be the hash value of shingle s and denote by H_X the collection of hash values of the shingles in X :

$$H_X = \{h(s) \mid s \text{ is a shingle in } X\}.$$

This mapping allows us to efficiently compare two shingles with relatively small probability of a false-positive. However, typical documents have a large number of shingles, so computing the Jaccard coefficient of H_X and H_Y for every pair of documents X and Y is still too expensive.

To speed up the computation of the Jaccard coefficient, we use the following randomized estimate. Assume that the hash function maps the shingles into the range $\{0, \dots, b - 1\}$ (where again, in practice $b = 2^{64}$ might be a suitable choice). Let $\Sigma(b)$ be the set of $b!$ permutations on $0, \dots, b - 1$. We choose a random permutation $\sigma \in \Sigma(b)$ and permute the two sets H_X and H_Y . The following theorem shows that the probability that the minimum values in the two permuted sets are equal is an unbiased estimate for the Jaccard coefficient of X and Y .

Theorem 11.3

Consider two documents X and Y and their collections of hashed shingles values H_X and H_Y . Choose $\sigma \in \Sigma(b)$ uniformly at random, let

$$m_X(\sigma) = \min\{\sigma(h(s)) \mid h(s) \in H_X\},$$

and similarly define m_Y . Then,

$$\text{Jaccard}(S_X, S_Y) = \Pr(m_X(\sigma) = m_Y(\sigma)).$$

Proof: Let $u = |H_X \cup H_Y|$ and $t = |H_X \cap H_Y|$. There are $u!$ permutations of $H_X \cup H_Y$ (we can ignore the values that do not appear in $H_X \cup H_Y$). Out of the $u!$ permutations, there are $t(u - 1)!$ permutations in which the minimum elements in the two sets are the same, since in this case there are t possible first elements one can choose first to be the minimum. Thus,

$$\Pr(m_X = m_Y) = \frac{t(u - 1)!}{u!} = \frac{t}{u} = \frac{|H_X \cap H_Y|}{|H_X \cup H_Y|} = \text{Jaccard}(S_X, S_Y).$$

To estimate the probability that $\Pr(m_x = m_y)$, we choose s permutations and count the number of permutations that give $m_x = m_y$. Thus, our estimate of $J(X, Y) = Jaccard(H_x, H_y)$ is

$$\tilde{J}(X, Y) = \frac{1}{s} \sum_{i=1}^s 1_{m_x(\sigma_i) = m_y(\sigma_i)}.$$

Applying a Chernoff type bound [43] (Exercise 4.15), we have

$$\Pr(|\tilde{J}(X, Y) - J(X, Y)| \geq \epsilon J(X, Y)) \leq 2e^{-2s(\epsilon)^2}.$$

Thus, for any $\epsilon > 0$, the failure probability decreases exponentially with s . Choosing s to be, for example, 100 in practice generally performs quite well.

The major advantage of the shingling algorithm arises when comparing all pairs of a set of n documents. We first choose a set of s random permutations. We then process each document and store its list of s minimal values under the s permutations. Comparing two documents requires comparisons of s pairs of integers. Thus, most of the computation is done in processing the individual documents and therefore is linear in n . The work to compare all documents can still be quadratic in n , which is efficient for small n . Further methods, such as using hashing to place items into buckets according to their s shingle values, can reduce the time further by avoiding the need to explicitly compare the s values for every pair.

11.4 RSA and Primality Testing

Randomization is an essential component of any modern cryptography system. As an example, we will discuss the RSA encryption system and the related randomized primality testing algorithm. While these cryptographic schemes rely on arguments from number theory, we focus here on how randomness is used within the algorithms and therefore quote without proof the relevant number theory results as needed.

11.4.1 Public Key Encryption System

To receive a secure message in a *public key encryption system* [18], Bob runs a protocol that generates two keys: a public key *Pub_Key* and a private key *Prv_Key*. Bob publishes the public key and keeps the private key secret. Associated with the public key is an encryption function $Enc()$, and associated with the private key is a decryption function $Dec()$. To send a secure message x to Bob, Alice computes $Enc(x)$ and sends it to Bob. The scheme is an efficient and secure encryption system if (1) $Dec(Enc(x)) = x$, that is, decoding an encoded message yields the original message; (2) the functions $Enc()$ and $Dec()$ can be computed efficiently (in time polynomial in the message's length); but (3) there is no efficient algorithm that computes x from $Enc(x)$ (decrypts the encryption function) without the knowledge of the private key *Prv_Key*. In practice, the algorithm that Bob uses to generate his private and public keys is itself public; the security of the encryption scheme is not based on obscuring how the encryption algorithm works. What keeps the private key secret is that it should be generated by a randomized algorithm, from a large domain of possible private keys. Indeed, the number of possible private keys must be superpolynomial in the size of the message. Otherwise, an adversary could try every possible private key to obtain a polynomial time algorithm. The random choice of private key becomes the essential obstacle that prevents an adversary from trivially replicating Bob's encryption process.

11.4.2 RSA

In the RSA system [55], the protocol for generating the public and private keys begins by generating two large random prime numbers p and q and an integer e , such that the greatest common divisor of $(p - 1)(q - 1)$ and e is 1. (This is commonly written as $\gcd((p - 1)(q - 1), e) = 1$. One RSA variant is to let $e = 3$, which means that p and q cannot be integers of the form $3x + 1$ for an integer x . Let $n = pq$ and $d = e^{-1} \bmod (p - 1)(q - 1)$. It is a basic fact from number theory that e has a multiplicative inverse modulo $(p - 1)(q - 1)$ if we choose e so that $\gcd((p - 1)(q - 1), e) = 1$. The public key that Bob publishes is (n, e) , and

$$\text{Enc}(x) = x^e \bmod n.$$

The private key that Bob keeps secret is (p, q, d) , and

$$\text{Dec}(y) = y^d \bmod n.$$

We first show that the decryption function correctly decodes the encrypted message. To decode Alice's message, Bob computes

$$\text{Dec}(\text{Enc}(x)) = x^{de} \bmod n.$$

Since d and e are multiplicative inverses modulo $(p - 1)(q - 1)$, we have that $de = 1 + k(p - 1)(q - 1)$ for some $k \neq 0$. Hence, for this k ,

$$\text{Dec}(\text{Enc}(x)) = x^{de} \bmod n = x^{1+k(p-1)(q-1)} \bmod n. \quad (11.2)$$

We would like to show that the last expression is equal to x . This follows from a well-known number-theoretic fact, Fermat's little theorem.

Theorem 11.4 (Fermat's little theorem)

If p is prime and $a \neq 0 \bmod p$, then

$$a^{p-1} = 1 \bmod p.$$

Applying Fermat's little theorem to (2), we have $x^{1+k(p-1)(q-1)} = x \bmod p$. This holds trivially when $x = 0 \bmod p$ and by Fermat's little theorem otherwise. Similarly, $x^{1+k(p-1)(q-1)} = x \bmod q$. It follows again from the number theory that if $x = a \bmod p$ and $x = a \bmod q$ for primes p and q that $x = a \bmod pq$; thus,

$$x^{1+k(p-1)(q-1)} = x \bmod pq = x \bmod n,$$

proving that the RSA protocol correctly decodes the encoded message. Furthermore, both the encoding and decoding are efficiently computable functions using repeated squaring for modular exponentiations. (To compute a number like $x^{16} \bmod p$, you repeatedly square to compute $x^2 \bmod p$, $x^4 \bmod p$, $x^8 \bmod p$, and $x^{16} \bmod p$; one can compute $x^n \bmod p$ in $O(\log n)$ multiplications modulo p .)

How secure is the RSA cryptosystem? First, notice that if an adversary can factor n , she can compute p and q and obtain Bob's private key. The RSA system depends on the assumption that it is computationally hard to factor a product of two large primes. It is widely believed that factoring a sufficiently

large number is computationally infeasible, and so this line of attack is ineffective, barring a breakthrough in factorization algorithms. Typically, in practice it is recommended that each prime is at least 768 bit [1], but longer keys can and should be used for greater security. If you want your RSA message to be unbreakable for the next 20 or 30 years, and you expect improvements in factoring algorithms over that time, you may want to use bigger primes.

As we have stated, in order for the adversary not to know what primes have been chosen for the private key, they should be chosen randomly; we discuss how to do this in the following. Even in choosing large random primes, it is important that the protocol avoids “easy” cases. For example, if one of the primes is small, the number is easier to factor, and that is why both primes in the key should be large. Similarly, if the two primes are close together, the factoring problem becomes easier. Finally, one must be sure to really choose the prime randomly; recently, an attack on RSA broke a large number of private keys, making use of the fact that several implementations did not choose their primes in a sufficiently random manner, allowing private key values n to be factored [36].

When the set of possible messages from Alice to Bob is small, an alternative line of attack for an adversary is to keep a table of the encrypted version of all possible messages. To defend against this weakness in the protocol, current implementations randomize the original message by adding a number of (easy to discard) extra random characters. This randomization phase—generally called “salting” [32]—significantly increases the domain of all possible messages, thus making this line of attack less feasible.

11.4.3 Primality Testing

The RSA and similar encryption systems require the generation of random large primes. By the prime number (e.g., Theorem 5.14 of [59]), the probability that a random integer in the range $[1, N]$ is prime is asymptotically $1/\ln N$. Thus, if we choose $\ln N$ random integers in the range $[1, N]$, we are more likely than not to have at least one prime number among these random numbers. (If we are particularly clever, and avoid numbers that are, for example, obviously divisible by 2, 3, and 5, we can find a prime number faster.) The challenge is to identify a prime number, that is, to efficiently test for primality of large integers. We present here an efficient randomized algorithm for this problem. Interestingly, the question of whether there is an efficient deterministic algorithm for primality testing has only relatively recently been affirmatively solved [2]. Even though deterministic algorithms are now known, this randomized algorithm is particularly quick and effective.

11.4.4 Miller–Rabin Primality Test

Algorithm 11.2 Miller–Rabin Primality Test

```

1: input: An odd integer  $n > 1$ .
2: Choose  $w \in \{2, \dots, n - 1\}$ 
3:  $s \leftarrow 0$ ;  $r \leftarrow n - 1$ ;
4: while  $s$  is even do
5:    $s = s + 1$ 
6:    $r \leftarrow r/2$ 
7: end while
8: Compute  $w^r, w^{2^r}, \dots, w^{2^s r} = w^{n-1}$ 
9: for  $i = 1, \dots, s$  do
10:  if  $w^{2^i r} = 1 \pmod n$  and  $w^{2^{i-1} r} \neq \pm 1 \pmod n$  then
11:    Return composite
12:  end if
13: end for
14: Return prime

```

The Miller–Rabin algorithm [53] is a randomized test with one-sided error. If the input is a prime number, the test always correctly confirms that the input is prime; if the input is a composite number, then with small probability the test can make a mistake and identify the input as prime. The error probability can be made arbitrarily small by repeating the test sufficiently number of times.

Given an input n , the test tries to randomly find a *witness* w demonstrating that the input n is composite. An integer $w \in \{2, \dots, n - 1\}$ is a witness for this primality test if it satisfies at least one of the following conditions:

1. $w^{n-1} \not\equiv 1 \pmod n$
2. $w^{2^i r} \not\equiv \pm 1 \pmod n$, and $w^{2^{i-1} r} \equiv 1 \pmod n$, for some integers r and $0 < i \leq s$, such that $r2^s = n - 1$

Condition (1) follows from Fermat’s little theorem; if $w^{n-1} \not\equiv 1 \pmod n$, Fermat’s little theorem says that n cannot be prime, so w provides a witness for the compositeness of n . Condition (2) gives an integer $x = w^{2^{i-1} r}$ such that $x^2 \equiv 1 \pmod n$ and $x \not\equiv \pm 1 \pmod n$. Thus, $x^2 - 1 = (x - 1)(x + 1)$ is divisible by n , but both $x - 1$ and $x + 1$ are each not themselves divisible by n . This is impossible when n is prime, so n must be composite.

The efficiency of the earlier conditions for screening out non-prime numbers is due to the following fact (see [59] for a detailed discussion and in particular Theorem 10.3):

Theorem 11.5

If n is not a prime number and w is chosen uniformly at random in the range $\{2, \dots, n - 1\}$, then with probability at least $3/4$, w is a witness according to the conditions earlier.

Hence, with probability $3/4$, each time we run the test, we will catch that n is composite. Repeating the test with k independently chosen random integers in the range $\{2, \dots, n - 1\}$, the error probability of the Miller–Rabin test is at most $(1/4)^k$.

11.5 Naive Bayesian Classifier

A naive Bayesian classifier [39] is a supervised learning algorithm that classifies objects by estimating conditional probabilities using the Bayesian rule in a simplified (“naive”) probabilistic model. In spite of its oversimplified assumptions, this method is very effective in many practical applications such as subject classification of text documents and junk e-mail filtering (see [40] and the references there). Strictly speaking, the algorithm is deterministic, and it makes no random steps. We include it here because it is one of the most practical and often-used algorithms based on a fundamental probabilistic concept.

Assume that we are given a collection of n training examples

$$\{(D_i(x_{i,1}, \dots, x_{m,i}), c_i) \mid i = 1, \dots, n\},$$

where $D_i = D_i(x_{1,i}, \dots, x_{m,i})$ is an object with features $x_{1,i}, \dots, x_{m,i}$ and c_i is the classification of the object.

Let C be the set of possible classes and X_i the set of values of the i th feature. For example, $D_i(x_{1,i}, \dots, x_{m,i})$ can be a text document with Boolean features $x_{1,i}, \dots, x_{m,i}$, where $x_{i,j} = 1$ if keyword j appears in document i , otherwise $x_{i,j} = 0$, and C can be a set of possible subjects or a {“spam,” “no-span”} classification.

The classification paradigm assumes that the training set is a sample from an unknown distribution in which the classification of an object is a (possibly probabilistic) function of the m features, that is, the classification of a new object $D(x_1, \dots, x_m)$ is fully characterized by the conditional probabilities

$$\Pr(c \in C | (x_1, \dots, x_m)) = \frac{\Pr((x_1, \dots, x_m) | c) \Pr(c)}{\Pr((x_1, \dots, x_m))}.$$

The main difficulty in applying this model is that we need to learn a large collection of conditional probabilities, corresponding to all possible combination of values of the m features. Even if each feature has just two values, we need to estimate 2^m conditional probabilities per class, which requires $\Omega(|C|2^m)$ samples. The training process is faster and requires significantly fewer examples if we assume a “naive” model in which the m features are independent. In that case,

$$\Pr((x_1, \dots, x_m) | c) = \prod_{j=1}^m \Pr(x_j | c), \quad \text{and} \quad \Pr((x_1, \dots, x_m)) = \prod_{j=1}^m \Pr(x_j).$$

With a constant number of possible values per feature, we only need to learn $O(m(|C| + 1) + |C|)$ probabilities. The training process is simple: $\Pr(x_i)$ is the fraction of objects where the i th feature equals x_i , $\Pr(x_i | c)$ is the fraction of objects classified c where the i th feature equals x_i , and $\Pr(c)$ is the fraction of objects classified c in the training set. (In practice, one often adds $1/2$ to the numerator in each of the fractions to guarantee that no probability equals 0.)

Once we train the classifier, the classification of a new document $D(x_1, \dots, x_m)$ is computed using the Bayesian rule:

$$\Pr(c | (x_1, \dots, x_m)) = \frac{\Pr(c) \prod_{j=1}^m \Pr(x_j | c)}{\prod_{j=1}^m \Pr(x_j)}.$$

Depending on the application, we can use the classification that maximizes the conditional probability (maximum likelihood classifier) or use the distribution over all possible classifications of D defined by the conditional probabilities.

The naive Bayesian classifier is efficient and simple to implement due to the “naive” assumption of independence. This assumption may lead to misleading outcomes when the classification depends on combinations of features. As a simple example, consider a collection of items characterized by two Boolean features X and Y . If $X = Y$, the item is in class A , and otherwise it is in class B . Assume further that for each value of X and Y the training set has an equal number of items in each class. All the conditional probabilities computed by the classifiers equal 0.5, and therefore the classifier is not better than a coin flip in this example. In practice, such phenomena are rare and the naive Bayesian classifier is often very effective. Verifying and explaining the practical success of this method is an active research area [19,20,49,65].

11.6 Randomized Greedy Heuristics

As a final example of how to use randomness, we offer another heuristic that remains open to theoretical analysis but proves useful in practice. Several greedy algorithms can be placed in the following natural framework. We have a collection of n elements that need to be placed (for some notion of placed); their placement will determine how good the solution is. Our greedy algorithm first orders

the n elements into some intuitively good ordering, and then elements are greedily placed one at a time according to some process.

A standard example is the first-fit decreasing algorithm for bin packing. We have n items a_1, a_2, \dots, a_n with sizes in the range $[0, 1]$, and several bins all of size 1, which we call b_1, b_2, \dots . We order the items in decreasing order in terms of their size and then place the items one at a time, placing each item in the lowest-numbered bin in which it can fit; that is, we place the item in bin b_k where k is the smallest number where the item can be placed given the placement of the preceding items. The goal is to minimize the number of nonempty bins, that is, the number of bins actually used. Intuitively, placing items in decreasing order is a good approach, as larger items are less easily placed, and first fit is a natural process for placing items. (Best fit, or placing each item in the bin with the least amount of free space where it can fit, is also possible.) As a more complex example of the same type, in the strip-packing problem, our items are rectangular boxes, and the goal is to fit the boxes into a larger rectangular box of fixed width W and minimum height. Again, a natural approach is to sort the items in decreasing order of area and to place items according to the bottom-left heuristic: place each box as far down vertically and then as much to the left as it can be placed. In some cases, these greedy heuristics can be shown to guarantee an approximation ratio; even in the worst case, they are guaranteed to be within some factor of the optimal solution.

The downside of using a greedy heuristic in this way is that it provides a single solution, but that is all. If time is available, one might hope to continue computing to find an improved solution. Obviously, one could adopt an entirely different approach, developing an algorithm based on techniques such as simulating annealing or genetic algorithms. But here we are focused on simplicity: can we better use the greedy algorithm we have in hand?

If the placement function is coded so that it takes the list of sorted elements as input, we can obtain additional possible solutions by simply providing the elements in a different order. But what order should we choose? Given that this chapter is based on randomized algorithms, one might be tempted to suggest we try orderings of elements chosen uniformly at random. But that seems like a poor idea; our heuristic started with an intuitively good ordering, and throwing that intuition away by using a completely random ordering is unlikely to be helpful.

Instead, we want a random ordering that is near our good ordering. There are multiple approaches that can be used to obtain such orderings. One natural approach is to repeatedly choose an element uniformly at random from the top k remaining elements for some parameter k . If the elements were sorted, this gives an ordering that is “close to” sorted, keeping the intuition intact but offering the flexibility of many more orderings [24,54]. An arguably more theoretically appealing approach is to repeatedly invoke the following process: take a coin that comes up heads with probability p , where p is a chosen parameter. Flip it, and if it comes up heads, take the next element in the sorted order for your permutation; otherwise, go on to the next element and continue [37]. (One can cycle back to the beginning if needed.) At each step, this is equivalent to choosing the i th element in the remaining ordered elements with probability proportional to $(1 - p)^i$. (The process can be programmed more efficiently in various ways.)

One advantage of this approach is that all orderings are possible to achieve. Indeed, more importantly, the probability an ordering is chosen is proportional to $(1 - p)^D$ where D is the Kendall tau distance, or the number of transpositions performed in a bubble sort, between the chosen ordering and the true sorted ordering. The original greedy ordering is the most likely, but it’s exponentially unlikely to be chosen. Instead, the outcome will almost surely be a sequence that is “mostly ordered.”

There are multiple variations on this theme. Many greedy algorithms change the order at each step. For example, the standard greedy algorithm for set cover at each step chooses to add to the cover the set that covers the most uncovered remaining elements. Randomized greedy algorithms can work here as well, although one must recompute the ordering at each step. Also, one need not keep the original greedy ordering as the baseline. A natural approach is to take the best ordering found thus far and use that as the ordering to randomize from. Finally, more can be done by adding local search as well.

A randomized greedy approach can be used to develop a variety of initial solutions, from which local search can be applied to look for locally optimal solutions. This general type of metaheuristic algorithm is known as a greedy randomized adaptive search procedure, or GRASP [24,54].

Improvements from randomized greedy schemes are highly problem and instance dependent. Results for several problems are given in [37], where the approach yields improvements of several percent after several hundred orderings and further improvements up through thousands of orderings. While gains for some problems over the basic greedy algorithm might be minimal, a key point in favor of randomized greedy approaches is the simplicity with which it can be implemented on top of the greedy algorithm. One loses very little in programming time for potentially interesting gains.

There is essentially nothing known that is theoretically provable about randomized greedy algorithms of this form. A better understanding of deterministic greedy algorithms of this form, which have been dubbed priority algorithms, was initiated by [6], but little is known about randomized variants.

Of course, the basic concept of doing multiple repeated randomized attempts in order to improve an algorithm has appeared in other settings. For example, one other potentially useful practical application arises in the randomized rounding of linear programs. In many cases, one can turn an optimization problem into an integer linear program, relax the integer constraint to solve the corresponding linear program, and then round the results of the linear program to obtain an integer program with the hope of obtaining a solution that is close to the optimal integer solution. In cases where an integer solution is not obtained, randomized rounding can be used: for example, a variable x with value 0.3 in the linear program solution can be rounded to 1 with probability 0.3 and 0 with probability 0.7, and similarly all variables can be independently randomly rounded. Repeated randomized rounding offers the opportunity to obtain multiple solutions, all governed by the same intuition of being “near” the solution from the linear program.

12.1 Underlying Principles

12.1.1 Introduction

The concept of approximation has been around for centuries, and it is used in all quantitative-based research areas. Examples include approximation of numbers (e.g., π , e , $\sqrt{2}$, etc.) as well as mathematical functions, physical laws, geometrical objects, etc. Modeling of physical phenomena is by approximating its behavior. Problems in many areas are very difficult to solve analytically, and sometimes they are impossible to solve with the current knowledge, skills, and tools. Therefore, one needs to resort to approximations. In this chapter, we concentrate on “relatively” new research areas for approximations, which are called *approximation algorithms* and *metaheuristics*.

Even before the 1960s, researchers in applied mathematics and graph theory had established upper and lower bounds for certain properties of graphs. For example, bounds had been established for the chromatic number, achromatic number, chromatic index, maximum clique, maximum independent set (MIS), etc. Some of these results were implementable and could be transformed into efficient algorithms that may be seen as the precursors of approximation algorithms. By the 1960s, it was understood that there were problems that computationally could be solved efficiently, whereas for other problems all the known algorithms required exponential time with respect to the input size. Heuristics were being developed to find quick solutions to problems that appeared to be computationally difficult to solve. Researchers were experimenting with heuristics, branch-and-bound procedures, and iterative improvement frameworks to evaluate their performance when solving actual problem instances. There were many claims being made, not all of which could be substantiated, about the performance of the procedures being developed to generate optimal and suboptimal solutions to combinatorial optimization problems.

Approximation algorithms, as we know them now, were formally introduced in the 1960s by Graham [1] and their most important feature is that they guarantee near-optimal solutions to *all* instances of the optimization problem being solved. These optimization problems could not be solved to optimality by the computing machines and algorithmic techniques available at that time. In the past 50 years there have been exponential improvements in the computer devices available; computing machines are orders of magnitude faster, can store significantly larger amount of data, and their cost and power consumption has decreased significantly. Also, in the past 50 years there has been tremendous growth of research in algorithmic techniques. These developments seem to imply that problems are nowadays more likely to be solved optimally than before, and that the need for approximation algorithms should have vanished, or at least decreased significantly by now. But this is not the case! There are two main reasons why solving a large class of problems to optimality is currently impossible and will remain in this state for the near future. First the size of the problem instances we are trying to solve has grown excessively over the past 50 years. New applications require the solution of problems with massive amounts of data, for example, DNA sequencing, VLSI design automation, weather prediction, Internet searching, etc. Second, most optimization problems that arise in practice are computationally intractable. This means that there are no known efficient algorithms for their solution and it has been conjectured that no such algorithms exist.

In the early 1970s, computer scientists developed the theory of NP-completeness (see Chapter 7) and showed that an extremely large number of decision problems fall into this class of computationally intractable problems. This theory tells us that the problems in this class are either all solvable via algorithms that take a polynomial number of steps for their solutions or none of them can. It is conjectured that all of the problems in this class do not have polynomial time algorithms for their solution. In practical terms this implies that even for relatively small problem instances, all algorithms for their solution take in the worst case exponential time with respect to the instance (or input) size. The fastest algorithms to solve NP-Complete problems take time $O(2^{n/2})$, $O(2^n)$, $O(n!)$, etc., where n is the number of inputs (see Sahni [3] for the definition of the Big-Oh notation). For most NP-Complete problems their best known algorithms take $O(2^n)$ time. Increasing the input size by one, for an algorithm that takes 2^n time, results in the doubling of the time needed to solve the problem instance. Even when n is 50 or 100, it would take, in the worst case, years for the fastest computer available today to solve the problem instance with this type of algorithms! For n in the millions, the time required to solve problems would be prohibitively large for most instances of the problem, not just the problem instances for which algorithms take the longest time to solve. This will remain unchanged even if new technologies were developed that would allow us to construct considerably faster computing machines. On the other hand, suppose that all NP-Complete problems can be solved in polynomial time. There is no guarantee that these polynomial time algorithms are low order polynomial time algorithms with small constants. In other words, these algorithms might not be practical. As we said before, a huge set of optimization problem that arise in practice have the property that their corresponding decision problems are NP-Complete problems. These optimization problems are called *NP-Hard* problems because computationally they are at least as hard to solve as the NP-Complete problems. But problem instances need to be solved every day when flights have to be scheduled, messages have to be routed through the Internet, computer code needs to be optimized, deadlocks in an operating system have to be detected, investment portfolios have to be optimized, energy consumption needs to be minimized, etc. In our everyday world we need to be able to cope with computational intractability.

We cope with NP-Completeness through restriction, randomization, and approximations. For example, one of the most basic NP-Complete problem is called 3-SAT (satisfiability of a Boolean expression in which all clauses have three literals, see Chapter 7). Formal verification for program correctness as well as other properties of computer programs can be reduced to 3-SAT problem instances. Most of these instances can be solved quickly. However this does not necessarily contradict the theory of NP-Completeness because these restricted instances of 3-SAT might fall into a class of instances that can be solved in polynomial time. So one way to cope with intractability is by characterizing the instances that arise in practice (restriction) and then developing efficient algorithms to solve such instances.

Another way to cope with intractability is via randomization (see Chapter 11). The idea is to design algorithms that make choices by flipping digital coins. For some problems such algorithms have been shown to generate near-optimal solutions with high probability. The third approach to cope with intractability is via approximation algorithms and metaheuristics, the main topic of this chapter.

One justification for approximations is based on computer intractability, but one can go even further and argue that one needs to apply approximation techniques even when the problems being solved are computationally tractable. The reason for this is that the input size may be very large or simply because we need to solve thousands of instances each fraction of a second. Also, in some applications the input has noise, so there is no need to solve a problem instance to optimality as the instance does not represent exactly the actual instance we want to solve. There are problems that are harder to solve than NP-Complete problems, so approximations for these problems are also required. In fact the situation is even worse, as there is a class of decision problems that are undecidable, that is, there is no algorithm to solve these problems. Chapter 7 discusses P, NP, NP-Completeness, and other complexity classes in more detail.

Our previous discussion gives the impression that approximation algorithms provide a solution to all of our problems, but that is not really the case. As it was established in the 1970s, for some problems one can generate near optimal solutions quickly, while for other problems generating provably good suboptimal solutions is computationally as difficult as generating optimal ones! In other words, generating provably good suboptimal solutions to some problems is as hard as generating optimal solutions to these problems (see [2]). To deal with the inapproximable problems there were a few techniques introduced in the 1980s and 1990s. These methodologies have been referred to as metaheuristics and include simulated annealing (SA), ant colony optimization (ACO), evolutionary computation (EC), tabu search (TS), memetic algorithms (MA), etc. There has been a tremendous amount of research in metaheuristics during the past two decades. Other previously established methodologies like local search, backtracking, and branch-and-bound have also been explored in the context of approximations. These techniques have been evaluated experimentally and have demonstrated their usefulness for solving large problem instances that arise in real world applications.

During the last two decades approximation algorithms have attracted considerable attention. This was a result of a stronger inapproximability methodology that could be applied to a wider range of problems and the development of new approximation algorithms for problems arising in established as well as in emerging application areas. Today approximation algorithms enjoy a stature comparable to that of algorithms in general and the area of metaheuristics has established itself as a fundamental area. The new stature is a byproduct of a natural expansion of research into more practical areas where solutions to real world problems are expected, as well as by the higher level of sophistication required to design and analyze these new procedures. The goal of approximation algorithms and metaheuristics is to provide the best possible solutions with the resources available and to guarantee that such solutions satisfy certain important properties. The research area of approximation algorithms and metaheuristics is huge, and we only have a few pages to talk about it.

12.1.2 Criteria to Judge Approximations

One can use many different criteria to judge approximation algorithms and metaheuristics. To name a few, we could use the quality of solutions generated, and the time and space complexity needed to generate it. One may measure the criteria in different ways, for example, we could use the worst case, average case, median case, etc. The evaluation could be analytic or experimental. Additional criteria include: characterization of data sets where the algorithm performs very well or very poorly; comparison with other algorithms using benchmarks or data sets arising in practice; tightness of bounds (bounds for quality of solution, time and space complexity); the value of the constants associated with the time complexity bound including the ones for the lower order terms; and so on. For some researchers the most important aspect of an approximation algorithm is that it is complex to analyze, but for others it is more important that the algorithm be complex and involve the use of sophisticated data structures.

For researchers working on problems directly applicable to the “real world,” experimental evaluation or evaluation on benchmarks is a more important criterion. Clearly, there is a wide variety of criteria one can use to evaluate approximation algorithms.

For any given optimization problem P , let A_1, A_2, \dots be the set of current algorithms that generate a feasible solution for each instance of problem P . Suppose that we select a set of performance criteria C and measure each one in a way we feel it is most important. How can we decide which algorithm is best for problem P with respect to C ? For example the criteria could be time and space complexity and in both cases we measure the worst case (asymptotic). We may visualize every algorithm as a point (or region) in multidimensional space. Now the basic approach used to compare feasible solutions for multiobjective function problems can also be used in this case to label some of the algorithms as *current Pareto optimal* with respect to C . Algorithm A is said to be *dominated* by algorithm B with respect to C , if for each criteria $c \in C$ algorithm B is “not worse” than A , and for at least one criteria $c \in C$ algorithm B is “better” than A . An algorithm A is said to be a *current Pareto optimal* algorithm with respect to C if none of the current algorithms dominates it. Later on in this chapter we apply this metric to specific algorithms.

For some problems it is very hard to judge the quality of the solution generated. For example, color quantization, which essentially means to approximate colors, can only be judged by viewing the resulting images and that is very subjective. Problems arising in practice (e.g., in the areas of bioinformatics, VLSI CAD, etc.) have multiobjective optimization functions, and therefore it is not simple to judge the quality of the solutions generated.

The main criterion used to compare approximation algorithms has been the quality of the solution generated. An important secondary criterion is the worst case time complexity. We are mainly interested in the worst case scenario for the solutions generated by our algorithms. There are many justifications for concentrating on the worst case behavior. The book entitled “Anitfragile,” by N. N. Taleb (Random House, 2012) mentions an interesting one relating to underestimation of events. He identified this issue as “... the Lucretius problem, after the Latin poetic philosopher who wrote that the fool believes that the tallest mountain in the world will be equal to the tallest one he has observed.”

12.1.3 Approximation Algorithms

The basic approximation methodologies are restriction (solution space and algorithmic), relaxation, rounding, partial brute force, randomization, and combinations of these methodologies. In what follows we discuss these techniques as well as formal notation, inapproximability and approximation classes.

12.1.3.1 Restriction (Solution Space)

The idea is to generate a solution to a given problem P by providing an optimal or suboptimal solution to a subproblem of P . A subproblem of a problem P means restricting the solution space for P by disallowing a subset of the feasible solutions. The idea is to restrict the solution space so that the resulting problem has some structure which can be exploited by an efficient algorithm that solves the problem optimally or suboptimally. For this approach to be effective, the subproblem must have the property that, for every problem instance, its optimal or suboptimal solution has an objective function value that is “close” to the optimal one for the original problem instance. The most common approach is to solve just one subproblem, but there are algorithms where more than one type of subproblems are solved and then the best of the solutions computed is the solution generated. In what follows we apply this technique to a couple of classical problems.

12.1.3.1.1 Application to Traveling Salesperson and Steiner Tree Problems

The traveling salesperson, Steiner tree, and spanning tree problems have a large number of applications. The *Steiner tree* problem consists of a graph $G = (V, E, W)$, where V is the set of vertices, T is a subset of V ($T \subseteq V$), E is the set of edges, and W is a function that assigns a positive value to each edge in such a way that for every pair of vertices a and b the weight of the edge $\{a, b\}$ is at most the weight of any path

from a to b . The problem is to find a tree that includes all the vertices in T plus some other vertices in the graph such that the sum of the weight of the edges in the tree is least possible. When $T = V$ the problem is called the *minimum weight (or cost) spanning tree* problem. The *traveling salesperson problem*, called the traveling salesman problem before the 1970s, is given an edge weighted complete graph, find a minimum weight tour that starts and ends at vertex one and visits every vertex *exactly* once. The weight of a tour is the sum of the weight of the edges in the tour.

Even before the 1960s, there were several well known polynomial time algorithms to construct minimum weight spanning trees for edge weighted graphs [3]. These simple greedy algorithms have low order polynomial time complexity bounds. It was known at that time that the same type of procedures would not generate an optimal tour for the traveling salesperson problem and would not construct optimal Steiner trees. However, in 1968 Moore [4] showed that for any set of points P in metric space $L_M \leq L_T \leq 2L_S$, where L_M , L_T , and L_S are the weights of a minimum weight spanning tree, a minimum weight tour (solution) for the traveling salesperson problem (TSP) and minimum weight Steiner tree for P , respectively.* Since every spanning tree for P is a Steiner tree for P and $L_M \leq L_T \leq 2L_S$ we know that a minimum weight spanning tree provides a solution to the Steiner tree problem whose total weight is at most twice the weight of an optimal Steiner tree.

In other words, any algorithm that generates a minimum weight spanning tree for the set of vertices T is a 2-approximation algorithm for the Steiner tree problem. This is called the *approximation ratio* or *approximation factor* for the algorithm. This criterion for measuring the quality of the solutions generated by an algorithm remains the most important one in use today. The approximation technique used in this case is restriction of the solution space. We are restricting the solution space by just allowing Steiner trees without any Steiner (additional) points. In fact we are constructing the best tree without any Steiner points, which is simply a minimum weight spanning tree for T .

The time complexity for our approximation method is the time complexity for solving the minimum weight spanning tree problem [3]. The bounds $L_M \leq L_T \leq 2L_S$ are established by first defining a simple transformation from any minimum weight Steiner tree into a TSP tour in such a way that $L_T \leq 2L_S$ [4]. Then by observing that the deletion of an edge in an optimum tour for the TSP problem results in a spanning tree, it follows that $L_M \leq L_T$. The *Steiner ratio* is defined as L_S/L_M . The above arguments show that the Steiner ratio is at least 1/2. Gilbert and Pollak [4] conjectured that the Steiner ratio in the Euclidean plane equals $\sqrt{3}/2$ (the .86603 ... conjecture). The proof of this conjecture and improved approximation algorithms for the Steiner tree problem are discussed in [5].

The above approach can also be used to establish a 2-approximation algorithm for the TSP problem for metric graphs as follows. First, construct a minimum weight spanning tree. Then the graph (actually multigraph) with all the vertices in G and two copies of each edge in the minimum weight spanning tree has always an Euler circuit. An *Euler circuit* is a path that starts and ends at the same vertex and visits all the edges in the graph exactly once. This is a relaxed tour that visits every city at least once. Since graph G is metric, this relaxed tour can be easily transformed into one that visits every city at most once without increasing the tour length. From the above analysis we can show that the cost of the tour constructed is at most twice the cost of an optimal tour. The algorithm takes polynomial time and results in a 2-approximation algorithm for the TSP problem. This approximation algorithm for the TSP is also referred to as the *double spanning tree algorithm*. The approximation technique behind this algorithm is also based on restriction as initially we are finding a relaxed tour the uses the least number of different edges, though each of those edges is traversed twice.

The best approximation algorithm known for the TSP defined over metric graphs is the one by Christofides [6]. The approximation ratio for this algorithm is 3/2, which is smaller than the approximation ratio of 2 for the above algorithm initially reported in [4,7]. However, looking at the bigger picture that includes the time complexity of the approximation algorithm, Christofides algorithm is not of the

* Note that for the MWST and the TSP problem the only "edges" allowed are those between any pair of points in P , but for the Steiner tree problem any point in the metric space may be a vertex in the Steiner tree.

same order as the ones given in [4,7]. Therefore, neither of these two approximation algorithms dominates the other as one has a smaller time complexity bound, whereas the other (Christofides algorithm) has a smaller worst case approximation ratio. Both of these algorithms are said to be Pareto optimal with respect to the worst case approximation ratio and worst case time complexity.

A closely related approach to restriction is *transformation-restriction*. The idea is to transform the problem instance to a restricted instance of the same problem. The difference is that the restricted problem instance is not a sub-problem of original problem instance as in the case of restriction, but it is a “simpler” problem of the same type. This approach has been applied to the problems of routing multi-terminal nets and embedding hyperedges in a cycle.

12.1.3.2 Restriction (Algorithmic)

Algorithmic restriction (or restriction via a procedure) is a technique similar to restricting the solution space. The restriction is limiting the solutions to those generated by an algorithm or a class of algorithms. Even though this restricts the solution space, in many situations it is difficult to characterize the restricted solution space. This is why we call this technique *algorithmic restriction*. Greedy methods fall into this category. Greedy algorithms generate a solution by making a sequence of irrevocable decisions. Each of these decisions is a best possible choice at that point, for example, select an edge of least weight, select the vertex of highest degree, or select the task with largest processing time requirement.

12.1.3.2.1 Application to Scheduling on Identical Machines

Let us now apply this methodology to a couple of scheduling problems. The first problem is scheduling a set of tasks on a set of identical machines (or processors) to minimize the makespan. The problem is given a set of n tasks denoted by T_1, T_2, \dots, T_n with processing time requirements t_1, t_2, \dots, t_n to be processed by a set of m identical machines. A partial order C is defined over the set of tasks to enforce a set of precedence constraints, or task dependencies. The partial order specifies that a machine cannot commence the processing of a task until all of its predecessors have been completed. Each task T_i has to be processed for t_i units of time by one of the machines. A (nonpreemptive) schedule is an assignment of tasks to time intervals on the machines in such a way that (1) each task is processed continuously for t_i units of time by one of the machines; (2) each machine processes at most one task at a time; and (3) the precedence constraints are satisfied. The *makespan* of a schedule is the latest time at which a task is being processed. The problem is to construct a minimum makespan schedule for any given set of partially ordered tasks to be processed by a set of identical machines.

Example 12.1

The number of tasks, n , is 8 and the number of machines, m , is 3. The processing time requirements for the tasks and the precedence constraints are given in Figure 12.1 where a directed graph is used to represent the task dependencies. Vertices represent tasks and the directed edges represent task dependencies. The integers next to the vertices represent the task processing requirements. Figure 12.2 depicts two schedules for this problem instance.

The *list scheduling* procedure constructs a schedule given an ordering of the tasks specified by a priority list L , which may be any permutation of the set of tasks. The list scheduling procedure finds the earliest time t when a machine is idle and an unassigned task ready to be processed is *available* (i.e., all its predecessors have completed). It then assigns the leftmost available task in the list L to an idle machine at time t and this step is repeated until all the tasks are scheduled.

For example, tasks may be ordered in decreasing (actually nonincreasing) order of their processing times. In this case, it is a greedy method with respect to the processing time requirements. The list could

FIGURE 12.2 (a) List schedules. Schedule (b) is an optimal schedule for Example 12.1. (From Gonzalez, T.F., *Handbook on Approximation Algorithms and Metaheuristics*, Chapman & Hall/CRC, Boca Raton, FL, 2007.)

be any ordering of the tasks. So this is algorithmic restriction. In this case, one can characterize the solution space. The solution space is restricted to schedules without forced “idle time,” that is, each feasible schedule is such that for every task i there is no idle time from the time at which all the predecessors of task i (in C) are completed to the time when the processing of task i begins. This is clearly a restriction of the solution space. Is the value of the optimal solution of the original problem equal to the one of the restricted problem? Figure 12.2 suggests that an optimal schedule can be generated by just finding a clever method to break ties, that is, by finding an optimal permutation of the tasks. Unfortunately one cannot prove that this is always the case because there are problem instances for which all optimal schedules for the original problem are not list schedules, that is, they all have forced idle time at some point! That is, all optimal schedules have idle time at some point even though at that point there is a task that is available (all its predecessors have been completed). Our technique is to generate one schedule without any forced idle time.

The main result in [1] is showing that for every problem instance, I , the schedule generated by this policy has a makespan that is bounded above by $(2 - 1/m)$ times the optimal makespan for the instance. This is expressed by

$$\frac{\hat{f}_I}{f_I^*} \leq 2 - \frac{1}{m}$$

where \hat{f}_I is the makespan of any possible list schedule for problem instance I , and f_I^* is the makespan of an optimal schedule for I .

This property is established in the following theorem.

Theorem 12.1

For every instance I of the identical machine scheduling problem, and every list schedule, $(\hat{f}_I/f_I^*) \leq 2 - (1/m)$

Proof: Let S be any list schedule for problem instance I with makespan \hat{f}_I . By construction of list schedules it cannot be that at some time t , for some $0 \leq t \leq \hat{f}_I$, all machines are idle. Let i_1 be the index of a task that finishes at time \hat{f}_I . For $j = 2, 3, \dots$, if task $T_{i_{j-1}}$ has at least one predecessor in C , then define i_j as the index of a task with latest finishing time that is a predecessor (in C) of task $T_{i_{j-1}}$. These tasks identified form a *chain* and let k be the number of tasks in the chain. By the definition of task T_{i_j} , it cannot be that there is an idle machine from the time when task T_{i_j} completes its processing to the time when task $T_{i_{j-1}}$ begins processing. Therefore, a machine can only be idle when another machine is executing a task in the chain. From these two observations we know that

$$m\hat{f}_I \leq (m-1) \sum_{j=1}^k t_{i_j} + \sum_{j=1}^n t_j$$

Since no machine can process more than one task at a time, and since no two tasks, one of which precedes the other in C , can be processed concurrently, we know that an optimal makespan schedule satisfies

$$f_I^* \geq \frac{1}{m} \sum_{j=1}^n t_j \quad \text{and} \quad f_I^* \geq \sum_{j=1}^k t_{i_j}$$

Substituting in the above inequality, we know that $\hat{f}_I/f_I^* \leq 2 - (1/m)$.

The second contribution in [1] was showing that the approximation ratio $(2 - 1/m)$ is the best possible for list schedules. This implies that the analysis of the approximation ratio for this algorithm cannot be improved. This was established by constructing problem instances (for all m and $n = 2m + 1$) and lists for which the schedule generated by the procedure has a makespan equal to $2 - 1/m$ times the optimal makespan for the instance.

The third important aspect of the results in [1] was showing that list scheduling has anomalies. To explain this we need to define some terms. The makespan of the list schedule for instance I using list L is denoted by $f_L(I)$. Suppose that instance I' is instance I , except that I' has an additional machine. Intuitively $f_L(I') \leq f_L(I)$ because with one additional machine all tasks should be finished earlier or, in the worst case, at the same time as $f_L(I)$. But this is not always the case for list schedules! There are problem instances and lists for which $f_L(I') > f_L(I)$. This is called an *anomaly*, because it is counterintuitive. Our expectation would be reasonable if list scheduling would generate minimum makespan schedules for all problem instances. But we have a procedure that for the most part generates suboptimal solutions. Guaranteeing that $f_L(I') \leq f_L(I)$ for all instances is not always possible in this type of environment. List scheduling suffers from other anomalies. For example, relaxing the precedence constraints, or decreasing the execution time of the tasks. In both of these cases one would expect schedules with smaller or the same makespan. But, this is not always the case. The main reason for discussing anomalies is that even today numerous papers are being published and systems are being deployed where “common sense” based procedures are being developed without any analytic justification and/or thorough experimental validation. Anomalies show that since we live for the most part in a “suboptimal” world, the effect of our decisions is not always the intended one; there are unintended consequences when one does not fully analyze the effects of approximation algorithms. An anomaly tends to arise in situations where its negative effect has the most impact.

It is interesting to note that the worst case behavior of list schedules arises when the task with largest processing requirement is being processed while the rest of the machines are idle. Can a significantly better approximation bound be established when ties are broken in favor of a task with largest processing time (*LPT ordered list schedules* or simply *LPT schedules*). The answer is no.

The problem with the LPT rule is that it only considers the processing requirements of the tasks ready to process but ignores the processing requirements of the tasks that follow it. We define the *weight of a directed path* as the sum of the processing time requirements of the tasks in the path. Any directed path that starts at task t with maximum total weight among all paths that start at task t is called a *critical path (CP) for task t* . The *CP schedule* is defined as a list schedule where the decision of which task to process next is a task whose CP “total time” is largest among the ready to be processed tasks. A CP schedule is optimal for many problem instances, however, Graham constructed problem instances for which the makespan of the CP schedule is $2 - 1/m$ times the length of an optimal schedule.

12.1.3.2.2 Application to Scheduling Independent Tasks

A restricted version of the above scheduling problem that has received considerable attention is when the tasks are independent, that is, there are no precedence constraints. Graham’s [8] elegant analysis for LPT scheduling has become a classic. In fact quite a few subsequent exact and approximation scheduling algorithms used his analysis technique.

Let I be any problem instance with n independent tasks and m identical machines. We use \hat{f}_I as the makespan for an LPT schedule for I and f_I^* as the one for an optimal schedule. In the next theorem we establish the approximation ratio for LPT schedules.

Theorem 12.2

For every scheduling problem instance I with n independent tasks and m identical machines, every LPT schedule satisfies $\hat{f}_I/f_I^* \leq (4/3) - (1/3m)$.

Proof: It is clear that LPT schedules are optimal for $m = 1$. Assume that $m \geq 2$. The proof is by contradiction. Suppose the above bound does not hold. Let I be a problem instance with the least number of tasks for which $\hat{f}_I/f_I^* > (4/3) - (1/3m)$. Let n be the number of tasks in I , m be the number of machines and assume that $t_1 \geq t_2 \geq \dots \geq t_n$. Let k be the smallest index of a task that finishes at time \hat{f}_I . It cannot be that $k < n$, as otherwise the problem instance T_1, T_2, \dots, T_k is also a counter-example and it has fewer tasks than instance I , but by assumption problem instance I is a counter example with the least number of tasks. Therefore, k must be equal to n .

By the definition of LPT schedules, we know that there cannot be idle time before task T_n begins execution. Therefore,

$$\sum_{i=1}^n t_i + (m-1)t_n \geq m\hat{f}_I$$

This is equivalent to

$$\hat{f}_I \leq \frac{1}{m} \sum_{i=1}^n t_i + \left(1 - \frac{1}{m}\right)t_n$$

Since each machine cannot process more than one task at a time, we know that $f_I^* \geq \sum_{i=1}^n t_i / m$. Combining these two bounds, we have

$$\frac{\hat{f}_I}{f_I^*} \leq 1 + \left(1 - \frac{1}{m}\right) \frac{t_n}{f_I^*}$$

Since I is a counter example for the theorem, this bound must be greater than $(4/3) - (1/3m)$. Simplifying we know that $f_i^* < 3t_n$. Since t_n is the task with smallest processing time requirement it must be that in an optimal schedule for instance I none of the machines can process three or more tasks. Therefore, the number of tasks n is at most $2m$. But one can show that LPT is an optimal schedule when $n \leq 2m$ and there is an optima schedule where every machine has at most two tasks. A contradiction.

For all m there are problem instances for which the ratio given by Theorem 2 is tight. One can prove that LPT schedules do not have the anomalies reported for list schedules.

Other approximation algorithms with improved performance were subsequently developed. Coffman et al. [9] introduced the multifit, MF, approach. A k attempt MF approach is denoted by MF_k . The MF_k procedure performs k binary search steps to find the smallest capacity c such that all the tasks can be packed into a set of m bins when packing using first fit with the tasks sorted in nondecreasing order of their processing times. The tasks assigned to bin i correspond to machine i and c is the makespan of the schedule. The approximation ratio has been shown to be $1.22 + 2^{-k}$ and the time complexity of the algorithm is $O(n \log n + kn \log m)$. Subsequent improvements to $1.2 + 2^{-k}$ [10] and $(72/61) + (1/2^k)$ [11] were possible within the same time complexity bound. However, the latter algorithm has a very large constant associated with the Big “oh” time complexity bound.

12.1.3.3 Relaxation and Related Methodologies

This approach is in a sense the opposite of “restricting the solution space.” In this case one augments the feasible solution space by including previously infeasible solutions. In this case one needs to solve a superproblem of P . An algorithm for P solves the superproblem (optimally or suboptimally) and then transforms such solution to one that is feasible for P . Approximation algorithms based on the linear programming (LP) approach fall under this category.

Khachiyan [12] developed a polynomial time algorithm for LP problems in the late 1970s. This result had a tremendous impact on research as it started a new wave of approximation algorithms. Two subsequent research accomplishments were at least as significant as Khachiyan’s [12] result. The first one was a faster polynomial time algorithm for solving LP problems developed by Karmakar [13]. The other major accomplishment was the work of Grötschel et al. [14,15]. They showed that it is possible to solve a LP problem with an exponential number of constraints (with respect to the number of variables) in time which is polynomial in the number of variables and the number of bits used to describe the input, given a *separation oracle* plus a bounding ball and a lower bound on the volume of the feasible solution space. Given a solution, the separation oracle determines in polynomial time whether or not the solution is feasible, and if it is not it finds a constraint that is violated. This technique has been shown to solve more general problems. Important developments have taken place during the past 20 years. Books [15,16] as well as Chapter 13 are excellent references for LP theory, algorithms, and applications. Among the first to apply this approach for the set and vertex cover problems include Lovász [17], Chvátal [18], Hochbaum [19], and Bar-Yehuda and Even [20] for the set and vertex cover problems and Gonzalez [21] for VLSI CAD problems.

In what follows we discuss several direct and indirect applications of relaxation to the vertex cover problem. These approaches include LP relaxation followed by deterministic or randomized rounding, α -vector, local ratio, and primal-dual.

12.1.3.3.1 Linear Programming and Rounding

Let us now consider the minimum weight vertex cover, which is a fundamental problem in the study of approximation algorithms. As input you are given a vertex weighted undirected graph G with the set of vertices $V = \{v_1, v_2, \dots, v_n\}$, edges $E = \{e_1, e_2, \dots, e_m\}$, and a positive real number (weight) w_i assigned to each vertex v_i . The problem is to find a minimum weight vertex cover, that is, a subset of vertices $C \subset V$ such that every edge is incident to at least one vertex in C . The weight of the vertex cover C is the sum of the weight of the vertices in C .

It is well known that the minimum weight vertex cover problem is an NP-hard problem. One can show that greedy methods based on selecting the vertex with minimum weight, maximum weight, minimum weight divided by the number of edges incident to it, or combinations of these approaches do not result in constant ratio approximation algorithms, that is, a c -approximation algorithm for some fixed constant c . Other approaches to solve the problem can also be shown to fail to provide a constant ratio approximation algorithm for the weighted vertex cover.

Another way to view the minimum weight vertex cover is by defining a 0/1 variable x_i for each vertex v_i in the graph. The 0/1 vector X defines a subset of vertices C as follows. Vertex v_i is in C if and only if $x_i = 1$. The set of vertices C defined by X is a vertex cover if and only if for every edge $\{i, j\}$ in the graph $x_i + x_j \geq 1$. Using the earlier notation, the vertex cover problem is formulated as a 0/1 integer linear programming (ILP) as follows:

$$\text{minimize } \sum_{i \in V} w_i x_i \tag{12.1}$$

$$\text{subject to } x_i + x_j \geq 1 \quad \forall \{i, j\} \in E \tag{12.2}$$

$$x_i \in \{0, 1\} \quad \forall i \in V \tag{12.3}$$

The 0/1 ILP is also an NP-hard problem.

Let us apply the relaxation technique. In this case, one relaxes the integer constraints for the x_i values. That is, we replace Constraint 12.3 ($x_i \in \{0, 1\}$) by $0 \leq x_i \leq 1$ (or simply $x_i \geq 0$, which in this case is equivalent). This means that we are augmenting the solution space by adding solutions that are not feasible for the original problem. This approach will at least provide us with what appears to be a good lower bound for the value of an optimal solution of the original problem, since every feasible solution to the original problem is a feasible solution to the relaxed problem (but the converse is not true). This relaxed problem is an instance of the LP problem which can be solved in polynomial time. Let X^* be an optimal solution to the LP problem. Clearly, X^* might not be a vertex cover as the x_i^* values can be fractional. The previous interpretation for the X^* values has been lost because it does not make sense to talk about a fractional part of a vertex being part of a vertex cover. To circumvent this situation, we need to use the X^* vector to construct a 0/1 vector \hat{X} that represents a vertex cover. In order for a vector \hat{X} to represent a vertex cover it needs to satisfy Inequality 12.2 (i.e., $\hat{x}_i + \hat{x}_j \geq 1$), for every edge $e_k = \{i, j\} \in E$. Clearly, the inequalities hold for X^* . This means that for each edge $e_k = \{i, j\} \in E$ at least one of x_i^* or x_j^* has value greater than or equal to 1/2. The vector \hat{X} defined from X^* as $\hat{x}_i = 1$ if $x_i^* \geq 1/2$ (rounding up) and $\hat{x}_i = 0$ if $x_i^* < 1/2$ (rounding down) represents a vertex cover. Furthermore, because of the rounding up the objective function value for the vertex cover \hat{X} is at most $2 \sum w_i x_i^*$. Since $\sum w_i x_i^*$ value is a lower bound for an optimal solution to the weighted vertex cover problem, we know that this procedure generates a vertex cover whose weight is at most twice the weight of an optimal cover, that is, it is a 2-approximation algorithm. This rounding process is called (deterministic) *LP-rounding*, and it has been applied to a large class of problems.

12.1.3.3.2 Randomized Rounding

Another way to round is via randomization, which means in this case that we flip a biased coin (with respect to the value of x_i^* [vertex cover problem] and perhaps other factors) to decide the value for \hat{x}_i . The probability of \hat{X} is a vertex cover and its expected weight can be computed analytically. By repeating this randomization process several times, one can show that a cover with weight at most twice the optimal one will be generated with very high probability. Since we have deterministic rounding for the vertex cover problem, it is clear that randomized rounding is not justified. However, for other problems it is justified. There is more complex randomized rounding for semidefinite programming (SDP).

Raghavan and Thompson [22] were the first to apply randomized rounding to solutions of relaxed LP problems to find near-optimal solutions. Since then this field has grown tremendously.

These rounding methods have the disadvantage that a LP problem needs to be solved. Experimental evaluations over several decades have shown that the simplex method solves quickly (in polynomial time) the LP problem. But the worst case time complexity is exponential with respect to the problem size. The ellipsoid algorithm and other more recent ones solve LP problems in polynomial time. Even though these algorithms have polynomial time complexity, there is a term that depends on the number of bits needed to represent the input. Much progress has been made in speeding-up these procedures. Additional information can be found in Chapter 13. Promising new LP packages include *CoinCLP* and *GUROBI* to solve large LP problem instances faster than other packages available for free to academicians.

12.1.3.3.3 α -Vector

All the remaining methods in this subsection are “independent” of LP, in the sense that the LP problem does not need to be solved. However, these methods are based on LP formulations to some extent. The first approach is called the α -vector method and we now apply it to the weighted vertex cover problem. For every vertex $i \in V$ we define $\delta(i)$ as the set of edges incident to vertex i . Let $\alpha = (\alpha_1, \alpha_2, \dots, \alpha_m)$ be any vector of m nonnegative real values, where $m = |E|$ is the number of edges in the graph. For all j multiply the j th edge inequality for the earlier LP formulation by α_j

$$\sum_{\{i,j\} \in e_k} (\alpha_k x_i + \alpha_k x_j) \geq \alpha_k \quad \forall e_k \in E \quad (12.4)$$

The total sum of these inequalities can be expressed as

$$\sum_{i \in V} \sum_{e_k \in \delta(i)} \alpha_k x_i \geq \sum_{e_k \in E} \alpha_k \quad (12.5)$$

Define $\beta_i = \sum_{e_k \in \delta(i)} \alpha_k$ for every vertex $i \in V$. In other words, let β_i be the sum of the α values of all the edges incident to vertex i . Substituting in the earlier inequality we know that

$$\sum_{i \in V} \beta_i x_i \geq \sum_{e_k \in E} \alpha_k \quad (12.6)$$

Suppose that the α vector is such that $w_i \geq \beta_i$ for all i . Then it follows that

$$\sum_{i \in V} w_i x_i \geq \sum_{i \in V} \beta_i x_i \geq \sum_{e_k \in E} \alpha_k \quad (12.7)$$

In other words, any vector α such that the resulting vector β computed from it satisfies $w_i \geq \beta_i$ provides us with the lower bound $\sum_{e_k \in E} \alpha_k$ for every vector X that represent a vertex cover. In other words if we assign a nonnegative weight to each edge in such a way that the sum of the weight of the edges incident to each vertex i is at most w_i , then the sum of the weights of the edges is a lower bound for an optimal solution.

This is a powerful lower bound. To get maximum strength we need to find a vector α such that $\sum_{e_k \in E} \alpha_k$ is maximum. But finding this vector is as hard as solving the LP problem described before. We will explain why this is the case later on. What if we find a maximal vector α , that is, a vector that cannot possibly be increased in any of its components? This is a simple task. It is just matter of starting with an α vector with all entries being zero and then increasing one of its components until it is no

longer possible to do so. We keep on doing this until there are no edges whose α value can be increased. In this maximal solution, we know that for each edge in the graph at least one of its endpoints has the property that $\beta_i = w_i$, as otherwise the maximality of α is contradicted. Define the vector \hat{X} from the α vector as follows: $x_i = 1$ if $\beta_i = w_i$, and $x_i = 0$, otherwise. Clearly, \hat{X} represents a vertex cover because for every edge in the graph we know that for at least one of its vertices has $\beta_i = w_i$. What is the weight of the vertex cover represented by \hat{X} ? We know that $\sum w_i \hat{x}_i = \sum \beta_i \hat{x}_i \leq 2 \sum \alpha_k$ because each α_k can contribute its value to at most two β_i s. Therefore we have a simple 2-approximation algorithm for the weighted vertex cover problem. Furthermore, the procedure to construct the vertex cover takes linear time with respect to the number of vertices and edges in the graph. The above algorithm can be proved to be a 2-approximation algorithm without using the ILP formulation. That is, the same result can be established by using simple combinatorial arguments [23].

12.1.3.3.4 Local Ratio

The *local ratio* approach was developed by Bar-Yehuda and Even [24]. Let us now apply it to the weighted vertex problem.

Initially, each vertex is assigned a cost which is simply its weight and it is referred to as the *remaining cost*. At each step the algorithm makes a “down payment” on a pair of vertices. This has the effect of decreasing the remaining cost of each of the two vertices. Label the edges in the graph $\{e_1, e_2, \dots, e_m\}$. The algorithm considers one edge at a time using this ordering. When the k th edge $e_k = \{i, j\}$ is considered, define γ_k as the minimum of the remaining cost of vertex i and vertex j . The edge makes a down payment of γ_k to each of its two endpoints and each of the two vertices has its remaining cost decreased by γ_k . The procedure stops when we have considered all the edges. All the vertices whose remaining cost is zero have been paid for completely and they are yours to keep. The remaining ones have not been paid for and there are “no refunds” (not even if you talk to the store manager). The vertices that have been paid for completely form a vertex cover. The weight of all the vertices in the cover generated by the procedure is at most twice $\sum_{e_k \in E} \gamma_k$, which is simply the sum of the down payments made. What is the weight of an optimal vertex cover? One can show it is at least $\sum_{e_k \in E} \gamma_k$. The reason is simple. Consider the first step when we introduce γ_1 for edge e_1 . Let I_0 be the initial problem instance and I_1 be the resulting instance after deleting edge e_1 and reducing the cost of the two endpoints of edge e_1 by γ_1 . One can easily establish that $f^*(I_0) \geq f^*(I_1) + \gamma_1$ and inductively that $f^*(I_0) \geq \sum_{e_k \in E} \gamma_k$ [25]. The algorithm is a 2-approximation algorithm for the weighted vertex cover. The approach is called *local ratio* because at each step one adds $2\gamma_k$ to the value of the solution generated and one accounts for γ_k value of an optimal solution. This local ratio approach has been successfully applied to solve optimally and suboptimally quite a few problems. The nice feature is that it is very simple to understand and does not require any LP knowledge or background.

12.1.3.3.5 Primal-Dual

The primal-dual approach is similar to the previous ones, but it uses the foundations of LP theory. Let us now apply it to the weight vertex cover problem using our previous formulation. The LP relaxation problem is

$$\text{minimize } \sum_{i \in V} w_i x_i \tag{12.8}$$

$$\text{subject to } x_i + x_j \geq 1 \quad \forall e_k = \{i, j\} \in E \tag{12.9}$$

$$x_i \geq 0 \quad \forall i \in V \tag{12.10}$$

The LP problem is called the *primal* problem. The corresponding dual problem is

$$\text{maximize } \sum_{e_k \in E} y_k \quad (12.11)$$

$$\text{subject to } \sum_{e_k \in \delta(i)} y_k \leq w_i \quad \forall i \in V \quad (12.12)$$

$$y_k \geq 0 \quad \forall e_k \in E \quad (12.13)$$

As you can see the Y vector is simply the α vector defined before, and the dual is to find a Y vector with maximum $\sum_{i \in V} y_i$. Linear programming theory [15,16] states that any feasible solution X to the primal problem and any feasible solution Y to the dual problem are such that

$$\sum_{e_k \in E} y_k \leq \sum_{i \in V} w_i x_i$$

This is called *weak duality*. *Strong duality* states that

$$\sum_{e_k \in E} y_k^* = \sum_{i \in V} w_i x_i^*$$

where

X^* is an optimal solution to the primal problem

Y^* is an optimal solution to the dual problem

Note that the dual variables are multiplied by weights which are the right hand side of the constraints in the primal problem. In this case all of them are one.

The primal-dual approach is based on the weak duality property. The idea is to first construct a feasible solution to the dual problem. This solution will give us a lower bound for the value of an optimal vertex cover. Then we use this solution to construct a solution to the primal problem. The idea is that the difference of the objective function value between the primal and dual solutions we constructed is “small.” In this case we construct a maximal vector Y (as we did with the α vector before). Then we note that since the Y vector is maximal, then for at least one of the endpoints (say i) of every edge must satisfy Inequality 12.12 tight, that is, $\sum_{e_k \in \delta(i)} y_k = w_i$. Now define vector X with $x_i = 1$ if Inequality 12.12 is tight in the dual solution. Clearly, X represent a feasible solution to the primal problem and its objective function value is at most $2 \sum_k y_k$.

It then follows by weak duality that an optimal weighted vertex cover has value at least $\sum_k y_k$ and we have a 2-approximation algorithm for the weighted vertex cover. It is simple to see that the algorithm takes linear time (with respect to the number of vertices and edges in the graph) to solve the problem.

There are other ways to construct a solution to the dual problem. For example, by increasing all the y values until one inequality becomes tight. Then we fix a set of y values and increase all the remaining ones until another inequality becomes tight. We repeat this process until all the values of the y are fixed [26]. The only issue with this procedure is that it takes $O(m^2)$ time, rather than just $O(m)$ as the previous one.

It is interesting to note that these relaxation techniques do not work for most problems. This is the case even when these problems are very similar in nature to the ones for which the techniques can be applied successfully. Consider the *MIS* problem. As input you are given an undirected graph $G(V, E)$. The problem is to find a largest set of vertices such that no two vertices are adjacent. The problem can be formulated as an ILP problem as the vertex cover problem, except that it is a maximization problem and the Constraint 12.2 is $x_i + x_j \leq 0$. Applying the same arguments as in the case of the vertex cover problem does not result in a constant ratio approximation! The interesting fact is that if there is a way to make this work and produce a constant ratio approximation in polynomial time, then all NP-Complete problems can be solved in polynomial time.

Linear programming has also been used as a tool to compute the approximation ratio of some algorithms. This type of research may eventually be called the *automatic analysis of approximation algorithms*.

Algorithms based on the primal-dual approach are for the most part faster, since they normally take (low) polynomial time with respect to the number of “objects” in the input. However, the LP-rounding approach can be applied to a much larger class of problems and it is more robust since the technique is more likely to be applicable after changing the objective function and/or constraints for a problem.

There are many other very interesting results that have been published in the last 15 years. Goemans and Williamson [27] developed improved approximation algorithms for the maxcut and satisfiability problems using *SDP*. This seminal work opened a new venue for the design of approximation algorithms. Goemans and Williamson [28] also developed powerful techniques for designing approximation algorithms based on the primal-dual approach. The dual-fitting and factor revealing approach is used in [29].

Approximations algorithms that are based on restriction and relaxation exist. These algorithms first restricts the solution space and then relaxes it resulting in a solution space that is different from the original one. Gonzalez and Gonzalez [30] have applied this approach successfully to the minimum edge length corridor problem.

12.1.3.4 Formal Notation

Let P be an optimization problem and let A be an algorithm that generates a feasible solution for every instance I of problem P . We use $\hat{f}_A(I)$ to denote the objective function value of the solution generated by algorithm A for instance I . We drop A and use $\hat{f}(I)$ when it is clear which algorithm is being used. Let $f^*(I)$ be the objective function value of an optimal solution for instance I . Note that normally we do not know the value of $f^*(I)$ exactly, but we use lower bounds which should be as tight as possible.

Sahni [31] defines as an ϵ -approximation algorithm for problem P an algorithm that generates a feasible solution for every problem instance I of P such that

$$\left| \frac{\hat{f}(I) - f^*(I)}{f^*(I)} \right| \leq \epsilon$$

It is assumed that $f^*(I) > 0$. For a minimization problem $\epsilon > 0$ and for a maximization problem $0 < \epsilon < 1$. In both cases ϵ represents the percentage of error. The algorithm is called an ϵ -approximation algorithm and the solution is said to be an ϵ -approximate solution. Graham’s list scheduling algorithm [1] is a $1 - 1/n$ approximation algorithm, and Sahni and Gonzalez [2] algorithm, which we discuss later on, for the k -maxcut problem is a $1/k$ -approximation algorithm. Note that this notation is different from the one discussed in previous sections. The difference is 1 unit, that is, the ϵ in this notation corresponds to $1 + \epsilon$ in the other. Note that, as in the research literature, we use both notations interchangeably. However, readers can easily disambiguate from the context.

Johnson [32] used a slightly different but equivalent notation. He uses the approximation ratio ρ to mean that for every problem instance I of P , the algorithm satisfies $(\hat{f}(I)/f^*(I)) \leq \rho$ for minimization problems, and $(f^*(I)/\hat{f}(I)) \leq \rho$ for maximization problems. The one for minimization problems is the same as the one we have been using [1]. The value for ρ is always greater than one, and the closer to one, the better the solution generated by the algorithm. One refers to ρ as the *approximation ratio* and the algorithm is a ρ -approximation algorithm. The list scheduling algorithm in the previous section is a $2 - (1/m)$ -approximation algorithm and the algorithm given in Section 12.1.3 for the k -maxcut problem is a $k/(k - 1)$ -approximation algorithm. Some researchers use $1/\rho$ as the approximation ratio for maximization problems. Using this notation, the algorithm in Section 12.1.3 for the k -maxcut problem is a $1 - (1/k)$ -approximation algorithm.

All the above forms are in use today. The most popular ones are ρ for minimization and $1/\rho$ for maximization. These are referred to as approximation ratios or approximation factors. We refer to all of these algorithms as ϵ -approximation algorithms. The point to remember is that one needs to be aware of the differences and be alert when reading the research literature.

In general it is preferred that ϵ and ρ are constants independent of the problem size. But, they can be dependent on the size of the problem instance I . For example, it may be $\ln n$, or n^ϵ for some problems, where n is some parameter of the problem that depends on I , for example, the number of nodes in the input graph, and ϵ depends on the algorithm being used to generate the solutions.

Normally one prefers an algorithm with a smaller approximation ratio. However it is not always the case that an algorithm with smaller approximation ratio always generates solutions closer to optimal than one with a larger approximation ratio. The main reason is that the notation is for the worst case ratio and the worst case does not always occur. But there are other subtle reasons too. For example, the lower bound for the optimal solution value used in the analysis of two different algorithms may be different. Let P be the shortest path minimization problem, given an edge weighted (positive integers) graph find a shortest path between vertices s and t . Let A be an algorithm with approximation ratio 2. In this case we use d as the lower bound for $f^*(I)$, where d is some parameter of the problem instance. Algorithm B is a 1.5-approximation algorithm, but $f^*(I)$ used to establish it is the exact optimal solution value. Suppose that for problem instance I the value of d is 5 and $f^*(I) = 8$. Algorithm A will generate a path with weight at most 10, whereas algorithm B will generate one with weight at most $1.5 \times 8 = 12$. So the solution generated by Algorithm B may be worse than the one generated by A even when both algorithms generate the worst possible solution for the instance.

One could argue that the average “error” makes more sense than worst case. The problem is to define and establish bounds for average “error.” There are many other pitfalls when using worst case ratios. It is important to keep in mind all of this when making comparisons between algorithms. In practice one may run several different approximation algorithms concurrently and output the best of the solutions. This has the disadvantage that the running time of this compound algorithm will be the one for the slowest algorithm. The analysis quickly becomes very difficult, but the solutions generated are in many cases significantly better than the one generated by one strategy.

More elaborate approximation algorithms have been developed that generate a solution for any fixed constant ϵ . Formally, a *Polynomial Time Approximation Scheme (PTAS)* for problem P is an algorithm A that given any fixed constant $\epsilon > 0$ it constructs a solution to problem P such that $|\hat{f}(I) - f^*(I)|/f^*(I) \leq \epsilon$ in polynomial time with respect to the length of the instance I . Note that the time complexity may be exponential with respect to $1/\epsilon$. For example, the time complexity could be $O(n^{1/\epsilon})$ or $O(n + 4^{O(1/\epsilon)})$. Equivalent PTAS is also defined using different notation, for example based on $(\hat{f}(I)/f^*(I)) \leq 1 + \epsilon$ for minimization problems. We will see examples of PTAS later on in this chapter.

Clearly, with respect to approximation ratio a PTAS is far better than an ϵ -approximation algorithms for some fixed ϵ . But the main drawback of all known PTAS is that they are not practical because the time complexity is exponential on $1/\epsilon$ or the constants associated with time complexity bound are huge. There may be PTAS that is practical for “natural” occurring problems, but none has been found yet. On the positive side, a PTAS establishes that a problem can be approximated for all fixed constants.

A PTAS is said to be a *Fully Polynomial Time Approximation Scheme (FPTAS)* if its time complexity is polynomial with respect to n (the problem size) and $1/\epsilon$. FPTAS are for the most part practical algorithms. We discuss one such FPTAS later on in this section.

There are a few problems for which a large approximation ratio applies only to problem instances where the value of the optimal solution is small. For these problems we use the following ratio. Informally, ρ_A^∞ is the smallest constant such that there exists a constant $K < \infty$ for which

$$\hat{f}(I) \leq \rho_A^\infty f^*(I) + K$$

The *asymptotic approximation ratio* is the multiplicative constant and it hides the additive constant K . This is most useful when K is small. The asymptotic notation is mainly used for the bin packing problem and its variants.

Approximation schemes based on asymptotic approximation algorithms have been developed. The first APTAS (asymptotic PTAS) was developed by Fernandez de la Vega and Lueker [33] for the bin packing problem. The first AFPTAS (asymptotic FPTAS) for the same problem was developed by Karmakar and Karp [34]. Randomized PTAS and FPTAS have also been developed [5].

12.1.3.5 Inapproximability and Approximation Classes

Sahni and Gonzalez [2] were the first to show that there are NP-hard optimization problems for which the existence of a constant ratio polynomial time approximation algorithm implies the existence of a polynomial time algorithm to generate an optimal solution. In other words, for these problems the complexity of generating a constant ratio approximation and an optimal solution are computationally equivalent problems. For these problems the approximation problem is NP-hard or simply inapproximable (under the assumption that $P \neq NP$). Later on, this notion was extended to mean that there is no polynomial time algorithm with approximation ratio r for a problem under some complexity theoretic hypothesis. The approximation ratio r is called the *inapproximability ratio* [5].

Consider the k -min-cluster problem. Given an edge-weighted undirected graph the k -min-cluster problem is to partition the set of vertices into k sets so as to minimize the sum of the weight of the edges with endpoints in the same group. The k -maxcut problem is defined as the k -min-cluster problem, except that the objective is to maximize the sum of the weight of the edges with endpoints in different sets.

Even though the k -min-cluster and the k -maxcut problems have exactly the same set of feasible and optimal solutions, there is a linear time algorithm for the k -maxcut problem that generates k -partitions with weight at least $(k - 1)/k$ times the weight of an optimal k -cut [2], whereas approximating the k -min-cluster problem is a computationally intractable problem [2]. The former problem has the property that a near optimal solution may be obtained as long as partial decisions are made optimally, whereas for the k -min-cluster an optimal partial decision may turn out to force a terrible overall solution (one local optimal decision may turn out to have devastating effects to the quality of the final solution). In other words, one strike and you are out.

Another interesting problem whose approximation problem is NP-hard is the TSP problem [2]. This is not exactly the same version of the TSP problem discussed earlier which we said has several constant ratio polynomial time approximation algorithms. The difference is that the graph may have any set of arbitrary weights on the edges, in other words, the graph is not restricted to be metric. On the other hands, the approximation algorithms given in [4,7] can be adapted easily to provide a constant ratio approximation to the version of the TSP problem for arbitrarily weighted graphs when a tour is defined as visiting each vertex in the graph *at least* once. Since Moore's approximation algorithms for the metric Steiner tree and metric TSP are based on the same idea, one would expect that the Steiner tree problem defined over arbitrarily weighted graphs is NP-hard to approximate. However, this is not the case. Moore's algorithm [4] can be modified to be a 2-approximation algorithm for this more general Steiner tree problem.

As pointed out in [35], Levner and Gens [36] added a couple of problems to the list of problems that are NP-hard to approximate. Garey and Johnson [37] show that the max clique problem has the property that if for some constant r there is a polynomial time r -approximation algorithm, then there is a polynomial time r' -approximation for any constant r' . Since then researchers had tried many different algorithms for the clique problem without success, it was conjectured that none existed, under the assumption that $P \neq NP$.

Garey and Johnson [38] showed that a class of NP-hard optimization problems that satisfy certain properties and whose corresponding decision problems are strongly NP-Complete have the property that if any one of them has a FPTAS, then $P = NP$. The properties are that the objective function value of every feasible solution is a positive integer, and the problem is *strongly* NP-hard. This means that the

problem is NP-hard even when the magnitude of the maximum number in the input is bounded by a polynomial on the input length. For example, the TSP problem is strongly NP-hard, whereas the knapsack problem is not, under the assumption that $P \neq NP$.

Informally, the class of *NP optimization problems*, *NPO*, is the set of all optimization problems Π which can be “recognized” in polynomial time. In the late 1980s Papadimitriou and Yannakakis [39] defined *MAXSNP* as a subclass of *NPO*. These problems can be approximated within a constant factor and have a nice logical characterization. They showed that if *max3sat*, *vertex cover*, *maxcut*, and some other problems in the class could be approximated in polynomial time with an arbitrary precision, then all *MAXSNP* problems have the same property. This fact was established by using *approximation preserving* reductions. In the 1990s Arora et al. [40], using complex arguments, showed that *max3sat* is hard to approximate within a factor of $1 + \epsilon$ for some $\epsilon > 0$ unless $P = NP$. Thus, all problems in *MAXSNP* do not admit a PTAS unless $P = NP$. This work led to major developments in the area of approximation algorithms, including inapproximability results for other problems, approximation preserving reductions, discovery of new inapproximability classes, and construction of approximation algorithms achieving optimal or near optimal ratios.

Feige et al. [41] showed that the clique problem could not be approximated to within some constant value. Applying the previous results in [38] it showed that the clique problem is inapproximable to within any constant. Feige [42] showed that the set cover is inapproximable within $\ln n$. Other inapproximable results appear in [43,44].

Ausiello et al. [45] introduced and studied the *differential ratio* error measurement. Informally, an algorithm is said to be a δ differential ratio approximation algorithm if for every instance I of P

$$\frac{\omega(I) - \hat{f}(I)}{\omega(I) - f^*(I)} \leq \delta$$

where $\omega(I)$ is the value of a worst solution for instance I . Differential ratio has some interesting properties for the complexity of the approximation problems. For some problems $\omega(I)$ may be unbounded in which case one has to limit its value. For example, when scheduling independent tasks on identical processors the worst schedule would postpone indefinitely the processing of a task. But for this problem one could limit $\omega(I)$ by restricting the feasible schedules to those without idle time on all machines at the same time.

Differential ratio destroys the artificial dissymmetry between “equivalent” minimization and maximization problems (for example, the k -max-cut and the k -min cluster discussed earlier) when it comes to approximation. This ratio uses the difference between the worst possible solution minus the solution generated by the algorithm, divided by the difference between the worst solution minus the best solution. Cornuejols et al. [46] also discussed a variation of differential ratio approximations since for the problem they studied they wanted the ratio to satisfy the following property: “A modification of the data that adds a constant to the objective function value should also leave the error measure unchanged.” That is, the “error” by the approximation algorithm should be the same as before. Differential ratio along with other similar notions are discussed in [45]. Ausiello et al. [45] also introduced *reductions that preserve approximability*. Since then there have been several new types of approximation preserving reductions. The main advantage of these reductions is that they enable us to define large classes of optimization problems that behave in the same way with respect to approximation. An *NPO* problem Π is said to be in *APX*, if it has a constant approximation ratio polynomial time algorithm. The class *PTAS* consists of all *NPO* problems which have PTAS. The class *FPTAS* is defined similarly. Other classes, *Poly-APX*, *Log-APX*, and *Exp-APX*, have also been defined.

As said before there are many different criteria to compare algorithms. What if we use both the approximation ratio and time complexity? For example, the simple linear time approximation algorithm for the k -maxcut problem in [2] and the complex one given in [27]. Both of these algorithms are current Pareto optimal as one is faster, but the other has worst case ration that is smaller.

The best algorithm to use also depends on the instance being solved. It makes a difference whether we are dealing with an instance of the TSP with optimal tour cost equal to one billion dollars and one with optimal cost equal to just a few pennies. Though, it also depends on the number of such instances being solved.

12.1.3.6 Partial Brute Force

The idea here is to solve by enumeration (or other techniques) part of the problem and then the remaining decisions can be made via a simple (perhaps greedy) procedure. The approach is to solve optimally the “most important part of the problem” and then solve suboptimally the remaining portion of the problem.

As mentioned before, Graham [8] studied the problem of scheduling tasks on identical machines, but restricted to the case where all the tasks are independent, that is, the set of precedence constraints is empty. We described and analyzed before an LPT procedure that guarantees solutions that are within a fixed ϵ value. We now apply the partial brute force approach to obtain a PTAS for this problem.

Graham [8], following a suggestion by Kleitman and Knuth, considered list schedules where the first portion of the list L consists of k tasks with the largest processing times arranged by their starting times in an optimal schedule for these k tasks (only). Then the list L has the remaining $n - k$ tasks in any order. The approximation ratio for this list schedule using list L is $1 + (1 - 1/m)/(1 + \lceil k/m \rceil)$. An optimal schedule for the largest k tasks can be constructed in $O(km^k)$ time by a straight forward branch and bound algorithm. In other words, this algorithm has approximation ratio $1 + \epsilon$ and time complexity $O(n + m^{(m-1-\epsilon m)/\epsilon})$. For any fixed constants m and ϵ the algorithm constructs in polynomial (linear) time with respect to n a schedule with makespan at most $1 + \epsilon$ times the optimal makespan. Note that for a fixed constant m the time complexity is polynomial with respect to n , but it is not polynomial with respect to $1/\epsilon$. This was the first algorithm of its kind and later on it was referred to as a *Polynomial Time Approximation Scheme (PTAS)*.

Clearly, with respect to approximation ratio, a PTAS is better than an ϵ -approximation algorithm for some fixed value ϵ . But their main drawback is that PTAS is not useful in practice because the time complexity is exponential on $1/\epsilon$ or the constants associated with the time complexity bound are large. This does not preclude the existence of a practical PTAS for “natural” occurring problem. However, a PTAS establishes that a problem can be approximated for all fixed constants.

12.1.3.7 Rounding

In the rounding technique one modifies the parameters of the problem instance to obtain another instance that can be easily solved optimally or suboptimally. We solve such instance and use it as a suboptimal solution to the original instance. Before applying this technique to obtain a FPTAS to the knapsack problem, additional notation needs to be defined.

The knapsack problem consists of n items with item i having a profit $p(i)$ and a weight $w(i)$, where each $p(i)$ and $w(i)$ is an integer. One is also given the weight capacity of the knapsack. The problem is to find a subset of items with total weight at most C and maximum total profit.

Via dynamic programming one can show that the knapsack problem can be solved in time $O\left(n * \min\left\{2^n, \sum p(i), C\right\}\right)$. Clearly, when $\min\left\{\sum p(i), C\right\} \leq poly(n)$, where $poly(n)$ is a polynomial on n , the problem can be solved in polynomial time with respect to n , the problem size. The problem is computationally intractable when the capacity of the knapsack and the sum of the profits are large provided that there is no optimal solution with a “small” number of items.

When given an instance I , the approach is to construct an instance I' which can be solved in polynomial time with respect to n , the number of items. Every feasible solution to I' is also a feasible one to I and the percentage difference between the optimal solutions to these two problems is bounded by $1 + \epsilon$. The rounding that we use leaves the weights of the items untouched, but the profits are rounded proportionally to $1/\epsilon$. For further details see Chapter 10 in [5].

The first FPTAS was developed by Ibarra and Kim [47] for the knapsack problem. Sahni [48] developed three different techniques based on rounding, interval partitioning, and separation to construct FPTAS for sequencing and scheduling problems. Horowitz and Sahni [49] developed FPTAS for scheduling on machines with different processing speeds. Gens and Levner [35] discuss a simple $O(n^3/\epsilon)$ FPTAS for the knapsack problem developed by Babat [50,51]. Lawler [52] developed techniques to speed up FPTAS for the knapsack and related problems. Additional results are discussed in [5].

12.1.3.8 Additional Classical Results

In the early 1970s, Garey et al. [53] as well as Johnson [54,55] developed the first set of polynomial time approximation algorithms for the bin packing problem. In the bin packing problem we are given a set of n items a_1, a_2, \dots, a_n , with size $0 < s(a_i) < 1$, and an unlimited number of bins with capacity 1. The goal is to find the minimum number of bins in such a way that the sum of the size of the items assigned to each bin is at most one. Research on the bin packing problem and its variants has attracted very talented investigators who have generated more than 650 papers, most of which deal with approximations. This work has been driven by numerous applications in engineering and information sciences. Interestingly several algorithmic methodologies were applied for the first time to the bin packing problem and then to problems in other areas.

12.1.4 Local Search and Metaheuristics

Local search techniques have a long history; they range from simple constructive and iterative improvement algorithms to rather complex methods that require significant fine-tuning and large search neighborhoods. Local search is perhaps one of the most natural ways to attempt to find an optimal (or suboptimal) solution to an optimization problem. The idea of “local” search is simple: Start from a solution and improve it by making local changes until no further progress is possible. Local search normally terminates at a local optimal. To escape from a local optimal solution several extensions have been developed. One very natural one is to expand the size of the neighborhood and make it very large. But finding the best neighbor to move to is most of the time an NP-hard problem. Therefore, an approximation solution is needed at this step. Stochastic local search algorithms use randomized movements in the neighborhood.

The study of local search sparked the study of modern heuristics, which have evolved and are now called *metaheuristics*. The term metaheuristics was coined by Glover [56] in 1986 and in general means “to find beyond in an upper level.” The main idea is to automate mechanisms to escape local optima. As discussed in Section 12.1.1, metaheuristics methodologies include TS, SA, ACO, EC, ILC (Iterated Local Search), MA, etc. One of the motivations for the study of metaheuristics is that it was recognized early on that constant ratio polynomial time approximation algorithms are not likely to exist for a large class of practical problems [2]. Metaheuristics do not guarantee that optimal or near optimal solutions can be found quickly for all problem instances. However, these programs do find near optimal solutions for many problem instances that arise in practice. These procedures are general in the sense that they apply to a wide range of problems. Metaheuristics include mechanisms to avoid being trapped in local optimal like local search. These are the most appealing aspects of metaheuristics. At some level metaheuristics explore the solution space (diversification) and then use the accumulated search experience to guide the search (intensification). They also include short term strategies tied to randomness, and medium and long term strategies based on the use of memory. Different metaheuristics make use of these search strategies at different levels. The idea is to explore the solution space and move to better neighborhoods with better local optimal solutions.

Metaheuristics fall into two categories: single point search and population-based strategies. TS, SA, and local search methods fall into the single point search strategy. The idea is that at different points they behave like local search, that is, move to better solutions in the local neighborhood. However, sometimes they jump out of the local neighborhood and continue from that point. These jumps are guided from past experience in the search. Methods like MA, genetic algorithms (GAs), and ACO are population-based. This means that at any given point a set of solutions are in existence. Then at each step the set evolves into another set and the process continues. The evolution is to local and nonlocal neighborhoods.

Metaheuristics can also be categorized as nature versus nonnature inspired. EC and ACO are nature inspired methodologies. Whereas TS and MA are not nature inspired methods. Some methodologies use memory to guide the search process and other methods are memoryless. Different levels of randomization are used in metaheuristics. In what follows we briefly discuss these methodologies.

12.1.4.1 Local Search

Local search is perhaps one of the most natural ways to attempt to find an optimal or suboptimal solution to an optimization problem. The idea of local search is simple: Start from a solution and improve it by making local changes until no further progress is possible. Most of the time it is simple to find an initial feasible solution, but there are problems where finding an initial feasible solution is a computationally intractable problem. In this case the problem is inapproximable in polynomial time unless $P \neq NP$. When the neighborhood to search for the next solution is very large, finding the best neighbor to move to is many times an NP-hard problem. Therefore, an approximation solution is needed at this step. Reactive search advocates the use of simple symbolic machine learning to automate the parameter tuning process and make it an integral (and fully documented) part of the algorithm. Parameters are normally tuned through a feedback loop that many times depend on the user. Reactive search attempts to mechanize this process. Stochastic local search algorithms have been introduced that make stochastic choices.

Lin and Kernighan [57] developed local search heuristics that established experimentally that instances of the TSP with up to 110 cities can be solved to optimality with 95% confidence in $O(n^2)$ time. This local search based procedure was applied to a set of randomly selected feasible solutions. The process was to perform $k = 2$ pairs of link (edge) interchanges that improved the length of the tour. On the other hand, Papadimitriou and Steiglitz [58] showed that for the TSP no local optimum of an efficiently searchable neighborhood can be within a constant factor of the optimal value unless $P = NP$. Since then there has been quite a bit of research activity in this area.

12.1.4.2 Tabu Search

The term *tabu search* (TS) was coined by Glover [56]. TS is based on *adaptive memory* and *responsive exploration*. The former allows for the effective and efficient search of the solution space. The latter is used to guide the search process by imposing restraints and inducements based on the information collected. Intensification and diversification are controlled by the information collected, rather than by a random process.

12.1.4.3 Simulated Annealing

In the early 1980s Kirkpatrick et al. [59] and independently Černý [60] introduced SA as a randomized local search algorithm to solve combinatorial optimization problems. SA is a local search algorithm, which means that it starts with an initial solution and then searches through the solution space by iteratively generating a new solution that is “near” to it. Sometimes the moves are to a worse solution to escape local optimal solutions. The probability of such moves decreases with time. This method is based on statistical mechanics (Metropolis algorithm). It was heavily inspired by an analogy between the physical annealing process of solids and the problem of solving large combinatorial optimization problems.

12.1.4.4 Evolutionary Computation

Evolutionary computation (EC) is a metaphor for building, applying, and studying algorithms based on Darwinian principles of natural selection. Algorithms that are based on evolutionary principles are called *Evolutionary Algorithms* (EAs). They are inspired by nature’s capability to evolve living beings well adapted to their environment. There have been a variety of slightly different EAs proposed over the years. Three different strands of EAs were developed independently of each other over time. These are *Evolutionary Programming* introduced by Fogel [61] and Fogel et al. [62], *Evolutionary Strategies* proposed by Rechenberg [63] and *GAs* initiated by Holland [64]. GAs are mainly applied to solve discrete problems. *Genetic Programming* and *Scatter Search* are more recent members of the EA family. EAs can be understood from a unified point of view with respect to their main components and the way they

explore the search space. The two main factors are recombination (crossover) which combine two or more individuals (solutions) and mutation (modification) of an individual (solution).

12.1.4.5 Ant Colony Optimization

This metaheuristic is inspired by the behavior of real ants, it was proposed by Dorigo and colleagues [65] in the early 1990s as a method for solving hard combinatorial optimization problems. The basic idea is to simulate the use of pheromone for finding shortest paths like the ones ants use to locate food. But also use random walks, like ants, to find other sources of food. These algorithms may be considered to be part of *swarm intelligence*, the research field that studies algorithms inspired by the observation of the behavior of *swarms*. Swarm intelligence algorithms are made up of simple individuals that cooperate through self-organization.

12.1.4.6 Memetic Algorithms

Moscato [66] introduced MA in the late 1980s to denote a family of metaheuristics which can be characterized as the hybridization of different algorithmic approaches for a given problem. It is a population-based approach in which a set of cooperating and competing agents are engaged in periods of individual improvement of the solutions while they sporadically interact. An important component is *problem and instance-dependent knowledge* which is used to speed-up the search process.

12.2 Impact on Practice

Approximation algorithms and metaheuristics have been developed to solve a wide variety of problems. A good portion of these results have only theoretical value due to the fact that the time complexity function for these algorithms is a high order polynomial and/or have huge constants associated with their time complexity bounds. However, these results are important because they establish what is possible now, and it may be that in the near future these algorithms will be transformed into practical ones. The rest of the approximation algorithms do not suffer from this pitfall, but some were designed for problems with limited applicability. However, the remaining approximation algorithms have real world applications. On the other hand, there is a huge number of important application areas, including new emerging ones, where approximation algorithms and metaheuristics have barely penetrated and we believe there is an enormous potential for approximation algorithms and metaheuristics in these areas. Our goal is to expose the reader to the areas of the approximation algorithms and metaheuristics as well as to the different methodologies used to design these algorithms. These areas are relatively young so it is fair to repeat the lyrics of an old popular song “The best is yet to come, you ain’t seen nothing yet.”

In the last couple of decades we have seen approximation algorithms being applied to traditional combinatorial optimization problems as well as problems arising in other areas of research activity. These areas include: VLSI design automation, networks (wired, sensor, and wireless), bioinformatics, game theory, computational geometry, graph problems, etc.

Most real world problems are solved via heuristics, without any significant analysis. However, more problems are being solved via approximation algorithms and metaheuristics as industry is being populated by computer science graduates. For example, content delivery networks, like the one built by *Akami*, have been using approximation algorithms to decide where data must reside for in order to facilitate its retrieval by users. Similar algorithmic problems arise when designing the software behind search engines (see Chapter 51). Manufacturing computing environments give rise to a large number of sequencing and scheduling problems. There is a rich set of approximation algorithms for this types of sequencing and scheduling problems [67].

Approximation algorithms and metaheuristics for graph, Steiner tree, TSP, clustering, logic, data mining, CAD placement, routing, and synchronization problems and their variations are extensively used in a variety of industrial settings.

12.3 Research Issues

There are many important research issues that need to be resolved. The most important one is to develop new methodologies to design approximation algorithms and metaheuristics. These new methodologies should be applicable to a wide range of problems and be amenable for analysis. Tools and techniques for the analysis of sophisticated approximation algorithms need to be developed.

A methodology for the experimental evaluation of approximation algorithms and metaheuristics needs to be developed. This area is in its infancy. Automatic tools for testing and verifying approximation claims are for the most part nonexistent. The research approaches seem to be divided into theory and experiments. There is a need to combine them into just one that deals with both aspects: theoretical analysis and experimental evaluation.

We also need to find the point where approximability ends and inapproximability begins for most problems. We need insights into how to find these points quickly. These break points are only known for a few problems.

The efficient use of energy when computing is a relatively new area of research where algorithmic strategies can be designed and used to significantly decrease energy consumption for computing.

12.4 Summary

In this chapter we have discussed the different methodologies to design approximation algorithms and metaheuristics. Approximation algorithms based on restriction, relaxation, partial enumeration, rounding, and local search were explored. We applied these techniques to well-known problems. We discussed the basic metaheuristics. These include: TS, SA, ACO, EC, and MA. We discussed the history of approximation algorithms and metaheuristics.

Acknowledgments

Preliminary versions of portions of this chapter and the two figures appeared in Chapters 1 through 3 of the *Handbook on Approximation Algorithms and Metaheuristics* [5].

Defining Terms

ϵ -approximation algorithm: For problem P it is an algorithm that generates a feasible solution for every problem instance I of P such that

$$\left| \frac{\hat{f}(I) - f^*(I)}{f^*(I)} \right| \leq \epsilon$$

It is assumed that $f^*(I) > 0$. There are variations of this notation.

Approximation Methodologies: Restriction, relaxation, partial enumeration, rounding, and local search.

APX: A problem with a polynomial time ϵ -approximation algorithm.

FPTAS: A PTAS whose time complexity is polynomial with respect to the length of the instance I and $1/\epsilon$.

MAXSNP: Problems that can be approximated within a constant factor and have a nice logical characterization.

P, NP, and NP-Completeness: See Chapter 7.

PTAS: For problem P it is an algorithm A that given any fixed constant $\epsilon > 0$ it constructs a solution to prob-

lem P such that $\left| \frac{\hat{f}(I) - f^*(I)}{f^*(I)} \right| \leq \epsilon$ in polynomial time with respect to the length of the instance I .

Further Information

13.1 Introduction

Bin packing, routing, scheduling, layout, and network design are generic examples of combinatorial optimization problems that often arise in computer engineering and decision support. Unfortunately, almost all interesting generic classes of combinatorial optimization problems are \mathcal{NP} -hard. The scale at which these problems arise in applications and the explosive exponential complexity of the search spaces preclude the use of simplistic enumeration and search techniques. Despite the worst-case intractability of combinatorial optimization, in practice we are able to solve many large problems and often with off-the-shelf software. Effective software for combinatorial optimization is usually problem specific and based on sophisticated algorithms that combine approximation methods with search schemes that exploit mathematical (not just syntactic) structure in the problem at hand.

TABLE 13.1 Paradigms in Combinatorial Optimization

Paradigm	Representation	Methodology
Integer programming	Linear constraints Linear objective integer variables	Linear programming and extensions
Search	State space discrete control	Dynamic programming A*
Local improvement	Neighborhoods fitness functions	Hill climbing Simulated annealing Tabu search Genetic algorithms
Constraint logic programming	Horn rules	Resolution Constraint solvers

Multidisciplinary interests in combinatorial optimization have led to several fairly distinct paradigms in the development of this subject. Each paradigm may be thought of as a particular combination of a *representation scheme* and a *methodology* (see Table 13.1). The most established of these, the *integer programming* paradigm, uses implicit algebraic forms (linear constraints) to represent combinatorial optimization and **linear programming** and its extensions as the workhorses in the design of the solution algorithms. It is this paradigm that forms the central theme of this chapter.

Other well-known paradigms in combinatorial optimization are *search*, *local improvement*, and *constraint logic programming* (CLP). Search uses state-space representations and partial enumeration techniques such as \mathcal{A}^* and dynamic programming. Local improvement requires only a representation of neighborhood in the solution space, and methodologies vary from simple hill climbing to the more sophisticated techniques of simulated annealing, tabu search, and genetic algorithms. CLP uses the syntax of Horn rules to represent combinatorial optimization problems and uses resolution to orchestrate the solution of these problems with the use of domain-specific constraint solvers. Whereas integer programming was developed and nurtured by the mathematical programming community, these other paradigms have been popularized by the artificial intelligence community.

An abstract formulation of combinatorial optimization is

$$(\text{CO}) \quad \min\{f(I) : I \in \mathcal{I}\}$$

where \mathcal{I} is a collection of subsets of a finite ground set $E = \{e_1, e_2, \dots, e_n\}$ and f is a criterion (objective) function that maps 2^E (the power set of E) to the reals. A *mixed integer linear program* (MILP) is of the form

$$(\text{MILP}) \quad \min_{\mathbf{x} \in \mathbb{R}^n} \{\mathbf{c}\mathbf{x} : \mathbf{A}\mathbf{x} \geq \mathbf{b}, \mathbf{x}_j \text{ integer } \forall j \in J\}$$

which seeks to minimize a linear function of the decision vector \mathbf{x} subject to linear inequality constraints and the requirement that a subset of the decision variables is integer valued. This model captures many variants. If $J = \{1, 2, \dots, n\}$, we say that the integer program is *pure*, and *mixed* otherwise. Linear equations and bounds on the variables can be easily accommodated in the inequality constraints. Notice that by adding in inequalities of the form $0 \leq \mathbf{x}_j \leq 1$ for a $j \in J$ we have forced \mathbf{x}_j to take value 0 or 1. It is such Boolean variables that help capture combinatorial optimization problems as special cases of MILP.

Pure integer programming with variables that take arbitrary integer values is a class which has strong connections to number theory and particularly the geometry of numbers and Presburger arithmetic. Although this is a fascinating subject with important applications in cryptography, in the interests of brevity we shall largely restrict our attention to MILP where the integer variables are Boolean.

The fact that MILPs subsume combinatorial optimization problems follows from two simple observations. The first is that a collection \mathcal{I} of subsets of a finite ground set E can always be represented by a corresponding collection of incidence vectors, which are $\{0, 1\}$ -vectors in \mathfrak{R}^E . Further, arbitrary nonlinear functions can be represented via piecewise linear approximations by using linear constraints and mixed variables (continuous and Boolean).

The next section contains a primer on linear inequalities, polyhedra, and linear programming. These are the tools we will need to analyze and solve integer programs. Section 13.4 is a testimony to the earlier cryptic comments on how integer programs model combinatorial optimization problems. In addition to working a number of examples of such integer programming formulations, we shall also review a formal representation theory of (Boolean) MILPs.

With any mixed integer program, we associate a *linear programming relaxation* obtained by simply ignoring the integrality restrictions on the variables. The point being, of course, that we have polynomial-time (and practical) algorithms for solving linear programs. Thus, the linear programming relaxation of (MILP) is given by

$$(LP) \min_{x \in \mathfrak{R}^n} \{ \mathbf{c}\mathbf{x} : \mathbf{A}\mathbf{x} \geq \mathbf{b} \}$$

The thesis underlying the integer linear programming approach to combinatorial optimization is that this linear programming relaxation retains enough of the structure of the combinatorial optimization problem to be a useful weak representation. In Section 13.5, we shall take a closer look at this thesis in that we shall encounter special structures for which this relaxation is *tight*. For general integer programs, there are several alternative schemes for generating linear programming relaxations with varying qualities of approximation. A general principle is that we often need to disaggregate integer formulations to obtain higher quality linear programming relaxations. To solve such huge linear programs, we need specialized techniques of large-scale linear programming. These aspects will be the content of Section 13.3.

The reader should note that the focus in this chapter is on solving hard combinatorial optimization problems. We catalog the special structures in integer programs that lead to tight linear programming relaxations (Section 13.5) and hence to polynomial-time algorithms. These include structures such as network flows, matching, and matroid optimization problems. Many hard problems actually have pieces of these nice structures embedded in them. Practitioners of combinatorial optimization have always used insights from special structures to devise strategies for hard problems.

The computational art of integer programming rests on useful interplays between search methodologies and linear programming relaxations. The paradigms of branch and bound (B-and-B) and branch and cut (B-and-C) are the two enormously effective partial enumeration schemes that have evolved at this interface. These will be discussed in Section 13.6. It may be noted that all general purpose integer programming software available today uses one or both of these paradigms.

The inherent complexity of integer linear programming has led to a long-standing research program in approximation methods for these problems. Linear programming relaxation and Lagrangian relaxation are two general approximation schemes that have been the real workhorses of computational practice. Primal-dual strategies and semidefinite relaxations are two recent entrants that appear to be very promising. Section 13.7 reviews these developments in the approximation of combinatorial optimization problems.

We conclude the chapter with brief comments on future prospects in combinatorial optimization from the algebraic modeling perspective. The original version of this chapter was written in the late 1990s. In revising the chapter and resurveying the field, we have had an opportunity to describe some significant advances that have happened in resolving some open conjectures as well as in new applications and improved computational techniques. However, to a large extent, none of the foundations have been shaken by these advances and we are confident that the original framework we laid out is still a good approach for appreciating the beauty and the nuances of this approach to combinatorial optimization.

13.2 Primer on Linear Programming

Polyhedral combinatorics is the study of embeddings of combinatorial structures in Euclidean space and their algebraic representations. We will make extensive use of some standard terminology from polyhedral theory. Definitions of terms not given in the brief review below can be found in Nemhauser and Wolsey (1988).

A (convex) *polyhedron* in \mathfrak{R}^n can be algebraically defined in two ways. The first and more straightforward definition is the *implicit* representation of a polyhedron in \mathfrak{R}^n as the solution set to a finite system of linear inequalities in n variables. A single linear inequality $\mathbf{ax} \leq a_0$; $\mathbf{a} \neq \mathbf{0}$ defines a *half-space* of \mathfrak{R}^n . Therefore, geometrically a polyhedron is the intersection set of a finite number of half-spaces.

A *polytope* is a bounded polyhedron. Every polytope is the convex closure of a finite set of points. Given a set of points whose convex combinations generate a polytope, we have an explicit or *parametric* algebraic representation of it. A *polyhedral cone* is the solution set of a system of homogeneous linear inequalities. Every (polyhedral) cone is the conical or positive closure of a finite set of vectors. These generators of the cone provide a parametric representation of the cone. And finally, a polyhedron can be alternatively defined as the Minkowski sum of a polytope and a cone. Moving from one representation of any of these polyhedral objects to another defines the essence of the computational burden of polyhedral combinatorics. This is particularly true if we are interested in *minimal* representations.

A set of points $\mathbf{x}^1, \dots, \mathbf{x}^m$ is *affinely independent* if the unique solution of $\sum_{i=1}^m \lambda_i \mathbf{x}^i = \mathbf{0}$, $\sum_{i=1}^m \lambda_i = 0$ is $\lambda_i = 0$ for $i = 1, \dots, m$. Note that the maximum number of affinely independent points in \mathfrak{R}^n is $n + 1$. A polyhedron P is of *dimension* k , $\dim P = k$, if the maximum number of affinely independent points in P is $k + 1$. A polyhedron $P \subseteq \mathfrak{R}^n$ of dimension n is called *full dimensional*. An inequality $\mathbf{ax} \leq a_0$ is called *valid* for a polyhedron P if it is satisfied by all \mathbf{x} in P . It is called *supporting* if in addition there is an $\tilde{\mathbf{x}}$ in P that satisfies $\mathbf{a}\tilde{\mathbf{x}} = a_0$. A *face* of the polyhedron is the set of all \mathbf{x} in P that also satisfies a valid inequality as an equality. In general, many valid inequalities might represent the same face. Faces other than P itself are called *proper*. A *facet* of P is a maximal nonempty and proper face. A facet is then a face of P with a dimension of $\dim P - 1$. A face of dimension zero, that is, a point v in P that is a face by itself, is called an *extreme point* of P . The extreme points are the elements of P that cannot be expressed as a strict convex combination of two distinct points in P . For a full-dimensional polyhedron, the valid inequality representing a facet is unique up to multiplication by a positive scalar, and facet-inducing inequalities give a minimal implicit representation of the polyhedron. Extreme points, on the other hand, give rise to minimal parametric representations of polytopes.

The two fundamental problems of linear programming (which are polynomially equivalent) follow:

1. *Solvability*: This is the problem of checking if a system of linear constraints on real (rational) variables is solvable or not. Geometrically, we have to check if a polyhedron, defined by such constraints, is nonempty.
2. *Optimization*: This is the problem (LP) of optimizing a linear objective function over a polyhedron described by a system of linear constraints.

Building on polarity in cones and polyhedra, duality in linear programming is a fundamental concept which is related to both the complexity of linear programming and to the design of algorithms for solvability and optimization. We will encounter the solvability version of duality (called *Farkas' Lemma*) while discussing the Fourier elimination technique subsequently. Here, we will state the main duality results for optimization. If we take the *primal* linear program to be

$$(P) \min_{\mathbf{x} \in \mathfrak{R}^n} \{\mathbf{c}\mathbf{x} : \mathbf{A}\mathbf{x} \geq \mathbf{b}\}$$

there is an associated *dual* linear program

$$(D) \max_{\mathbf{y} \in \mathfrak{R}^m} \{\mathbf{b}^T \mathbf{y} : A^T \mathbf{y} = \mathbf{c}^T, \mathbf{y} \geq \mathbf{0}\}$$

and the two problems satisfy the following:

1. For any $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ feasible in (P) and (D) (i.e., they satisfy the respective constraints), we have $\mathbf{c}\hat{\mathbf{x}} \geq \mathbf{b}^T\hat{\mathbf{y}}$ (*weak duality*). Consequently, (P) has a finite optimal solution if and only if (D) does.
2. The pair \mathbf{x}^* and \mathbf{y}^* are optimal solutions for (P) and (D), respectively, if and only if \mathbf{x}^* and \mathbf{y}^* are feasible in (P) and (D) (i.e., they satisfy the respective constraints) and $\mathbf{c}\mathbf{x}^* = \mathbf{b}^T\mathbf{y}^*$ (*strong duality*).
3. The pair \mathbf{x}^* and \mathbf{y}^* are optimal solutions for (P) and (D), respectively, if and only if \mathbf{x}^* and \mathbf{y}^* are feasible in (P) and (D) (i.e., they satisfy the respective constraints) and $(A\mathbf{x}^* - \mathbf{b})^T\mathbf{y}^* = 0$ (*complementary slackness*).

The strong duality condition gives us a good stopping criterion for optimization algorithms. The complementary slackness condition, on the other hand, gives us a constructive tool for moving from dual to primal solutions and vice versa. The weak duality condition gives us a technique for obtaining lower bounds for minimization problems and upper bounds for maximization problems.

Note that the properties just given have been stated for linear programs in a particular form. The reader should be able to check that if, for example, the primal is of the form

$$(P') \min_{\mathbf{x} \in \mathfrak{R}^n} \{\mathbf{c}\mathbf{x} : A\mathbf{x} = \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$$

then the corresponding dual will have the form

$$(D') \max_{\mathbf{y} \in \mathfrak{R}^m} \{\mathbf{b}^T \mathbf{y} : A^T \mathbf{y} \leq \mathbf{c}^T\}$$

The tricks needed for seeing this are that any equation can be written as two inequalities, an unrestricted variable can be substituted by the difference of two nonnegatively constrained variables, and an inequality can be treated as an equality by adding a nonnegatively constrained variable to the lesser side. Using these tricks, the reader could also check that duality in linear programming is involutory (i.e., the dual of the dual is the primal).

13.2.1 Algorithms for Linear Programming

We will now take a quick tour of some algorithms for linear programming. We start with the classical technique of Fourier (1824) which is interesting because of its really simple syntactic specification. It leads to simple proofs of the duality principle of linear programming (solvability) that has been alluded to. We will then review the simplex method of linear programming, a method that has been finely honed over almost five decades. We will spend some time with the ellipsoid method and, in particular, with the polynomial equivalence of solvability (optimization) and separation problems, for this aspect of the ellipsoid method has had a major impact on the identification of many tractable classes of combinatorial optimization problems. We conclude the primer with a description of Karmarkar's (1984) breakthrough, which was an important landmark in the brief history of linear programming. A noteworthy role of interior point methods has been to make practical the theoretical demonstrations of tractability of various aspects of linear programming, including solvability and optimization, that were provided via the ellipsoid method.

13.2.2 Fourier's Scheme for Linear Inequalities

Constraint systems of linear *inequalities* of the form $A\mathbf{x} \leq \mathbf{b}$, where A is an $m \times n$ matrix of real numbers, are widely used in mathematical models. Testing the solvability of such a system is equivalent to linear programming.

Suppose we wish to eliminate the first variable x_1 from the system $A\mathbf{x} \leq \mathbf{b}$. Let us denote

$$I^+ = \{i : A_{i1} > 0\} \quad I^- = \{i : A_{i1} < 0\} \quad I^0 = \{i : A_{i1} = 0\}$$

Our goal is to create an equivalent system of linear inequalities $\tilde{A}\tilde{\mathbf{x}} \leq \tilde{\mathbf{b}}$ defined on the variables $\tilde{\mathbf{x}} = (x_2, x_3, \dots, x_n)$:

- If I^+ is empty then we can simply delete all the inequalities with indices in I^- since they can be trivially satisfied by choosing a large enough value for x_1 . Similarly, if I^- is empty we can discard all inequalities in I^+ .
- For each $k \in I^+$, $l \in I^-$ we add $-A_{l1}$ times the inequality $A_k\mathbf{x} \leq \mathbf{b}_k$ to A_{l1} times $A_l\mathbf{x} \leq \mathbf{b}_l$. In these new inequalities, the coefficient of x_1 is wiped out, that is, x_1 is eliminated. Add these new inequalities to those already in I^0 .
- The inequalities $\{\tilde{A}_{i1}\tilde{\mathbf{x}} \leq \tilde{\mathbf{b}}_i\}$ for all $i \in I^0$ represent the equivalent system on the variables $\tilde{\mathbf{x}} = (x_2, x_3, \dots, x_n)$.

Repeat this construction with $\tilde{A}\tilde{\mathbf{x}} \leq \tilde{\mathbf{b}}$ to eliminate x_2 and so on until all variables are eliminated. If the resulting $\tilde{\mathbf{b}}$ (after eliminating x_n) is nonnegative, we declare the original (and intermediate) inequality systems as being consistent. Otherwise, $\tilde{\mathbf{b}} \not\geq 0$ and we declare the system inconsistent.

As an illustration of the power of elimination as a tool for theorem proving, we show now that Farkas Lemma is a simple consequence of the correctness of Fourier elimination. The lemma gives a direct proof that solvability of linear inequalities is in $\mathcal{NP} \cap \text{co}\mathcal{NP}$.

Farkas Lemma 13.1 (Duality in Linear Programming: Solvability)

Exactly one of the alternatives

$$\text{I. } \exists \mathbf{x} \in \mathfrak{R}^n : A\mathbf{x} \leq \mathbf{b}$$

$$\text{II. } \exists \mathbf{y} \in \mathfrak{R}_+^m : \mathbf{y}^t A = \mathbf{0}, \mathbf{y}^t \mathbf{b} < 0$$

is true for any given real matrices A , \mathbf{b} .

Proof 13.1

Let us analyze the case when Fourier elimination provides a proof of the inconsistency of a given linear inequality system $A\mathbf{x} \leq \mathbf{b}$. The method clearly converts the given system into $RA\mathbf{x} \leq R\mathbf{b}$ where RA is zero and $R\mathbf{b}$ has at least one negative component. Therefore, there is some row of R , say, \mathbf{r} , such that $\mathbf{r}A = \mathbf{0}$ and $\mathbf{r}\mathbf{b} < 0$. Thus $\neg\text{I}$ implies II. It is easy to see that I and II cannot both be true for fixed A , \mathbf{b} .

* Note that the final $\tilde{\mathbf{b}}$ may not be defined if all of the inequalities are deleted by the monotone sign condition of the first step of the construction described. In such a situation, we declare the system $A\mathbf{x} \leq \mathbf{b}$ *strongly consistent* since it is consistent for any choice of \mathbf{b} in \mathfrak{R}^m . To avoid making repeated references to this exceptional situation, let us simply assume that it does not occur. The reader is urged to verify that this assumption is indeed benign.

In general, the Fourier elimination method is quite inefficient. Let k be any positive integer and n the number of variables be $2^k + k + 2$. If the input inequalities have left-hand sides of the form $\pm x_r, \pm x_s, \pm x_t$, for all possible $1 \leq r < s < t \leq n$, it is easy to prove by induction that after k variables are eliminated, by Fourier's method, we would have at least $2^{n/2}$ inequalities. The method is therefore exponential in the worst case, and the explosion in the number of inequalities has been noted, in practice as well, on a wide variety of problems. We will discuss the central idea of minimal generators of the projection cone that results in a much improved elimination method.

First, let us identify the set of variables to be eliminated. Let the input system be of the form

$$P = \{(\mathbf{x}, \mathbf{u}) \in \mathfrak{R}^{n_1+n_2} \mid A\mathbf{x} + B\mathbf{u} \leq \mathbf{b}\}$$

where \mathbf{u} is the set to be eliminated. The projection of P onto \mathbf{x} or equivalently the effect of eliminating the \mathbf{u} variables is

$$P_{\mathbf{x}} = \{\mathbf{x} \in \mathfrak{R}^{n_1} \mid \mathbf{u} \in \mathfrak{R}^{n_2} \text{ such that } A\mathbf{x} + B\mathbf{u} \leq \mathbf{b}\}$$

Now W , the *projection cone* of P , is given by

$$W = \{\mathbf{w} \in \mathfrak{R}^m \mid \mathbf{w}B = \mathbf{0}, \mathbf{w} \geq \mathbf{0}\}$$

A simple application of Farkas Lemma yields a description of $P_{\mathbf{x}}$ in terms of W .

Projection Lemma 13.2

Let G be any set of generators (e.g., the set of extreme rays) of the cone W . Then $P_{\mathbf{x}} = \{\mathbf{x} \in \mathfrak{R}^{n_1} \mid (\mathbf{g}A)\mathbf{x} \leq \mathbf{g}b \forall \mathbf{g} \in G\}$.

The lemma, sometimes attributed to Černikov (1961), reduces the computation of $P_{\mathbf{x}}$ to enumerating the extreme rays of the cone W or equivalently the extreme points of the polytope $W \cap \left\{ \mathbf{w} \in \mathfrak{R}^m \mid \sum_{i=1}^m w_i = 1 \right\}$.

13.2.3 Simplex Method

Consider a polyhedron $\mathcal{K} = \{\mathbf{x} \in \mathfrak{R}^n : A\mathbf{x} = \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$. Now \mathcal{K} cannot contain an infinite (in both directions) line since it is lying within the nonnegative orthant of \mathfrak{R}^n . Such a polyhedron is called a *pointed* polyhedron. Given a pointed polyhedron \mathcal{K} , we observe the following:

- If $\mathcal{K} \neq \emptyset$, then \mathcal{K} has at least one extreme point.
- If $\min\{\mathbf{c}\mathbf{x} : A\mathbf{x} = \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$ has an optimal solution, then it has an optimal extreme point solution.

These observations together are sometimes called the *fundamental theorem* of linear programming since they suggest simple finite tests for both solvability and optimization. To generate all extreme points of \mathcal{K} , in order to find an optimal solution, is an impractical idea. However, we may try to run a partial search of the space of extreme points for an optimal solution. A simple local improvement search strategy of moving from extreme point to adjacent extreme point until we get to a local optimum is nothing but the simplex method of linear programming. The local optimum also turns out to be a global optimum because of the convexity of the polyhedron \mathcal{K} and the linearity of the objective function $\mathbf{c}\mathbf{x}$.

The simplex method walks along edge paths on the combinatorial graph structure defined by the boundary of convex polyhedra. Since these graphs are quite dense (Balinski's theorem states that the graph of d -dimensional polyhedron must be d -connected [Ziegler, 1995]) and possibly large (the Lower Bound Theorem states that the number of vertices can be exponential in the dimension [Ziegler, 1995]), it is indeed somewhat of a miracle that it manages to get to an optimal extreme point as quickly as it does. Empirical and probabilistic analyses indicate that the number of iterations of the simplex method is just slightly more than linear in the dimension of the primal polyhedron. However, there is no known variant of the simplex method with a worst-case polynomial guarantee on the number of iterations. Even a polynomial bound on the diameter of polyhedral graphs is not known.

Procedure 13.1 Primal Simplex (\mathcal{K} , c):

0. **Initialize:**

$\mathbf{x}_0 :=$ an extreme point of \mathcal{K}

$k := 0$

1. **Iterative step:**

do

If for all edge directions \mathcal{D}_k at \mathbf{x}_k , the objective function is nondecreasing, i.e.,

$$c\mathbf{d} \geq 0 \quad \forall \mathbf{d} \in \mathcal{D}_k$$

then exit and return optimal \mathbf{x}_k .

Else pick some \mathbf{d}_k in \mathcal{D}_k such that $c\mathbf{d}_k < 0$.

If $\mathbf{d}_k \geq 0$ **then** declare the linear program unbounded in objective value and exit.

Else $\mathbf{x}_{k+1} := \mathbf{x}_k + \theta_k * \mathbf{d}_k$, where

$$\theta_k = \max\{\theta : \mathbf{x}_k + \theta * \mathbf{d}_k \geq 0\}$$

$k := k + 1$

od

2. **End**

Remark 13.1

In the initialization step, we assumed that an extreme point \mathbf{x}_0 of the polyhedron \mathcal{K} is available. This also assumes that the solvability of the constraints defining \mathcal{K} has been established. These assumptions are reasonable since we can formulate the solvability problem as an optimization problem, with a self-evident extreme point, whose optimal solution either establishes unsolvability of $A\mathbf{x} = \mathbf{b}$, $\mathbf{x} \geq \mathbf{0}$ or provides an extreme point of \mathcal{K} . Such an optimization problem is usually called a phase I model. The point being, of course, that the simplex method, as just described, can be invoked on the *phase I model* and, if successful, can be invoked once again to carry out the intended minimization of $c\mathbf{x}$. There are several different formulations of the phase I model that have been advocated. Here is one:

$$\min\{v_0 : A\mathbf{x} + \mathbf{b}v_0 = \mathbf{b}, \mathbf{x} \geq \mathbf{0}, v_0 \geq 0\}$$

The solution $(\mathbf{x}, v_0)^T = (0, \dots, 0, 1)$ is a self-evident extreme point and $v_0 = 0$ at an optimal solution of this model is a necessary and sufficient condition for the solvability of $A\mathbf{x} = \mathbf{b}$, $\mathbf{x} \geq \mathbf{0}$.

Remark 13.2

The scheme for generating improving edge directions uses an algebraic representation of the extreme points as certain bases, called *feasible bases*, of the vector space generated by the columns of the matrix A . It is possible to have linear programs for which an extreme point is geometrically overdetermined (degenerate), that is, there are more than d facets of \mathcal{K} that contain the extreme point, where d is the dimension of \mathcal{K} . In such a situation, there would be several feasible bases corresponding to the same extreme point. When this happens, the linear program is said to be *primal degenerate*.

Remark 13.3

There are two sources of nondeterminism in the primal simplex procedure. The first involves the choice of edge direction \mathbf{d}_k made in step 1. At a typical iteration, there may be many edge directions that are improving in the sense that $\mathbf{c}\mathbf{d}_k < 0$. Dantzig's rule, the maximum improvement rule, and steepest descent rule are some of the many rules that have been used to make the choice of edge direction in the simplex method. There is, unfortunately, no clearly dominant rule and successful codes exploit the empirical and analytic insights that have been gained over the years to resolve the edge selection nondeterminism in simplex methods. The second source of nondeterminism arises from degeneracy. When there are multiple feasible bases corresponding to an extreme point, the simplex method has to pivot from basis to adjacent basis by picking an entering basic variable (a pseudoEdge direction) and by dropping one of the old ones. A wrong choice of the leaving variables may lead to cycling in the sequence of feasible bases generated at this extreme point. Cycling is a serious problem when linear programs are highly degenerate as in the case of linear relaxations of many combinatorial optimization problems. The lexicographic rule (perturbation rule) for the choice of leaving variables in the simplex method is a provably finite method (i.e., all cycles are broken). A clever method proposed by Bland (cf. Schrijver, 1986) preorders the rows and columns of the matrix A . In the case of nondeterminism in either entering or leaving variable choices, Bland's rule just picks the lowest index candidate. All cycles are avoided by this rule also.

The simplex method has been the veritable workhorse of linear programming for four decades now. However, as already noted, we do not know of a simplex method that has worst-case bounds that are polynomial. In fact, Klee and Minty exploited the sensitivity of the original simplex method of Dantzig, to projective scaling of the data, and constructed exponential examples for it. Recently, Spielman and Tang (2001) introduced the concept of smoothed analysis and smoothed complexity of algorithms, which is a hybrid of worst-case and average-case analysis of algorithms. Essentially, this involves the study of performance of algorithms under small random Gaussian perturbations of the coefficients of the constraint matrix. The authors show that a variant of the simplex algorithm, known as the *shadow vertex simplex algorithm* (Gass and Saaty, 1955), has polynomial smoothed complexity.

The ellipsoid method of Shor (1970), was devised to overcome poor scaling in convex programming problems and, therefore, turned out to be the natural choice of an algorithm to first establish polynomial-time solvability of linear programming. Later, Karmarkar (1984) took care of both projection and scaling simultaneously and arrived at a superior algorithm.

13.2.4 Ellipsoid Algorithm

The ellipsoid algorithm of Shor (1970) gained prominence in the late 1970s when Hačijan (1979) (pronounced Khachiyan) showed that this convex programming method specializes to a polynomial-time

algorithm for linear programming problems. This theoretical breakthrough naturally led to intense study of this method and its properties. The survey paper by Bland et al. (1981) and the monograph by Akgül (1984) attest to this fact. The direct theoretical consequences for combinatorial optimization problems were independently documented by Padberg and Rao (1981), Karp and Papadimitriou (1982), and Grötschel et al. (1988). The ability of this method to implicitly handle linear programs with an exponential list of constraints and maintain polynomial-time convergence is a characteristic that is the key to its applications in combinatorial optimization. For an elegant treatment of the many deep theoretical consequences of the ellipsoid algorithm, the reader is directed to the monograph by Lovász (1986) and the book by Grötschel et al. (1988).

Computational experience with the ellipsoid algorithm, however, showed a disappointing gap between the theoretical promise and practical efficiency of this method in the solution of linear programming problems. Dense matrix computations as well as the slow average-case convergence properties are the reasons most often cited for this behavior of the ellipsoid algorithm. On the positive side though, it has been noted (cf. Ecker and Kupferschmid, 1983) that the ellipsoid method is competitive with the best known algorithms for (nonlinear) convex programming problems.

Let us consider the problem of testing if a polyhedron $\mathcal{Q} \in \mathfrak{R}^d$, defined by linear inequalities, is non-empty. For technical reasons, let us assume that \mathcal{Q} is rational, that is, all extreme points and rays of \mathcal{Q} are rational vectors or, equivalently, that all inequalities in some description of \mathcal{Q} involve only rational coefficients. The ellipsoid method does not require the linear inequalities describing \mathcal{Q} to be explicitly specified. It suffices to have an oracle representation of \mathcal{Q} . Several different types of oracles can be used in conjunction with the ellipsoid method (Padberg and Rao, 1981; Karp and Papadimitriou, 1982; Grötschel et al., 1988). We will use the *strong separation oracle*:

Oracle: Strong Separation(\mathcal{Q}, \mathbf{y})

Given a vector $\mathbf{y} \in \mathfrak{R}^d$, decide whether $\mathbf{y} \in \mathcal{Q}$, and if not find a hyperplane that separates \mathbf{y} from \mathcal{Q} ; more precisely, find a vector $\mathbf{c} \in \mathfrak{R}^d$ such that $\mathbf{c}^T \mathbf{y} < \min\{\mathbf{c}^T \mathbf{x} \mid \mathbf{x} \in \mathcal{Q}\}$.

The ellipsoid algorithm initially chooses an ellipsoid large enough to contain a part of the polyhedron \mathcal{Q} if it is nonempty. This is easily accomplished because we know that if \mathcal{Q} is nonempty then it has a rational solution whose (binary encoding) length is bounded by a polynomial function of the length of the largest coefficient in the linear program and the dimension of the space.

The center of the ellipsoid is a feasible point if the separation oracle tells us so. In this case, the algorithm terminates with the coordinates of the center as a solution. Otherwise, the separation oracle outputs an inequality that separates the center point of the ellipsoid from the polyhedron \mathcal{Q} . We translate the hyperplane defined by this inequality to the center point. The hyperplane slices the ellipsoid into two halves, one of which can be discarded. The algorithm now creates a new ellipsoid that is the minimum volume ellipsoid containing the remaining half of the old one. The algorithm questions if the new center is feasible and so on. The key is that the new ellipsoid has substantially smaller volume than the previous one. When the volume of the current ellipsoid shrinks to a sufficiently small value, we are able to conclude that \mathcal{Q} is empty. This fact is used to show the polynomial-time convergence of the algorithm.

The crux of the complexity analysis of the algorithm is on the a priori determination of the iteration bound. This in turn depends on three factors. The volume of the initial ellipsoid E_0 , the rate of volume shrinkage ($\text{vol}(E_{k+1})/\text{vol}(E_k) < e^{-\frac{1}{2d}}$), and the volume threshold at which we can safely conclude that \mathcal{Q} must be empty. The assumption of \mathcal{Q} being a rational polyhedron is used to argue that \mathcal{Q} can be modified into a full-dimensional polytope without affecting the decision question: "Is \mathcal{Q} non-empty?" After careful accounting for all of these technical details and some others (e.g., compensating for the roundoff errors caused by the square root computation in the algorithm), it is possible to establish the following fundamental result.

Theorem 13.1

There exists a polynomial $g(d, \phi)$ such that the ellipsoid method runs in time bounded by $T g(d, \phi)$, where ϕ is an upper bound on the size of linear inequalities in some description of \mathcal{Q} and T is the maximum time required by the oracle $\text{Strong Separation}(\mathcal{Q}, \mathbf{y})$ on inputs \mathbf{y} of size at most $g(d, \phi)$.

The size of a linear inequality is just the length of the encoding of all of the coefficients needed to describe the inequality. A direct implication of the theorem is that solvability of linear inequalities can be checked in polynomial time if strong separation can be solved in polynomial time. This implies that the standard linear programming solvability question has a polynomial-time algorithm (since separation can be effected by simply checking all of the constraints). Happily, this approach provides polynomial-time algorithms for much more than just the standard case of linear programming solvability. The theorem can be extended to show that the optimization of a linear objective function over \mathcal{Q} also reduces to a polynomial number of calls to the strong separation oracle on \mathcal{Q} . A converse to this theorem also holds, namely, separation can be solved by a polynomial number of calls to a solvability/optimization oracle (Grötschel et al., 1982). Thus, optimization and separation are polynomially equivalent. This provides a very powerful technique for identifying tractable classes of optimization problems. Semidefinite programming (SDP) and submodular function minimization are two important classes of optimization problems that can be solved in polynomial time using this property of the ellipsoid method.

13.2.5 Semidefinite Programming

The following optimization problem defined on symmetric $(n \times n)$ real matrices

$$(\text{SDP}) \quad \min_{X \in \mathfrak{R}^{n \times n}} \left\{ \sum_{ij} C \cdot X : A \cdot X = B, X \succeq 0 \right\}$$

is called a *semidefinite program*. Note that $X \succeq 0$ denotes the requirement that X is a positive semidefinite matrix, and $F \cdot G$ for $n \times n$ matrices F and G denotes the product matrix $(F_{ij} * G_{ij})$. From the definition of positive semidefinite matrices, $X \succeq 0$ is equivalent to

$$\mathbf{q}^T X \mathbf{q} \geq 0 \quad \text{for every } \mathbf{q} \in \mathfrak{R}^n$$

Thus, SDP is really a linear program on $O(n^2)$ variables with an (uncountably) infinite number of linear inequality constraints. Fortunately, the strong separation oracle is easily realized for these constraints. For a given symmetric X , we use Cholesky factorization to identify the minimum eigenvalue λ_{\min} . If λ_{\min} is nonnegative then $X \succeq 0$ and if, on the other hand, λ_{\min} is negative we have a separating inequality

$$\boldsymbol{\gamma}_{\min}^T X \boldsymbol{\gamma}_{\min} \geq 0$$

where $\boldsymbol{\gamma}_{\min}$ is the eigenvector corresponding to λ_{\min} . Since the Cholesky factorization can be computed by an $O(n^3)$ algorithm, we have a polynomial-time separation oracle and an efficient algorithm for SDP via the ellipsoid method. Alizadeh (1995) has shown that interior point methods can also be adapted to solving SDP to within an additive error ϵ in time polynomial in the size of the input and $\log 1/\epsilon$.

This result has been used to construct efficient approximation algorithms for maximum stable sets and cuts of graphs, Shannon capacity of graphs, and minimum colorings of graphs. It has been used to define hierarchies of relaxations for integer linear programs that strictly improve on known

exponential-size linear programming relaxations. We shall encounter the use of SDP in the approximation of a maximum weight cut of a given vertex-weighted graph in Section 13.7.

13.2.6 Minimizing Submodular Set Functions

The minimization of submodular set functions is another important class of optimization problems for which ellipsoidal and projective scaling algorithms provide polynomial-time solution methods.

Definition 13.1

Let N be a finite set. A real valued set function f defined on the subsets of N is submodular if $f(X \cup Y) + f(X \cap Y) \leq f(X) + f(Y)$ for $X, Y \subseteq N$.

Example 13.1

Let $G = (V, E)$ be an undirected graph with V as the node set and E as the edge set. Let $c_{ij} \geq 0$ be the weight or capacity associated with edge $(ij) \in E$. For $S \subseteq V$, define the cut function $c(S) = \sum_{i \in S, j \in V \setminus S} c_{ij}$. The cut function defined on the subsets of V is submodular since $c(X) + c(Y) - c(X \cup Y) - c(X \cap Y) = \sum_{i \in X \setminus Y, j \in Y \setminus X} 2c_{ij} \geq 0$.

The optimization problem of interest is

$$\min\{f(X) : X \subseteq N\}$$

The following remarkable construction that connects submodular function minimization with convex function minimization is due to Lovász (see Grötschel et al., 1988).

Definition 13.2

The Lovász extension $\hat{f}(\cdot)$ of a submodular function $f(\cdot)$ satisfies

- $\hat{f} : [0, 1]^N \rightarrow \mathfrak{R}$.
- $\hat{f}(\mathbf{x}) = \sum_{I \in \mathcal{I}} \lambda_I f(\mathbf{x}_I)$ where $\mathbf{x} = \sum_{I \in \mathcal{I}} \lambda_I \mathbf{x}_I$, $\mathbf{x} \in [0, 1]^N$, \mathbf{x}_I is the incidence vector of I for each $I \in \mathcal{I}$, $\lambda_I > 0$ for each I in \mathcal{I} , and $\mathcal{I} = \{I_1, I_2, \dots, I_k\}$ with $\emptyset \neq I_1 \subset I_2 \subset \dots \subset I_k \subseteq N$. Note that the representation $\mathbf{x} = \sum_{I \in \mathcal{I}} \lambda_I \mathbf{x}_I$ is unique given that the $\lambda_I > 0$ and that the sets in \mathcal{I} are nested.

It is easy to check that $\hat{f}(\cdot)$ is a convex function. Lovász also showed that the minimization of the submodular function $f(\cdot)$ is a special case of convex programming by proving

$$\min\{f(X) : X \subseteq N\} = \min\{\hat{f}(\mathbf{x}) : \mathbf{x} \in [0, 1]^N\}$$

Further, if \mathbf{x}^* is an optimal solution to the convex program and

$$\mathbf{x}^* = \sum_{I \in \mathcal{I}} \lambda_I \mathbf{x}_I$$

then for each $\lambda_i > 0$, it can be shown that $I \in \mathcal{I}$ minimizes f . The ellipsoid method can be used to solve this convex program (and hence submodular minimization) using a polynomial number of calls to an oracle for f [this oracle returns the value of $f(X)$ when input X].

13.2.7 Interior Point Methods

The announcement of the polynomial solvability of linear programming followed by the probabilistic analyses of the simplex method in the early 1980s left researchers in linear programming with a dilemma. We had one method that was good in a theoretical sense but poor in practice and another that was good in practice (and on average) but poor in a theoretical worst-case sense. This left the door wide open for a method that was good in both senses. Narendra Karmarkar closed this gap with a breathtaking new projective scaling algorithm. In retrospect, the new algorithm has been identified with a class of nonlinear programming methods known as logarithmic barrier methods. Implementations of a primal-dual variant of the logarithmic barrier method have proven to be the best approach at present. It is this variant that we describe.

It is well known that moving through the interior of the feasible region of a linear program using the negative of the gradient of the objective function, as the movement direction, runs into trouble because of getting *jammed* into corners (in high dimensions, corners make up most of the interior of a polyhedron). This jamming can be overcome if the negative gradient is balanced with a *centering* direction. The centering direction in Karmarkar's algorithm is based on the *analytic center* \mathbf{y}_c of a full-dimensional polyhedron $\mathcal{D} = \{\mathbf{y} : A^T \mathbf{y} \leq \mathbf{c}\}$ which is the unique optimal solution to

$$\max \left\{ \sum_{j=1}^n \ell n(\mathbf{z}_j) : A^T \mathbf{y} + \mathbf{z} = \mathbf{c} \right\}$$

Recall the primal and dual forms of a linear program may be taken as

$$(P) \quad \min \{\mathbf{c}\mathbf{x} : A\mathbf{x} = \mathbf{b}, \mathbf{x} \geq \mathbf{0}\}$$

$$(D) \quad \max \{\mathbf{b}^T \mathbf{y} : A^T \mathbf{y} \leq \mathbf{c}\}$$

The logarithmic barrier formulation of the dual (D) is

$$(D_\mu) \quad \max \left\{ \mathbf{b}^T \mathbf{y} + \mu \sum_{j=1}^n \ell n(\mathbf{z}_j) : A^T \mathbf{y} + \mathbf{z} = \mathbf{c} \right\}$$

Notice that (D_μ) is equivalent to (D) as $\mu \rightarrow 0^+$. The optimality (Karush-Kuhn-Tucker) conditions for (D_μ) are given by

$$\begin{aligned} D_x D_z \mathbf{e} &= \mu \mathbf{e} \\ A\mathbf{x} &= \mathbf{b} \\ A^T \mathbf{y} + \mathbf{z} &= \mathbf{c} \end{aligned} \tag{13.1}$$

where D_x and D_z denote $n \times n$ diagonal matrices whose diagonals are \mathbf{x} and \mathbf{z} , respectively. Notice that if we set μ to 0, the above conditions are precisely the primal-dual optimality conditions: complementary

slackness, primal and dual feasibility of a pair of optimal (P) and (D) solutions. The problem has been reduced to solving the equations in \mathbf{x} , \mathbf{y} , \mathbf{z} . The classical technique for solving equations is Newton's method, which prescribes the directions,

$$\begin{aligned}\Delta\mathbf{y} &= -(AD_x D_z^{-1} A^T)^{-1} AD_z^{-1} (\mu\mathbf{e} - D_x D_z \mathbf{e}) \Delta\mathbf{z} = -A^T \Delta\mathbf{y} \Delta\mathbf{x} \\ &= D_z^{-1} (\mu\mathbf{e} - D_x D_z \mathbf{e}) - D_x D_z^{-1} \Delta\mathbf{z}\end{aligned}\quad (13.2)$$

The strategy is to take one Newton step, reduce μ , and iterate until the optimization is complete. The criterion for stopping can be determined by checking for feasibility (\mathbf{x} , $\mathbf{z} \geq \mathbf{0}$) and if the duality gap ($\mathbf{x}^T \mathbf{z}$) is close enough to 0. We are now ready to describe the algorithm.

Procedure 13.2 Primal–Dual Interior:

0. Initialize:

$$\mathbf{x}_0 > \mathbf{0}, \mathbf{y}_0 \in \mathfrak{R}^m, \mathbf{z}_0 > \mathbf{0}, \mu_0 > 0, \epsilon > 0, \rho > 0$$

$$k := 0$$

1. Iterative step:

do

Stop if $A\mathbf{x}_k = \mathbf{b}$, $A^T \mathbf{y}_k + \mathbf{z}_k = \mathbf{c}$ and $\mathbf{x}_k^T \mathbf{z}_k \leq \epsilon$.

$$\mathbf{x}_{k+1} \leftarrow \mathbf{x}_k + \alpha_k^P \Delta\mathbf{x}_k$$

$$\mathbf{y}_{k+1} \leftarrow \mathbf{y}_k + \alpha_k^D \Delta\mathbf{y}_k$$

$$\mathbf{z}_{k+1} \leftarrow \mathbf{z}_k + \alpha_k^D \Delta\mathbf{z}_k$$

/ $\Delta\mathbf{x}_k, \Delta\mathbf{y}_k, \Delta\mathbf{z}_k$ are the Newton directions from (1) */*

$$\mu_{k+1} \leftarrow \rho \mu_k$$

$$k := k + 1$$

od

2. End

Remark 13.4

The step sizes α_k^P and α_k^D are chosen to keep \mathbf{x}_{k+1} and \mathbf{z}_{k+1} strictly positive. The ability in the primal–dual scheme to choose separate step sizes for the primal and dual variables is a major advantage that this method has over the pure primal or dual methods. Empirically, this advantage translates to a significant reduction in the number of iterations.

Remark 13.5

The stopping condition essentially checks for primal and dual feasibility and near complementary slackness. Exact complementary slackness is not possible with interior solutions. It is possible to maintain primal and dual feasibility through the algorithm, but this would require a phase I construction via artificial variables. Empirically, this feasible variant has not been found to be worthwhile. In any case, when the algorithm terminates with an interior solution, a post-processing step is usually invoked to obtain optimal extreme point solutions for the primal and dual. This is usually called the *purification* of solutions and is based on a clever scheme described by Megiddo (1991).

Remark 13.6

Instead of using Newton steps to drive the solutions to satisfy the optimality conditions of (D_μ) , Mehrotra (1992) suggested a predictor–corrector approach based on power series approximations. This approach has the added advantage of providing a rational scheme for reducing the value of μ . It is the predictor–corrector-based primal–dual interior method that is considered the current winner in interior point methods. The OBI code of Lustig et al. (1994) is based on this scheme.

Remark 13.7

CPLEX, a general purpose linear (and integer) programming solver, contains implementations of interior point methods. Computational studies in the late 1990s of parallel implementations of simplex and interior point methods on the SGI power challenge (SGI R8000) platform indicated that on all but a few small linear programs in the NETLIB linear programming benchmark problem set, interior point methods dominated the simplex method in run times. New advances in handling Cholesky factorizations in parallel were apparently the reason for this exceptional performance of interior point methods. For the simplex method, CPLEX incorporated efficient methods of solving triangular linear systems and faster updating of reduced costs for identifying improving edge directions. For the interior point method, the same code included improvements in computing Cholesky factorizations and better use of level-two cache available in contemporary computing architectures. Using CPLEX 6.5 and CPLEX 5.0, Bixby et al. (2001) carried out extensive computational testing comparing the two codes with respect to the performance of the Primal simplex, Dual simplex, and Interior Point methods as well as a comparison of the performance of these three methods. While CPLEX 6.5 considerably outperformed CPLEX 5.0 for all the three methods, the comparison among the three methods was inconclusive. However, as stated by Bixby et al. (2001), the computational testing was biased against interior point method because of the inferior floating point performance of the machine used and the nonimplementation of the parallel features on shared memory machines. In a recent review of interior point methods, Jacek Gondzio (2012) compared CPLEX 11.0.1 with matrix-free interior point methods for addressing LP relaxations of quadratic assignment problems and some challenging linear optimization problems in quantum physics. Gondzio concludes that the iterative methods of linear algebra are worth considering in situations where direct matrix factorizations are impractical.

Remark 13.8

Karmarkar (1990) has proposed an interior-point approach for integer programming problems. The main idea is to reformulate an integer program as the minimization of a quadratic energy function over linear constraints on continuous variables. Interior-point methods are applied to this formulation to find local optima.

13.3 Large-Scale Linear Programming in Combinatorial Optimization

Linear programming problems with thousands of rows and columns are routinely solved either by variants of the simplex method or by interior point methods. However, for several linear programs that arise in combinatorial optimization, the number of columns (or rows in the dual) are too numerous to be enumerated explicitly. The columns, however, often have a structure which is exploited to generate the

columns as and when required in the simplex method. Such an approach, which is referred to as *column generation*, is illustrated next on the *cutting stock problem* (Gilmore and Gomory, 1963), which is also known as the *bin packing problem* in the computer science literature.

13.3.1 Cutting Stock Problem

Rolls of sheet metal of standard length L are used to cut required lengths l_i , $i = 1, 2, \dots, m$. The j th cutting pattern should be such that a_{ij} , the number of sheets of length l_i cut from one roll of standard length L , must satisfy $\sum_{i=1}^m a_{ij}l_i \leq L$. Suppose n_i , $i = 1, 2, \dots, m$ sheets of length l_i are required. The problem is to find cutting patterns so as to minimize the number of rolls of standard length L that are used to meet the requirements. A linear programming formulation of the problem is as follows.

Let x_j , $j = 1, 2, \dots, n$, denote the number of times the j th cutting pattern is used. In general, x_j , $j = 1, 2, \dots, n$ should be an integer but in the next formulation the variables are permitted to be fractional.

$$\begin{aligned} \text{(P1) Min } & \sum_{j=1}^n x_j \\ \text{Subject to } & \sum_{j=1}^n a_{ij}x_j \geq n_i \quad i = 1, 2, \dots, m \\ & x_j \geq 0 \quad j = 1, 2, \dots, n \\ \text{where } & \sum_{i=1}^m l_i a_{ij} \leq L \quad j = 1, 2, \dots, n \end{aligned}$$

The formulation can easily be extended to allow for the possibility of p standard lengths L_k , $k = 1, 2, \dots, p$, from which the n_i units of length l_i , $i = 1, 2, \dots, m$, are to be cut.

The cutting stock problem can also be viewed as a bin packing problem. Several bins, each of standard capacity L , are to be packed with n_i units of item i , each of which uses up capacity of l_i in a bin. The problem is to minimize the number of bins used.

13.3.2 Column Generation

In general, the number of columns in (P1) is too large to enumerate all of the columns explicitly. The simplex method, however, does not require all of the columns to be explicitly written down. Given a basic feasible solution and the corresponding simplex multipliers w_i , $i = 1, 2, \dots, m$, the column to enter the basis is determined by applying dynamic programming to solve the following knapsack problem:

$$\begin{aligned} \text{(P2) } z = \text{Max } & \sum_{i=1}^m w_i a_i \\ \text{Subject to } & \sum_{i=1}^m l_i a_i \leq L \\ & a_i \geq 0 \text{ and integer, for } i = 1, 2, \dots, m \end{aligned}$$

Let a_i^* , $i = 1, 2, \dots, m$, denote an optimal solution to (P2). If $z > 1$, the k th column to enter the basis has coefficients $a_{ik} = a_i^*$, $i = 1, 2, \dots, m$.

Using the identified columns, a new improved (in terms of the objective function value) basis is obtained, and the column generation procedure is repeated. A major iteration is one in which (P2) is solved to identify, if there is one, a column to enter the basis. Between two major iterations, several minor iterations may be performed to optimize the linear program using only the available (generated) columns.

If $z \leq 1$, the current basic feasible solution is optimal to (P1). From a computational point of view, alternative strategies are possible. For instance, instead of solving (P2) to optimality, a column to enter the basis can be identified as soon as a feasible solution to (P2) with an objective function value greater than 1 has been found. Such an approach would reduce the time required to solve (P2) but may increase the number of iterations required to solve (P1).

A column once generated may be retained, even if it comes out of the basis at a subsequent iteration, so as to avoid generating the same column again later on. However, at a particular iteration some columns, which appear unattractive in terms of their reduced costs, may be discarded in order to avoid having to store a large number of columns. Such columns can always be generated again subsequently, if necessary. The rationale for this approach is that such unattractive columns will rarely be required subsequently.

The dual of (P1) has a large number of rows. Hence, column generation may be viewed as row generation in the dual. In other words, in the dual we start with only a few constraints explicitly written down. Given an optimal solution \mathbf{w} to the current dual problem (i.e., with only a few constraints which have been explicitly written down) find a constraint that is violated by \mathbf{w} or conclude that no such constraint exists. The problem to be solved for identifying a violated constraint, if any, is exactly the separation problem that we encountered in the section on algorithms for linear programming.

13.3.3 Decomposition and Compact Representations

Large-scale linear programs sometimes have a block diagonal structure with a few additional constraints linking the different blocks. The linking constraints are referred to as the master constraints and the various blocks of constraints are referred to as subproblem constraints. Using the representation theorem of polyhedra (see, for instance, Nemhauser and Wolsey, 1988), the decomposition approach of Dantzig and Wolfe (1961) is to convert the original problem to an equivalent linear program with a small number of constraints but with a large number of columns or variables. In the cutting stock problem described in the preceding section, the columns are generated, as and when required, by solving a knapsack problem via dynamic programming. In the Dantzig–Wolfe decomposition scheme, the columns are generated, as and when required, by solving appropriate linear programs on the subproblem constraints.

It is interesting to note that the reverse of decomposition is also possible. In other words, suppose we start with a statement of a problem and an associated linear programming formulation with a large number of columns (or rows in the dual). If the column generation (or row generation in the dual) can be accomplished by solving a linear program, then a *compact* formulation of the original problem can be obtained. Here compact refers to the number of rows and columns being bounded by a polynomial function of the input length of the original problem. This result due to Martin (1991) enables one to solve the problem in the polynomial time by solving the compact formulation using interior point methods.

13.4 Integer Linear Programs

Integer linear programming problems (ILPs) are linear programs in which all of the variables are restricted to be integers. If only some but not all variables are restricted to be integers, the problem is referred to as a mixed integer program. Many combinatorial problems can be formulated as integer linear programs in which all of the variables are restricted to be 0 or 1. We will first discuss several examples of combinatorial optimization problems and their formulation as integer programs. Then we

will review a general representation theory for integer programs that gives a formal measure of the expressiveness of this algebraic approach. We conclude this section with a representation theorem due to Benders (1962), which has been very useful in solving certain large-scale combinatorial optimization problems in practice.

13.4.1 Example Formulations

13.4.1.1 Covering and Packing Problems

A wide variety of location and scheduling problems can be formulated as set covering or set packing or set partitioning problems. The three different types of *covering and packing* problems can be succinctly stated as follows: Given (1) a finite set of elements $\mathcal{M} = \{1, 2, \dots, m\}$, and (2) a family F of subsets of \mathcal{M} with each member $F_j, j = 1, 2, \dots, n$ having a profit (or cost) c_j associated with it, find a collection, S , of the members of F that maximizes the profit (or minimizes the cost) while ensuring that every element of \mathcal{M} is in one of the following:

- (P3): at most one member of S (set packing problem)
- (P4): at least one member of S (set covering problem)
- (P5): exactly one member of S (set partitioning problem)

The three problems (P3), (P4), and (P5) can be formulated as ILPs as follows:

Let A denote the $m \times n$ matrix where

$$A_{ij} = \begin{cases} 1 & \text{if element } i \in F_j \\ 0 & \text{otherwise} \end{cases}$$

The decision variables are $x_j, j = 1, 2, \dots, n$ where

$$x_{ij} = \begin{cases} 1 & \text{if } F_j \text{ is chosen} \\ 0 & \text{otherwise} \end{cases}$$

The set packing problem is

$$\begin{aligned} & \text{(P3) Max } \mathbf{c}\mathbf{x} \\ & \text{Subject to } \mathbf{A}\mathbf{x} \leq \mathbf{e}_m \\ & \mathbf{x}_j = 0 \text{ or } 1, \quad j = 1, 2, \dots, n \end{aligned}$$

where \mathbf{e}_m is an m -dimensional column vector of ones.

The set covering problem (P4) is (P3) with less than or equal to constraints replaced by greater than or equal to constraints and the objective is to minimize rather than maximize. The set partitioning problem (P5) is (P3) with the constraints written as equalities. The set partitioning problem can be converted to a set packing problem or set covering problem (see Padberg, 1995) using standard transformations. If the right-hand side vector \mathbf{e}_m is replaced by a nonnegative integer vector \mathbf{b} , (P3) is referred to as the generalized set packing problem.

The airline crew scheduling problem is a classic example of the set partitioning or the set covering problem. Each element of \mathcal{M} corresponds to a flight segment. Each subset F_j corresponds to an acceptable set of flight segments of a crew. The problem is to cover, at minimum cost, each flight segment exactly once. This is a set partitioning problem. If *dead heading* of crew is permitted, we have the set covering problem.

13.4.1.2 Packing and Covering Problems in a Graph

Suppose A is the node-edge incidence matrix of a graph. Now, (P3) is a weighted matching problem. If in addition, the right-hand side vector \mathbf{e}_m is replaced by a nonnegative integer vector \mathbf{b} , (P3) is referred to as a weighted \mathbf{b} -matching problem. In this case, each variable \mathbf{x}_j which is restricted to be an integer may have a positive upper bound of u_j . Problem (P4) is now referred to as the weighted edge covering problem. Note that by substituting for $\mathbf{x}_j = 1 - \mathbf{y}_j$, where $\mathbf{y}_j = 0$ or 1 , the weighted edge covering problem is transformed to a weighted \mathbf{b} -matching problem in which the variables are restricted to be 0 or 1 .

Suppose A is the edge-node incidence matrix of a graph. Now, (P3) is referred to as the weighted vertex packing problem and (P4) is referred to as the weighted vertex covering problem. The *set packing* problem can be transformed to a weighted vertex packing problem in a graph G as follows:

G contains a node for each \mathbf{x}_j and an edge between nodes j and k exists if and only if the columns $A_{.j}$ and $A_{.k}$ are not orthogonal. G is called the *intersection graph* of A . The set packing problem is equivalent to the weighted vertex packing problem on G . Given G , the complement graph \bar{G} has the same node set as G and there is an edge between nodes j and k in \bar{G} if and only if there is no such corresponding edge in G . A clique in a graph is a subset, k , of nodes of G such that the subgraph induced by k is complete. Clearly, the weighted vertex packing problem in G is equivalent to finding a maximum weighted clique in \bar{G} .

13.4.1.3 Plant Location Problems

Given a set of customer locations $N = \{1, 2, \dots, n\}$ and a set of potential sites for plants $M = \{1, 2, \dots, m\}$, the plant location problem is to identify the sites where the plants are to be located so that the customers are served at a minimum cost. There is a fixed cost \mathbf{f}_i of locating the plant at site i and the cost of serving customer j from site i is \mathbf{c}_{ij} . The decision variables are: \mathbf{y}_i is set to 1 if a plant is located at site i and to 0 otherwise; \mathbf{x}_{ij} is set to 1 if site i serves customer j and to 0 otherwise.

A formulation of the problem is

$$\begin{aligned}
 \text{(P6) Min } & \sum_{i=1}^m \sum_{j=1}^n \mathbf{c}_{ij} \mathbf{x}_{ij} + \sum_{i=1}^m \mathbf{f}_i \mathbf{y}_i \\
 \text{subject to } & \sum_{i=1}^m \mathbf{x}_{ij} = 1 \quad j = 1, 2, \dots, n \\
 & \mathbf{x}_{ij} - \mathbf{y}_i \leq 0 \quad i = 1, 2, \dots, m; \quad j = 1, 2, \dots, n \\
 & \mathbf{y}_i = 0 \text{ or } 1 \quad i = 1, 2, \dots, m \\
 & \mathbf{x}_{ij} = 0 \text{ or } 1 \quad i = 1, 2, \dots, m; \quad j = 1, 2, \dots, n
 \end{aligned}$$

Note that the constraints $\mathbf{x}_{ij} - \mathbf{y}_i \leq 0$ are required to ensure that customer j may be served from site i only if a plant is located at site i . Note that the constraints $\mathbf{y}_i = 0$ or 1 force an optimal solution in which $\mathbf{x}_{ij} = 0$ or 1 . Consequently, the $\mathbf{x}_{ij} = 0$ or 1 constraints may be replaced by nonnegativity constraints $\mathbf{x}_{ij} \geq 0$.

The linear programming relaxation associated with (P6) is obtained by replacing constraints $\mathbf{y}_i = 0$ or 1 and $\mathbf{x}_{ij} = 0$ or 1 by nonnegativity constraints on \mathbf{x}_{ij} and \mathbf{y}_i . The upper bound constraints on \mathbf{y}_i are not required provided $\mathbf{f}_i \geq 0, i = 1, 2, \dots, m$. The upper bound constraints on \mathbf{x}_{ij} are not required in view of constraints $\sum_{i=1}^m \mathbf{x}_{ij} = 1$.

Remark 13.9

It is frequently possible to formulate the same combinatorial problem as two or more different ILPs. Suppose we have two ILP formulations (F1) and (F2) of the given combinatorial problem with both (F1) and (F2) being minimizing problems. Formulation (F1) is said to be stronger than (F2) if (LP1), the linear programming relaxation of (F1), always has an optimal objective function value which is greater than or equal to the optimal objective function value of (LP2), which is the linear programming relaxation of (F2).

It is possible to reduce the number of constraints in (P6) by replacing the constraints $\mathbf{x}_{ij} - \mathbf{y}_i \leq 0$ by an aggregate:

$$\sum_{j=1}^n \mathbf{x}_{ij} - n\mathbf{y}_i \leq 0 \quad i = 1, 2, \dots, m$$

However, the disaggregated (P6) is a stronger formulation than the formulation obtained by aggregating the constraints as previously. By using standard transformations, (P6) can also be converted into a set packing problem.

13.4.1.4 Satisfiability and Inference Problems

In propositional logic, a truth assignment is an assignment of true or false to each atomic proposition $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n$. A literal is an atomic proposition \mathbf{x}_j or its negation $\neg\mathbf{x}_j$. For propositions in conjunctive normal form, a clause is a disjunction of literals and the proposition is a conjunction of clauses. A clause is obviously satisfied by a given truth assignment if at least one of its literals is true. The satisfiability problem consists of determining whether there exists a truth assignment to atomic propositions such that a set S of clauses is satisfied.

Let T_i denote the set of atomic propositions such that if any one of them is assigned true, the clause $i \in S$ is satisfied. Similarly, let F_i denote the set of atomic propositions such that if any one of them is assigned false, the clause $i \in S$ is satisfied.

The decision variables are

$$\mathbf{x}_j = \begin{cases} 1 & \text{if atomic proposition } j \text{ is assigned true} \\ 0 & \text{if atomic proposition } j \text{ is assigned false} \end{cases}$$

The satisfiability problem is to find a feasible solution to

$$(P7) \quad \sum_{j \in T_i} \mathbf{x}_j - \sum_{j \in F_i} \mathbf{x}_j \geq 1 - |F_i| \quad i \in S$$

$$\mathbf{x}_j = 0 \text{ or } 1 \quad \text{for } j = 1, 2, \dots, n$$

By substituting $\mathbf{x}_j = 1 - \mathbf{y}_j$, where $\mathbf{y}_j = 0$ or 1 , for $j \in F_i$, (P7) is equivalent to the set covering problem

$$(P8) \quad \text{Min} \sum_{j=1}^n (\mathbf{x}_j + \mathbf{y}_j) \tag{13.3}$$

$$\text{subject to } \sum_{j \in I_i} x_j + \sum_{j \in F_i} y_j \geq 1 \quad i \in S \tag{13.4}$$

$$x_j + y_j \geq 1 \quad j = 1, 2, \dots, n \tag{13.5}$$

$$x_j, y_j = 0 \text{ or } 1 \quad j = 1, 2, \dots, n \tag{13.6}$$

Clearly, (P7) is feasible if and only if (P8) has an optimal objective function value equal to n .

Given a set S of clauses and an additional clause $k \notin S$, the logical inference problem is to find out whether every truth assignment that satisfies all of the clauses in S also satisfies the clause k . The logical inference problem is

$$\begin{aligned} \text{(P9) Min } & \sum_{j \in T_k} x_j - \sum_{j \in F_k} x_j \\ \text{subject to } & \sum_{j \in T_i} x_j - \sum_{j \in F_i} x_j \geq 1 - |F_i| \quad i \in S \\ & x_j = 0 \text{ or } 1 \quad j = 1, 2, \dots, n \end{aligned}$$

The clause k is implied by the set of clauses S , if and only if (P9) has an optimal objective function value greater than $-|F_k|$. It is also straightforward to express the MAX-SAT problem (i.e., find a truth assignment that maximizes the number of satisfied clauses in a given set S) as an integer linear program.

13.4.1.5 Multiprocessor Scheduling

Given n jobs and m processors, the problem is to allocate each job to one and only one of the processors so as to minimize the make span time, that is, minimize the completion time of all of the jobs. The processors may not be identical and, hence, job j if allocated to processor i requires p_{ij} units of time. The multiprocessor scheduling problem is

$$\begin{aligned} \text{(P10) Min } & T \\ \text{subject to } & \sum_{i=1}^m x_{ij} = 1 \quad j = 1, 2, \dots, n \\ & \sum_{j=1}^n p_{ij} x_{ij} - T \leq 0 \quad i = 1, 2, \dots, m \\ & x_{ij} = 0 \text{ or } 1 \end{aligned}$$

Note that if all p_{ij} are integers, the optimal solution will be such that T is an integer.

Remark 13.10

Protein Folding is a challenging optimization problem in biology which has seen a great deal of research by computational scientists and structural biologists. The computational complexity has been established even for very restricted lattice models to be NP-Hard and even hard to approximate within a

guaranteed factor. Chandru et al. (2003) survey the hardness results for lattice embeddings of the folding problem and also review the results on approximation methods with a guarantee of $\frac{1}{3}$ of optimal due to Newman for folding in the plane and $\frac{3}{8}$ for folding in 3D which is due to Hart and Istrail for the so-called *Hydrophobic-Hydrophilic (HP) model* of energy minimization. For the same HP model, Chandru et al. (2004) show that the lattice version of the protein folding problem can be formulated as an Integer Programming problem and show that B-and-B methods can improve on the approximations produced by the approximation methods mentioned above.

13.4.2 Jeroslow's Representability Theorem

Jeroslow (1989), building on joint work with Lowe (see Jeroslow and Lowe [1984]), characterized subsets of n -space that can be represented as the feasible region of a mixed integer (Boolean) program. They proved that a set is the feasible region of some mixed integer/linear programming problem (MILP) if and only if it is the union of finitely many polyhedra having the same recession cone (defined subsequently). Although this result is not widely known, it might well be regarded as the fundamental theorem of mixed integer modeling.

The basic idea of Jeroslow's results is that any set that can be represented in a mixed integer model can be represented in a disjunctive programming problem (i.e., a problem with either/or constraints). A *recession direction* for a set S in n -space is a vector \mathbf{x} such that $s + \alpha\mathbf{x} \in S$ for all $s \in S$ and all $\alpha \geq 0$. The set of recession directions is denoted $\text{rec}(S)$. Consider the general mixed integer constraint set

$$\begin{aligned} \mathbf{f}(\mathbf{x}, \mathbf{y}, \boldsymbol{\lambda}) &\leq \mathbf{b} \\ \mathbf{x} \in \mathfrak{R}^n, \quad \mathbf{y} \in \mathfrak{R}^p & \\ \boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_k), \quad \text{with } \lambda_j \in \{0, 1\} & \text{ for } j = 1, \dots, k \end{aligned} \tag{13.7}$$

Here \mathbf{f} is a vector-valued function, so that $\mathbf{f}(\mathbf{x}, \mathbf{y}, \boldsymbol{\lambda}) \leq \mathbf{b}$ represents a set of constraints. We say that a set $S \subset \mathfrak{R}^n$ is *represented* by Equation 13.7 if,

$$\mathbf{x} \in S \quad \text{if and only if } (\mathbf{x}, \mathbf{y}, \boldsymbol{\lambda}) \text{ satisfies Equation 13.7 for some } \mathbf{y}, \boldsymbol{\lambda}.$$

If \mathbf{f} is a linear transformation, so that Equation 13.7 is a MILP constraint set, we will say that S is *MILP representable*. The main result can now be stated.

Theorem 13.2

A set in n -space is *MILP representable* if and only if it is the union of finitely many polyhedra having the same set of recession directions (Jeroslow and Lowe, 1984; Jeroslow, 1989).

13.4.3 Benders's Representation

Any MILP can be reformulated so that there is only one continuous variable. This reformulation, due to Benders (1962), will in general have an exponential number of constraints. Analogous to column generation, discussed earlier, these rows (constraints) can be generated as and when required.

Consider the (MILP)

$$\max \{\mathbf{c}\mathbf{x} + \mathbf{d}\mathbf{y} : \mathbf{A}\mathbf{x} + \mathbf{G}\mathbf{y} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0}, \mathbf{y} \geq \mathbf{0} \text{ and integer}\}$$

Suppose the integer variables \mathbf{y} are fixed at some values. Then, the associated linear program is

$$(LP) \quad \max \{ \mathbf{c}\mathbf{x} : \mathbf{x} \in \mathcal{P} = \{ \mathbf{x} : A\mathbf{x} \leq \mathbf{b} - G\mathbf{y}, \mathbf{x} \geq \mathbf{0} \} \}$$

and its dual is

$$(DLP) \quad \min \{ \mathbf{w}(\mathbf{b} - G\mathbf{y}) : \mathbf{w} \in \mathcal{Q} = \{ \mathbf{w} : \mathbf{w}A \geq \mathbf{c}, \mathbf{w} \geq \mathbf{0} \} \}$$

Let $\{\mathbf{w}^k\}$, $k = 1, 2, \dots, K$ be the extreme points of \mathcal{Q} and $\{\mathbf{u}^j\}$, $j = 1, 2, \dots, J$ be the extreme rays of the recession cone of \mathcal{Q} , $\mathcal{C}_{\mathcal{Q}} = \{ \mathbf{u} : \mathbf{u}A \geq \mathbf{0}, \mathbf{u} \geq \mathbf{0} \}$. Note that if \mathcal{Q} is nonempty, the $\{\mathbf{u}^j\}$ are all of the extreme rays of \mathcal{Q} .

From linear programming duality, we know that if \mathcal{Q} is empty and $\mathbf{u}^j(\mathbf{b} - G\mathbf{y}) \geq 0$, $j = 1, 2, \dots, J$ for some $\mathbf{y} \geq \mathbf{0}$ and integer then (LP) and consequently (MILP) have an unbounded solution. If \mathcal{Q} is nonempty and $\mathbf{u}^j(\mathbf{b} - G\mathbf{y}) \geq 0$, $j = 1, 2, \dots, J$ for some $\mathbf{y} \geq \mathbf{0}$ and integer then (LP) has a finite optimum given by

$$\min_k \{ \mathbf{w}^k(\mathbf{b} - G\mathbf{y}) \}$$

Hence, an equivalent formulation of (MILP) is

$$\begin{aligned} \text{Max } & \alpha \\ & \alpha \leq \mathbf{d}\mathbf{y} + \mathbf{w}^k(\mathbf{b} - G\mathbf{y}), \quad k = 1, 2, \dots, K \\ & \mathbf{u}^j(\mathbf{b} - G\mathbf{y}) \geq 0, \quad j = 1, 2, \dots, J \\ & \mathbf{y} \geq \mathbf{0} \text{ and integer} \\ & \alpha \text{ unrestricted} \end{aligned}$$

which has only one continuous variable α as promised.

13.5 Polyhedral Combinatorics

One of the main purposes of writing down an algebraic formulation of a combinatorial optimization problem as an integer program is to then examine the linear programming relaxation and understand how well it represents the discrete integer program. There are somewhat special but rich classes of such formulations for which the linear programming relaxation is sharp or tight. These correspond to linear programs that have integer valued extreme points. Such polyhedra are called *integral polyhedra*.

13.5.1 Special Structures and Integral Polyhedra

A natural question of interest is whether the LP associated with an ILP has only integral extreme points. For instance, the linear programs associated with matching and edge covering polytopes in a bipartite graph have only integral vertices. Clearly, in such a situation, the ILP can be solved as LP. A polyhedron or a polytope is referred to as being integral if it is either empty or has only integral vertices.

Definition 13.3

A $0, \pm 1$ matrix is totally unimodular if the determinant of every square submatrix is 0 or ± 1 .

Theorem 13.3

Let

$$A = \begin{pmatrix} A_1 \\ A_2 \\ A_3 \end{pmatrix}$$

be a 0, ±1 matrix and

$$\mathbf{b} = \begin{pmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 \\ \mathbf{b}_3 \end{pmatrix}$$

be a vector of appropriate dimensions (Hoffman and Kruskal, 1956). Then A is totally unimodular if and only if the polyhedron

$$P(A, \mathbf{b}) = \{\mathbf{x} : A_1\mathbf{x} \leq \mathbf{b}_1; A_2\mathbf{x} \geq \mathbf{b}_2; A_3\mathbf{x} = \mathbf{b}_3; \mathbf{x} \geq 0\}$$

is integral for all integral vectors \mathbf{b} .

The constraint matrix associated with a network flow problem (see, for instance, Ahuja et al., 1993) is totally unimodular. Note that for a given integral \mathbf{b} , $P(A, \mathbf{b})$ may be integral even if A is not totally unimodular.

Definition 13.4

A polyhedron defined by a system of linear constraints is totally dual integral (TDI) if for each objective function with integral coefficient the dual linear program has an integral optimal solution whenever an optimal solution exists.

Theorem 13.4

(Edmonds and Giles, 1977). If $P(A) = \{\mathbf{x} : A\mathbf{x} \leq \mathbf{b}\}$ is TDI and \mathbf{b} is integral, then $P(A)$ is integral.

Hoffman and Kruskal (1956) have, in fact, shown that the polyhedron $P(A, \mathbf{b})$ defined in Theorem 13.3 is TDI. This follows from Theorem 13.3 and the fact that A is totally unimodular if and only if A^T is totally unimodular.

Balanced matrices, first introduced by Berge (1972), have important implications for packing and covering problems (see also Berge and Las Vergnas, 1970).

Definition 13.5

A 0, 1 matrix is balanced if it does not contain a square submatrix of odd order with two 1s per row and column.

Theorem 13.5

Let A be a balanced 0, 1 matrix (Berge, 1972; Fulkerson et al., 1974). Then the set packing, set covering, and set partitioning polytopes associated with A are integral, that is, the polytopes

$$P(A) = \{\mathbf{x} : \mathbf{x} \geq \mathbf{0}; A\mathbf{x} \leq \mathbf{1}\}$$

$$Q(A) = \{\mathbf{x} : \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}; A\mathbf{x} \geq \mathbf{1}\}$$

$$R(A) = \{\mathbf{x} : \mathbf{x} \geq \mathbf{0}; A\mathbf{x} = \mathbf{1}\}$$

are integral.

Let

$$A = \begin{pmatrix} A_1 \\ A_2 \\ A_3 \end{pmatrix}$$

be a balanced 0, 1 matrix. Fulkerson et al. (1974) have shown that the polytope $P(A) = \{\mathbf{x} : A_1\mathbf{x} \leq \mathbf{1}; A_2\mathbf{x} \geq \mathbf{1}; A_3\mathbf{x} = \mathbf{1}; \mathbf{x} \geq \mathbf{0}\}$ is TDI and by the theorem of Edmonds and Giles (1977) it follows that $P(A)$ is integral.

Truemper (1992) has extended the definition of balanced matrices to include 0, ± 1 matrices.

Definition 13.6

A 0, ± 1 matrix is balanced if for every square submatrix with exactly two nonzero entries in each row and each column, the sum of the entries is a multiple of 4.

Theorem 13.6

Suppose A is a balanced 0, ± 1 matrix (Conforti and Cornuejols, 1992b). Let $\mathbf{n}(A)$ denote the column vector whose i th component is the number of -1 s in the i th row of A . Then the polytopes

$$P(A) = \{\mathbf{x} : A\mathbf{x} \leq \mathbf{1} - \mathbf{n}(A); \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}\}$$

$$Q(A) = \{\mathbf{x} : A\mathbf{x} \geq \mathbf{1} - \mathbf{n}(A); \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}\}$$

$$R(A) = \{\mathbf{x} : A\mathbf{x} = \mathbf{1} - \mathbf{n}(A); \mathbf{0} \leq \mathbf{x} \leq \mathbf{1}\}$$

are integral.

Note that a 0, ± 1 matrix A is balanced if and only if A^T is balanced. Moreover, A is balanced (totally unimodular) if and only if every submatrix of A is balanced (totally unimodular). Thus, if A is balanced (totally unimodular), it follows that Theorem 13.6 (Theorem 13.3) holds for every submatrix of A .

Totally unimodular matrices constitute a subclass of balanced matrices, that is, a totally unimodular 0, ± 1 matrix is always balanced. This follows from a theorem of Camion (1965), which states that a

$$A = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \end{bmatrix} \quad A = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 1 \end{bmatrix}$$

FIGURE 13.1 A balanced matrix and a perfect matrix. (From Chandru, V. and Rao, M. R., *ACM Comput. Survey*, 28, 55, 1996.)

$0, \pm 1$ is totally unimodular if and only if for every square submatrix with an even number of nonzero entries in each row and in each column, the sum of the entries equals a multiple of 4. The 4×4 matrix in Figure 13.1 illustrates the fact that a balanced matrix is not necessarily totally unimodular. Balanced $0, \pm 1$ matrices have implications for solving the satisfiability problem. If the given set of clauses defines a balanced $0, \pm 1$ matrix, then as shown by Conforti and Cornuejols (1992b), the satisfiability problem is trivial to solve and the associated MAXSAT problem is solvable in polynomial time by linear programming. A survey of balanced matrices is in Conforti et al. (1994a,b).

Definition 13.7

A $0, 1$ matrix A is perfect if the set packing polytope $P(A) = \{\mathbf{x} : A\mathbf{x} \leq \mathbf{1}; \mathbf{x} \geq \mathbf{0}\}$ is integral.

The chromatic number of a graph is the minimum number of colors required to color the vertices of the graph so that no two vertices with the same color have an edge incident between them. A graph G is perfect if for every node induced subgraph H , the chromatic number of H equals the number of nodes in the maximum clique of H .

Recall that the complement graph of G is the graph \bar{G} with the same node set as G but the edge set comprises only of all the edges not in G . The perfect graph conjecture due to Berge (1961) is that G is perfect if and only if \bar{G} is perfect. This conjecture was proved by Lovász (1972). The strong perfect graph conjecture, also due to Berge (1961), is that G is perfect if and only if it contains no induced sub graph which is an odd hole of length of 5 or more, or an odd antihole which is the complement of an odd hole of length 5 or more. A proof of this conjecture was announced by Chudnovsky, Robertson, Seymour and Thomas in 2002 and published in 2006 (Chudnovsky et al., 2006).

The connections between the integrality of the set packing polytope and the notion of a perfect graph, as defined by Berge (1961, 1970), are given in Fulkerson (1970), Lovasz (1972), Padberg (1974), and Chvátal (1975).

Theorem 13.7

Let A be $0, 1$ matrix whose columns correspond to the nodes of a graph G and whose rows are the incidence vectors of the maximal cliques of G (Fulkerson, 1970; Lovasz, 1972; Chvátal, 1975). The graph G is perfect if and only if A is perfect.

Let G_A denote the intersection graph associated with a given $0, 1$ matrix A (see Section 13.4). Clearly, a row of A is the incidence vector of a clique in G_A . In order for A to be perfect, every maximal clique of G_A must be represented as a row of A because inequalities defined by maximal cliques are facet defining. Thus, by Theorem 13.7, it follows that a $0, 1$ matrix A is perfect if and only if the undominated (a row of

A is dominated if its support is contained in the support of another row of A) rows of A form the clique-node incidence matrix of a perfect graph.

Balanced matrices with 0, 1 entries constitute a subclass of 0, 1 perfect matrices, that is, if a 0, 1 matrix A is balanced, then A is perfect. The 4×3 matrix in Figure 13.1 is an example of a matrix that is perfect but not balanced.

Definition 13.8

A 0, 1 matrix A is ideal if the set covering polytope

$$Q(A) = \{x : Ax \geq \mathbf{1}; \mathbf{0} \leq x \leq \mathbf{1}\}$$

is integral.

Properties of ideal matrices are described by Lehman (1979), Padberg (1993), and Cornuejols and Novick (1994). The notion of a 0, 1 perfect (ideal) matrix has a natural extension to a 0, ± 1 perfect (ideal) matrix. Some results pertaining to 0, ± 1 ideal matrices are contained in Hooker (1992), whereas some results pertaining to 0, ± 1 perfect matrices are given in Conforti et al. (1993).

An interesting combinatorial problem is to check whether a given 0, ± 1 matrix is totally unimodular, balanced, or perfect. Seymour's (1980) characterization of totally unimodular matrices provides a polynomial-time algorithm to test whether a given 0, 1 matrix is totally unimodular. Conforti et al. (1999) give a polynomial-time algorithm to check whether a 0, 1 matrix is balanced. This has been extended by Conforti et al. (1994a,b) to check in polynomial time whether a 0, ± 1 matrix is balanced. An open problem is that of checking in polynomial time whether a 0, 1 matrix is perfect. For linear matrices (a matrix is linear if it does not contain a 2×2 submatrix of all ones), this problem has been solved by Fonlupt and Zemirline (1981) and Conforti and Rao (1993).

13.5.2 Matroids

Matroids and submodular functions have been studied extensively, especially from the point of view of combinatorial optimization (see, for instance, Nemhauser and Wolsey, 1988). Matroids have nice properties that lead to efficient algorithms for the associated optimization problems. One of the interesting examples of a matroid is the problem of finding a maximum or minimum weight spanning tree in a graph. Two different but equivalent definitions of a matroid are given first. A greedy algorithm to solve a linear optimization problem over a matroid is presented. The matroid intersection problem is then discussed briefly.

Definition 13.9

Let $N = \{1, 2, \dots, n\}$ be a finite set and let \mathcal{F} be a set of subsets of N . Then $I = (N, \mathcal{F})$ is an independence system if $S_1 \in \mathcal{F}$ implies that $S_2 \in \mathcal{F}$ for all $S_2 \subseteq S_1$. Elements of \mathcal{F} are called *independent sets*. A set $S \in \mathcal{F}$ is a maximal independent set if $S \cup \{j\} \notin \mathcal{F}$ for all $j \in N \setminus S$. A maximal independent set T is a maximum if $|T| \geq |S|$ for all $S \in \mathcal{F}$.

The rank $r(Y)$ of a subset $Y \subseteq N$ is the cardinality of the maximum independent subset $X \subseteq Y$. Note that $r(\emptyset) = 0$, $r(X) \leq |X|$ for $X \subseteq N$ and the rank function is nondecreasing, that is, $r(X) \leq r(Y)$ for $X \subseteq Y \subseteq N$.

A *matroid* $M = (N, \mathcal{F})$ is an independence system in which every maximal independent set is a maximum.

Example 13.2

Let $G = (V, E)$ be an undirected connected graph with V as the node set and E as the edge set.

1. Let $I = (E, \mathcal{F})$ where $F \in \mathcal{F}$ if $F \subseteq E$ is such that at most one edge in F is incident to each node of V , that is, $F \in \mathcal{F}$ if F is a matching in G . Then $I = (E, \mathcal{F})$ is an independence system but not a matroid.
2. Let $M = (E, \mathcal{F})$ where $F \in \mathcal{F}$ if $F \subseteq E$ is such that $G_F = (V, F)$ is a forest, that is, G_F contains no cycles. Then $M = (E, \mathcal{F})$ is a matroid and maximal independent sets of M are spanning trees.

An alternative but equivalent definition of matroids is in terms of submodular functions.

Definition 13.10

A nondecreasing integer valued submodular function r defined on the subsets of N is called a *matroid rank function* if $r(\emptyset) = 0$ and $r(\{j\}) \leq 1$ for $j \in N$. The pair (N, r) is called a matroid.

A nondecreasing, integer-valued, submodular function f , defined on the subsets of N , is called a *polymatroid function* if $f(\emptyset) = 0$. The pair (N, r) is called a *polymatroid*.

13.5.2.1 Matroid Optimization

To decide whether an optimization problem over a matroid is polynomially solvable or not, we need to first address the issue of representation of a matroid. If the matroid is given either by listing the independent sets or by its rank function, many of the associated linear optimization problems are trivial to solve. However, matroids associated with graphs are completely described by the graph and the condition for independence. For instance, the matroid in which the maximal independent sets are spanning forests, the graph $G = (V, E)$ and the independence condition of no cycles describes the matroid.

Most of the algorithms for matroid optimization problems require a test to determine whether a specified subset is independent. We assume the existence of an oracle or subroutine to do this checking in running time, which is a polynomial function of $|N| = n$.

13.5.2.1.1 Maximum Weight Independent Set

Given a matroid $M = (N, \mathcal{F})$ and weights w_j for $j \in N$, the problem of finding a maximum weight independent set is $\max_{F \in \mathcal{F}} \left\{ \sum_{j \in F} w_j \right\}$. The greedy algorithm to solve this problem is as follows:

Procedure 13.3 Greedy:

0. **Initialize:** Order the elements of N so that $w_i \geq w_{i+1}$, $i = 1, 2, \dots, n - 1$. Let $T = \emptyset$, $i = 1$.
1. **If** $w_i \leq 0$ or $i > n$, **stop** T is optimal, i.e., $x_j = 1$ for $j \in T$ and $x_j = 0$ for $j \notin T$. **If** $w_i > 0$ and $T \cup \{i\} \in \mathcal{F}$, add element i to T .
2. **Increment** i by 1 and return to step 1.

Edmonds (1970, 1971) derived a complete description of the *matroid polytope*, the convex hull of the characteristic vectors of independent sets of a matroid. While this description has a large (exponential) number of constraints, it permits the treatment of linear optimization problems on independent sets of matroids as linear programs. Cunningham (1984) describes a polynomial algorithm to solve the separation problem for the matroid polytope. The matroid polytope and the associated greedy algorithm have been extended to polymatroids (Edmonds, 1970; McDiarmid, 1975).

The separation problem for a polymatroid is equivalent to the problem of minimizing a submodular function defined over the subsets of N (see Nemhauser and Wolsey, 1988). A class of submodular functions that have some additional properties can be minimized in polynomial time by solving a maximum flow problem (Rhys, 1970; Picard and Ratliff, 1975). The general submodular function can be minimized in polynomial time by the ellipsoid algorithm (Grötschel et al., 1988).

The uncapacitated plant location problem formulated in Section 13.4 can be reduced to maximizing a submodular function. Hence, it follows that maximizing a submodular function is \mathcal{NP} -hard.

13.5.2.2 Matroid Intersection

A matroid intersection problem involves finding an independent set contained in two or more matroids defined on the same set of elements.

Let $G = (V_1, V_2, E)$ be a bipartite graph. Let $M_i = (E, \mathcal{F}_i)$, $i = 1, 2$, where $F \in \mathcal{F}_i$ if $F \subseteq E$ is such that no more than one edge of F is incident to each node in V_i . The set of matchings in G constitutes the intersection of the two matroids M_i , $i = 1, 2$. The problem of finding a maximum weight independent set in the intersection of two matroids can be solved in polynomial time (Lawler, 1975; Edmonds, 1970, 1979; Frank, 1981). The two (poly) matroid intersection polytope has been studied by Edmonds (1979).

The problem of testing whether a graph contains a Hamiltonian path is \mathcal{NP} -complete. Since this problem can be reduced to the problem of finding a maximum cardinality independent set in the intersection of three matroids, it follows that the matroid intersection problem involving three or more matroids is \mathcal{NP} -hard.

13.5.3 Valid Inequalities, Facets, and Cutting Plane Methods

Earlier in this section, we were concerned with conditions under which the packing and covering polytopes are integral. But, in general, these polytopes are not integral, and additional inequalities are required to have a complete linear description of the convex hull of integer solutions. The existence of finitely many such linear inequalities is guaranteed by Weyl's (1935) Theorem.

Consider the feasible region of an ILP given by

$$P_I = \{\mathbf{x} : \mathbf{Ax} \leq \mathbf{b}; \mathbf{x} \geq \mathbf{0} \text{ and integer}\} \tag{13.8}$$

Recall that an inequality $\mathbf{fx} \leq f_0$ is referred to as a valid inequality for P_I if $\mathbf{fx}^* \leq f_0$ for all $\mathbf{x}^* \in P_I$. A valid linear inequality for $P_I(\mathbf{A}, \mathbf{b})$ is said to be facet defining if it intersects $P_I(\mathbf{A}, \mathbf{b})$ in a face of dimension one less than the dimension of $P_I(\mathbf{A}, \mathbf{b})$. In the example shown in Figure 13.2, the inequality $\mathbf{x}_2 + \mathbf{x}_3 \leq 1$ is a facet defining inequality of the integer hull.

Let $\mathbf{u} \geq \mathbf{0}$ be a row vector of appropriate size. Clearly $\mathbf{uAx} \leq \mathbf{ub}$ holds for every \mathbf{x} in P_I . Let $(\mathbf{uA})_j$ denote the j th component of the row vector \mathbf{uA} and $\lfloor (\mathbf{uA})_j \rfloor$ denote the largest integer less than or equal to $(\mathbf{uA})_j$. Now, since $\mathbf{x} \in P_I$ is a vector of nonnegative integers, it follows that $\sum_j \lfloor (\mathbf{uA})_j \rfloor x_j \leq \lfloor \mathbf{ub} \rfloor$ is a valid inequality for P_I . This scheme can be used to generate many valid inequalities by using different $\mathbf{u} \geq \mathbf{0}$. Any set of generated valid inequalities may be added to the constraints in Equation 13.7 and the process of generating them may be repeated with the enhanced set of inequalities. This iterative procedure of generating valid inequalities is called *Gomory–Chvátal (GC) rounding*. It is remarkable that this simple

FIGURE 13.2 Relaxation, cuts, and facets. (From Chandru, V. and Rao, M. R., *ACM Comput. Survey*, 28, 55, 1996.)

scheme is complete, that is, every valid inequality of P_I can be generated by finite application of GC rounding (Chvátal, 1973; Schrijver, 1986).

The number of inequalities needed to describe the convex hull of P_I is usually exponential in the size of A . But to solve an optimization problem on P_I , one is only interested in obtaining a partial description of P_I that facilitates the identification of an integer solution and prove its optimality. This is the underlying basis of any cutting plane approach to combinatorial problems.

13.5.3.1 Cutting Plane Method

Consider the optimization problem

$$\max\{c\mathbf{x} : \mathbf{x} \in P_I = \{\mathbf{x} : A\mathbf{x} \leq \mathbf{b}; \mathbf{x} \geq \mathbf{0} \text{ and integer}\}\}$$

The generic *cutting plane* method as applied to this formulation is given as follows.

Procedure 13.4 Cutting Plane:

1. Initialize $A' \leftarrow A$ and $\mathbf{b}' \leftarrow \mathbf{b}$.
2. Find an optimal solution $\bar{\mathbf{x}}$ to the linear program

$$\max\{c\mathbf{x} : A'\mathbf{x} \leq \mathbf{b}'; \mathbf{x} \geq \mathbf{0}\}$$

If $\bar{\mathbf{x}} \in P_I$, stop and return $\bar{\mathbf{x}}$.

3. Generate a valid inequality $\mathbf{f}\mathbf{x} \leq f_0$ for P_I such that $\mathbf{f}\bar{\mathbf{x}} > f_0$ (the inequality “cuts” $\bar{\mathbf{x}}$).
4. Add the inequality to the constraint system, update

$$A' \leftarrow \begin{pmatrix} A' \\ \mathbf{f} \end{pmatrix}, \quad \mathbf{b}' \leftarrow \begin{pmatrix} \mathbf{b}' \\ f_0 \end{pmatrix}$$

Go to step 2.

In step 3 of the cutting plane method, we require a suitable application of the GC rounding scheme (or some alternative method of identifying a cutting plane). Notice that while the GC rounding scheme will generate valid inequalities, the identification of one that cuts off the current solution to the linear

programming relaxation is all that is needed. Gomory (1958) provided just such a specialization of the rounding scheme that generates a cutting plane. Although this met the theoretical challenge of designing a sound and complete cutting plane method for integer linear programming, it turned out to be a weak method in practice. Successful cutting plane methods, in use today, use considerable additional insights into the structure of facet-defining cutting planes. Using facet cuts makes a huge difference in the speed of convergence of these methods. Also, the idea of combining cutting plane methods with search methods has been found to have a lot of merit. These B-and-C methods will be discussed in the next section.

13.5.3.2 **b**-Matching Problem

Consider the **b**-matching problem:

$$\max\{\mathbf{c}\mathbf{x} : \mathbf{A}\mathbf{x} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0} \text{ and integer}\} \quad (13.9)$$

where A is the node–edge incidence matrix of an undirected graph and \mathbf{b} is a vector of positive integers. Let G be the undirected graph whose node–edge incidence matrix is given by A and let $W \subseteq V$ be any subset of nodes of G (i.e., subset of rows of A) such that

$$\mathbf{b}(W) = \sum_{i \in W} \mathbf{b}_i$$

is odd. Then the inequality

$$\mathbf{x}(W) = \sum_{e \in E(W)} \mathbf{x}_e \leq \frac{1}{2}(\mathbf{b}(W) - 1) \quad (13.10)$$

is a valid inequality for integer solutions to Equation 13.8 where $E(W) \subseteq E$ is the set of edges of G having both ends in W . Edmonds (1965) has shown that the inequalities Equations 13.8 and 13.9 define the integral **b**-matching polytope. Note that the number of inequalities Equation 13.9 is exponential in the number of nodes of G . An instance of the successful application of the idea of using only a partial description of P_I is in the blossom algorithm for the matching problem, due to Edmonds (1965).

As we saw, an implication of the ellipsoid method for linear programming is that the linear program over P_I can be solved in polynomial time if and only if the associated separation problem (also referred to as the constraint identification problem, see Section 13.2) can be solved in polynomial time, see Grötschel et al. (1982), Karp and Papadimitriou (1982), and Padberg and Rao (1981). The separation problem for the **b**-matching problem with or without upper bounds was shown by Padberg and Rao (1982), to be solvable in polynomial time. The procedure involves a minor modification of the algorithm of Gomory and Hu (1961) for multiterminal networks. However, no polynomial (in the number of nodes of the graph) linear programming formulation of this separation problem is known. A related unresolved issue is whether there exists a polynomial size (compact) formulation for the **b**-matching problem. Yannakakis (1988) has shown that, under a symmetry assumption, such a formulation is impossible.

However, Kaibel et al. (2012) have shown that the symmetry assumption can make a big difference. Considering matchings of size of $\lfloor \log(n) \rfloor$, where n is the number of vertices in the graph, they show that there is a polynomial size nonsymmetric extended formulation while there is no compact symmetric extended formulation. Fiorini et al. (2012) have shown that the max-cut, traveling salesman and stable set problems cannot have a polynomial size extended formulation. But it is still an open question whether the perfect matching problem has a compact representation. Conforti et al. (2012) provide a survey on extended formulations.

13.5.3.3 Other Combinatorial Problems

Besides the matching problem, several other combinatorial problems and their associated polytopes have been well studied and some families of facet defining inequalities have been identified. For instance, the set packing, graph partitioning, plant location, max-cut, traveling salesman, and Steiner tree problems have been extensively studied from a polyhedral point of view (see, for instance, Nemhauser and Wolsey, 1988).

These combinatorial problems belong to the class of \mathcal{NP} -complete problems. In terms of a worst-case analysis, no polynomial-time algorithms are known for these problems. Nevertheless, using a cutting plane approach with B-and-B or B-and-C (see Section 13.6), large instances of these problems have been successfully solved, see Crowder et al. (1983), for general 0–1 problems, Barahona et al. (1989) for the max-cut problem, Padberg and Rinaldi (1991) for the traveling salesman problem (TSP), and Chopra et al. (1992) for the Steiner tree problem.

13.6 Partial Enumeration Methods

In many instances, to find an optimal solution to ILP, the structure of the problem is exploited together with some sort of partial enumeration. In this section, we review the B-and-B and B-and-C methods for solving an ILP.

13.6.1 Branch and Bound

The B-and-B method is a systematic scheme for implicitly enumerating the finitely many feasible solutions to an ILP. Although, theoretically the size of the enumeration tree is exponential in the problem parameters, in most cases, the method eliminates a large number of feasible solutions. The key features of B-and-B method are

1. *Selection/removal* of one or more problems from a candidate list of problems
2. *Relaxation* of the selected problem so as to obtain a lower bound (on a minimization problem) on the optimal objective function value for the selected problem
3. *Fathoming*, if possible, of the selected problem
4. *Branching* strategy is needed if the selected problem is not fathomed. Branching creates subproblems, which are added to the candidate list of problems

The four steps are repeated until the candidate list is empty. The B-and-B method sequentially examines problems that are added and removed from a candidate list of problems.

Initialization. Initially, the candidate list contains only the original ILP, which is denoted as

$$(P) \quad \min\{\mathbf{c}\mathbf{x} : A\mathbf{x} \leq \mathbf{b}, \mathbf{x} \geq \mathbf{0} \text{ and integer}\}$$

Let $F(P)$ denote the feasible region of (P) and $z(P)$ denote the optimal objective function value of (P) . For any $\bar{\mathbf{x}}$ in $F(P)$, let $z_p(\bar{\mathbf{x}}) = \mathbf{c}\bar{\mathbf{x}}$.

Frequently, heuristic procedures are first applied to get a good feasible solution to (P) . The best solution known for (P) is referred to as the current incumbent solution. The corresponding objective function value is denoted as z_i . In most instances, the initial heuristic solution is neither optimal nor at least immediately certified to be optimal. Thus, further analysis is required to ensure that an optimal solution to (P) is obtained. If no feasible solution to (P) is known, z_i is set to ∞ .

Selection/removal. In each iterative step of B-and-B, a problem is selected and removed from the candidate list for further analysis. The selected problem is henceforth referred to as the candidate problem (CP). The algorithm terminates if there is no problem to select from the candidate list. Initially, there is no issue of selection since the candidate list contains only the problem (P) . However, as the algorithm proceeds, there would be many problems on the candidate list and a selection rule is required.

Appropriate selection rules, also referred to as branching strategies, are discussed later. Conceptually, several problems may be simultaneously selected and removed from the candidate list. However, most sequential implementations of B-and-B select only one problem from the candidate list and this is assumed henceforth. Parallel aspects of B-and-B on 0–1 integer linear programs are discussed in Cannon and Hoffman (1990) and for the case of TSP in Applegate et al. (1994).

The computational time required for the B-and-B algorithm depends crucially on the order in which the problems in the candidate list are examined. A number of clever heuristic rules may be employed in devising such strategies. Two general purpose selection strategies that are commonly used are as follows:

1. Choose the problem that was added last to the candidate list. This last-in–first-out rule (LIFO) is also called *depth first search* (DFS) since the selected candidate problem increases the depth of the active enumeration tree.
2. Choose the problem on the candidate list that has the least lower bound. Ties may be broken by choosing the problem that was added last to the candidate list. This rule would require that a lower bound be obtained for each of the problems on the candidate list. In other words, when a problem is added to the candidate list, an associated lower bound should also be stored. This may be accomplished by using ad hoc rules or by solving a relaxation of each problem before it is added to the candidate list.

Rule 1 is known to empirically dominate rule 2 when storage requirements for candidate list and computation time to solve (P) are taken into account. However, some analysis indicates that rule 2 can be shown to be superior if minimizing the number of candidate problems to be solved is the criterion (see Parker and Rardin, 1988).

Relaxation. In order to analyze the selected candidate problem (CP), a **relaxation** (CP_R) of (CP) is solved to obtain a lower bound $z(CP_R) \leq z(CP)$. (CP_R) is a relaxation of (CP) if

1. $F(CP) \subseteq F(CP_R)$
2. For $\bar{\mathbf{x}} \in F(CP)$, $z_{CP_R}(\bar{\mathbf{x}}) \leq z_{CP}(\bar{\mathbf{x}})$
3. For $\bar{\mathbf{x}}, \hat{\mathbf{x}} \in F(CP)$, $z_{CP_R}(\bar{\mathbf{x}}) \leq z_{CP_R}(\hat{\mathbf{x}})$ implies that $z_{CP}(\bar{\mathbf{x}}) \leq z_{CP}(\hat{\mathbf{x}})$

Relaxations are needed because the candidate problems are typically hard to solve. The relaxations used most often are either linear programming or Lagrangian relaxations of (CP), see Section 13.7 for details. Sometimes, instead of solving a relaxation of (CP), a lower bound is obtained by using some ad hoc rules such as penalty functions.

Fathoming. A candidate problem is fathomed if

- (FC1) analysis of (CP_R) reveals that (CP) is infeasible. For instance, if $F(CP_R) = \phi$, then $F(CP) = \phi$.
- (FC2) analysis of (CP_R) reveals that (CP) has no feasible solution better than the current incumbent solution. For instance, if $z(CP_R) \geq z_p$, then $z(CP) \geq z(CP_R) \geq z_p$.
- (FC3) analysis of (CP_R) reveals an optimal solution of (CP). For instance, if the optimal solution, \mathbf{x}_R , to (CP_R) is feasible in (CP), then (\mathbf{x}_R) is an optimal solution to (CP) and $z(CP) = \mathbf{c}\mathbf{x}_R$.
- (FC4) analysis of (CP_R) reveals that (CP) is dominated by some other problem, say, CP^* , in the candidate list. For instance, if it can be shown that $z(CP^*) \leq z(CP)$, then there is no need to analyze (CP) further.

If a candidate problem (CP) is fathomed using any of the preceding criteria, then further examination of (CP) or its descendants (subproblems) obtained by separation is not required. If (FC3) holds, and $z(CP) < z_p$, the incumbent is updated as \mathbf{x}_R and z_I is updated as $z(CP)$.

Separation/branching. If the candidate problem (CP) is not fathomed, then CP is separated into several problems, say, (CP_1), (CP_2), ..., (CP_q), where $\bigcup_{i=1}^q F(CP_i) = F(CP)$ and, typically,

$$F(CP_i) \cap F(CP_j) = \phi \quad \forall i \neq j$$

For instance, a separation of (CP) into (CP_i) , $i = 1, 2, \dots, q$, is obtained by fixing a single variable, say, x_j , to one of the q possible values of x_j in an optimal solution to (CP) . The choice of the variable to fix depends on the separation strategy, which is also part of the branching strategy. After separation, the subproblems are added to the candidate list. Each subproblem (CP_i) is a restriction of (CP) since $F(CP_i) \subseteq F(CP)$. Consequently, $z(CP) \leq z(CP_i)$ and $z(CP) = \min_i z(CP_i)$.

The various steps in the B-and-B algorithm are outlined as follows.

Procedure 13.5 B-and-B:

0. **Initialize:** Given the problem (P) , the incumbent value z_I is obtained by applying some heuristic (if a feasible solution to (P) is not available, set $z_I = +\infty$). Initialize the candidate list $C \leftarrow \{(P)\}$.
1. **Optimality:** If $C = \emptyset$ and $z_I = +\infty$, then (P) is infeasible, stop. Stop also if $C = \emptyset$ and $z_I < +\infty$, the incumbent is an optimal solution to (P) .
2. **Selection:** Using some candidate selection rule, select and remove a problem $(CP) \in C$.
3. **Bound:** Obtain a lower bound for (CP) by either solving a relaxation (CP_R) of (CP) or by applying some ad-hoc rules. If (CP_R) is infeasible, return to Step 1. Else, let x_R be an optimal solution of (CP_R) .
4. **Fathom:** If $z(CP_R) \geq z_I$, return to step 1. Else if x_R is feasible in (CP) and $z(CP) < z_I$, set $z_I \leftarrow z(CP)$, update the incumbent as x_R and return to step 1. Finally, if x_R is feasible in (CP) but $z(CP) \geq z_I$, return to step 1.
5. **Separation:** Using some separation or branching rule, separate (CP) into (CP_i) , $i = 1, 2, \dots, q$ and set $C \leftarrow C \cup \{(CP_1), (CP_2), \dots, (CP_q)\}$ and return to step 1.
6. **End Procedure.**

Although the B-and-B method is easy to understand, the implementation of this scheme for a particular ILP is a nontrivial task requiring the following:

1. A relaxation strategy with efficient procedures for solving these relaxations
2. Efficient data structures for handling the rather complicated bookkeeping of the candidate list
3. Clever strategies for selecting promising candidate problems
4. Separation or branching strategies that could effectively prune the enumeration tree

A key problem is that of devising a relaxation strategy, that is, to find *good relaxations*, which are significantly easier to solve than the original problems and tend to give sharp lower bounds. Since these two are conflicting, one has to find a reasonable tradeoff.

13.6.2 Branch and Cut

In the past few years, the B-and-C method has become popular for solving NP-complete combinatorial optimization problems. As the name suggests, the B-and-C method incorporates the features of both the B-and-B method just presented and the cutting plane method presented previously. The main difference between the B-and-C method and the general B-and-B scheme is in the bound step (step 3).

A distinguishing feature of the B-and-C method is that the relaxation (CP_R) of the candidate problem (CP) is a linear programming problem, and, instead of merely solving (CP_R) , an attempt is made to solve (CP) by using cutting planes to tighten the relaxation. If (CP_R) contains inequalities that are valid for (CP) but not for the given ILP, then the GC rounding procedure may generate inequalities that are valid for (CP) but not for the ILP. In the B-and-C method, the inequalities that are generated are always valid for the ILP and hence can be used globally in the enumeration tree.

Another feature of the B-and-C method is that often heuristic methods are used to convert some of the fractional solutions, encountered during the cutting plane phase, into feasible solutions of the (CP) or more generally of the given ILP. Such feasible solutions naturally provide upper bounds for the ILP. Some of these upper bounds may be better than the previously identified best upper bound and, if so, the current incumbent is updated accordingly.

We thus obtain the B-and-C method by replacing the bound step (step 3) of the B-and-B method by steps 3(a) and 3(b) and also by replacing the fathom step (step 4) by steps 4(a) and 4(b) given subsequently.

3(a) **Bound:** Let (CP_R) be the LP relaxation of (CP). Attempt to solve (CP) by a cutting plane method which generates valid inequalities for (P). Update the constraint System of (P) and the incumbent as appropriate.

Let $F\mathbf{x} \leq \mathbf{f}$ denote all of the valid inequalities generated during this phase. Update the constraint system of (P) to include all of the generated inequalities, that is, set $A^T \leftarrow (A^T, F^T)$ and $\mathbf{b}^T \leftarrow (\mathbf{b}^T, \mathbf{f}^T)$. The constraints for all of the problems in the candidate list are also to be updated.

During the cutting plane phase, apply heuristic methods to convert some of the identified fractional solutions into feasible solutions to (P). If a feasible solution, $\bar{\mathbf{x}}$, to (P), is obtained such that $c\bar{\mathbf{x}} < z_p$, update the incumbent to $\bar{\mathbf{x}}$ and z_l to $c\bar{\mathbf{x}}$. Hence, the remaining changes to B-and-B are as follows:

3(b) **If** (CP) is solved go to step 4(a). **Else**, let $\hat{\mathbf{x}}$ be the solution obtained when the cutting plane phase is terminated (we are unable to identify a valid inequality of (P) that is violated by $\hat{\mathbf{x}}$). Go to step 4(b).

4(b) **Fathom by Optimality:** Let \mathbf{x}^* be an optimal solution to (CP). If $z(CP) < z_p$, set $\mathbf{x}_l \leftarrow z(CP)$ and update the incumbent as \mathbf{x}^* . Return to step 1.

4(b) **Fathom by Bound:** If $c\hat{\mathbf{x}} \geq z_p$, return to Step 1.
Else go to step 5.

The incorporation of a cutting plane phase into the B-and-B scheme involves several technicalities which require careful design and implementation of the B-and-C algorithm. Details of the state of the art in cutting plane algorithms including the B-and-C algorithm are reviewed in Jünger et al. (1995).

13.7 Approximation in Combinatorial Optimization

The inherent complexity of integer linear programming has led to a long-standing research program in approximation methods for these problems. Linear programming relaxation and Lagrangian relaxation are two general approximation schemes that have been the real workhorses of computational practice. Semidefinite relaxation is a recent entrant that appears to be very promising. In this section, we present a brief review of these developments in the approximation of combinatorial optimization problems.

In the past few years, there has been significant progress in our understanding of performance guarantees for approximation of \mathcal{NP} -hard combinatorial optimization problems. A ρ -approximate algorithm for an optimization problem is an approximation algorithm that delivers a feasible solution with objective value within a factor of ρ of optimal (think of minimization problems and $\rho \geq 1$). For some combinatorial optimization problems, it is possible to *efficiently* find solutions that are arbitrarily close to optimal even though finding the true optimal is hard. If this were true of most of the problems of interest, we would be in good shape. However, the recent results of Arora et al. (1992) indicate exactly the opposite conclusion.

A polynomial-time approximation scheme (PTAS) for an optimization problem is a family of algorithms, A_ρ , such that for each $\rho > 1$, A_ρ is a polynomial-time ρ -approximate algorithm. Despite concentrated effort spanning about two decades, the situation in the early 1990s was that for many combinatorial optimization problems, we had no PTAS and no evidence to suggest the nonexistence of such schemes either. This led Papadimitriou and Yannakakis (1991) to define a new complexity class (using reductions that preserve approximate solutions) called MAXSNP, and they identified several complete languages in this class. The work of Arora et al. (1992) completed this agenda by showing that, assuming $\mathcal{P} \neq \mathcal{NP}$, there is no PTAS for a MAXSNP-complete problem.

An implication of these theoretical developments is that for most combinatorial optimization problems, we have to be quite satisfied with performance guarantee factors ρ that are of some small fixed value. (There are problems, like the general TSP for which there are no ρ -approximate algorithms for any finite value of ρ , assuming of course that $\mathcal{P} \neq \mathcal{NP}$.) Thus, one avenue of research is to go problem by problem and knock ρ down to its smallest possible value. A different approach would be to look for other notions of good approximations based on probabilistic guarantees or empirical validation. Let us see how the polyhedral combinatorics perspective helps in each of these directions.

13.7.1 LP Relaxation and Randomized Rounding

Consider the well-known problem of finding the *smallest weight vertex cover* in a graph. We are given a graph $G(V, E)$ and a nonnegative weight $w(v)$ for each vertex $v \in V$. We want to find the smallest total weight subset of vertices S such that each edge of G has at least one end in S . (This problem is known to be MAXSNP-hard.) An integer programming formulation of this problem is given by

$$\min \left\{ \sum_{v \in V} w(v)x(v) : x(u) + x(v) \geq 1, \quad \forall (u, v) \in E, \quad x(v) \in \{0, 1\} \quad \forall v \in V \right\}$$

To obtain the linear programming relaxation, we substitute the $x(v) \in \{0, 1\}$ constraint with $x(v) \geq 0$ for each $v \in V$. Let x^* denote an optimal solution to this relaxation. Now let us round the fractional parts of x^* in the usual way, that is, values of 0.5 and up are rounded to 1 and smaller values down to 0. Let \hat{x} be the 0–1 solution obtained. First note that $\hat{x}(v) \leq 2x^*(v)$ for each $v \in V$. Also, for each $(u, v) \in E$, since $x^*(u) + x^*(v) \geq 1$, at least one of $\hat{x}(u)$ and $\hat{x}(v)$ must be set to 1. Hence \hat{x} is the incidence vector of a vertex cover of G whose total weight is within twice the total weight of the linear programming relaxation (which is a lower bound on the weight of the optimal vertex cover). Thus, we have a 2-approximate algorithm for this problem, which solves a linear programming relaxation and uses rounding to obtain a feasible solution.

The deterministic rounding of the fractional solution worked quite well for the vertex cover problem. One gets a lot more power from this approach by adding in randomization to the rounding step. Raghavan and Thompson (1987) proposed the following obvious randomized rounding scheme. Given a 0–1 integer program, solve its linear programming relaxation to obtain an optimal x^* . Treat the $x_j^* \in [0, 1]$ as probabilities, that is, let probability $\{x_j = 1\} = x_j^*$, to randomly round the fractional solution to a 0–1 solution. Using Chernoff bounds on the tails of the binomial distribution, Raghavan and Thompson (1987) were able to show, for specific problems, that with high probability, this scheme produces integer solutions which are close to optimal. In certain problems, this rounding method may not always produce a feasible solution. In such cases, the expected values have to be computed as conditioned on feasible solutions produced by rounding. More complex (nonlinear) randomized rounding schemes have been recently studied and have been found to be extremely effective. We will see an example of nonlinear rounding in the context of semidefinite relaxations of the max-cut problem in the following.

13.7.2 Primal–Dual Approximation

The linear programming relaxation of the vertex cover problem, as we saw previously, is given by

$$(P_{VC}) \quad \min \left\{ \sum_{v \in V} w(v)x(v) : x(u) + x(v) \geq 1, \quad \forall (u, v) \in E, \quad x(v) \geq 0 \quad \forall v \in V \right\}$$

and its dual is

$$(D_{VC}) \quad \max \left\{ \sum_{(u,v) \in E} \mathbf{y}(u,v) : \sum_{(u,v) \in E} \mathbf{y}(u,v) \leq \mathbf{w}(v), \quad \forall v \in V, \quad \mathbf{y}(u,v) \geq 0 \quad \forall (u,v) \in E \right\}$$

The primal–dual approximation approach would first obtain an optimal solution \mathbf{y}^* to the dual problem (D_{VC}) . Let $\hat{V} \subseteq V$ denote the set of vertices for which the dual constraints are tight, that is,

$$\hat{V} = \left\{ v \in V : \sum_{(u,v) \in E} \mathbf{y}^*(u,v) = \mathbf{w}(v) \right\}$$

The approximate vertex cover is taken to be \hat{V} . It follows from complementary slackness that \hat{V} is a vertex cover. Using the fact that each edge (u, v) is in the star of at most two vertices (u and v), it also follows that \hat{V} is a 2-approximate solution to the minimum weight vertex cover problem.

In general, the primal–dual approximation strategy is to use a dual solution to the linear programming relaxation, along with complementary slackness conditions as a heuristic to generate an integer (primal) feasible solution, which for many problems turns out to be a good approximation of the optimal solution to the original integer program.

Remark 13.11

A recent survey of primal-dual approximation algorithms and some related interesting results are presented in Williamson (2000).

13.7.3 Semidefinite Relaxation and Rounding

The idea of using SDP to solve combinatorial optimization problems appears to have originated in the work of Lovász (1979) on the Shannon capacity of graphs. Grötschel et al. (1988) later used the same technique to compute a maximum stable set of vertices in perfect graphs via the ellipsoid method. Recently, Lovász and Schrijver (1991) resurrected the technique to present a fascinating theory of semidefinite relaxations for general 0–1 integer linear programs. We will not present the full-blown theory here but instead will present an excellent application of this methodology to the problem of finding the maximum weight cut of a graph. This application of semidefinite relaxation for approximating MAXCUT is due to Goemans and Williamson (1994).

We begin with a quadratic Boolean formulation of MAXCUT

$$\max \left\{ \frac{1}{2} \sum_{(u,v) \in E} \mathbf{w}(u,v)(1 - \mathbf{x}(u)\mathbf{x}(v)) : \mathbf{x}(v) \in \{-1, 1\} \quad \forall v \in V \right\}$$

where $G(V, E)$ is the graph and $\mathbf{w}(u, v)$ is the nonnegative weight on edge (u, v) . Any $\{-1, 1\}$ vector of \mathbf{x} values provides a bipartition of the vertex set of G . The expression $(1 - \mathbf{x}(u)\mathbf{x}(v))$ evaluates to 0 if u and v are on the same side of the bipartition and to 2 otherwise. Thus, the optimization problem does indeed represent exactly the MAXCUT problem.

Next we reformulate the problem in the following way:

- We square the number of variables by substituting each $\mathbf{x}(v)$ with $\boldsymbol{\chi}(v)$ an n -vector of variables (where n is the number of vertices of the graph).

- The quadratic term $\mathbf{x}(u)\mathbf{x}(v)$ is replaced by $\boldsymbol{\chi}(u) \cdot \boldsymbol{\chi}(v)$, which is the inner product of the vectors.
- Instead of the $\{-1, 1\}$ restriction on the $\mathbf{x}(v)$, we use the Euclidean normalization $\|\boldsymbol{\chi}(v)\| = 1$ on the $\boldsymbol{\chi}(v)$.

Thus, we now have a problem

$$\max \left\{ \frac{1}{2} \sum_{(u,v) \in E} \mathbf{w}(u,v)(1 - \boldsymbol{\chi}(u) \cdot \boldsymbol{\chi}(v)) : \|\boldsymbol{\chi}(v)\| = 1 \forall v \in V \right\}$$

which is a relaxation of the MAXCUT problem (note that if we force only the first component of the $\boldsymbol{\chi}(v)$ to have nonzero value, we would just have the old formulation as a special case).

The final step is in noting that this reformulation is nothing but a semidefinite program. To see this we introduce $n \times n$ Gram matrix Y of the unit vectors $\boldsymbol{\chi}(v)$. So $Y = X^T X$ where $X = (\boldsymbol{\chi}(v) : v \in V)$. Thus, the relaxation of MAXCUT can now be stated as a semidefinite program,

$$\max \left\{ \frac{1}{2} \sum_{(u,v) \in E} \mathbf{w}(u,v)(1 - Y_{(u,v)}) : Y \succeq 0, Y_{(u,v)} = 1 \forall v \in V \right\}$$

Recall from Section 13.2 that we are able to solve such semidefinite programs to an additive error ε in time polynomial in the input length and $\log 1/\varepsilon$ by using either the ellipsoid method or interior point methods.

Let $\boldsymbol{\chi}^*$ denote the near optimal solution to the SDP relaxation of MAXCUT (convince yourself that $\boldsymbol{\chi}^*$ can be reconstructed from an optimal Y^* solution). Now we encounter the final trick of Goemans and Williamson. The approximate maximum weight cut is extracted from $\boldsymbol{\chi}^*$ by randomized rounding. We simply pick a random hyperplane H passing through the origin. All of the $v \in V$ lying to one side of H get assigned to one side of the cut and the rest to the other. Goemans and Williamson observed the following inequality.

Lemma 13.3

For $\boldsymbol{\chi}_1$ and $\boldsymbol{\chi}_2$, two random n -vectors of unit norm, let $\mathbf{x}(1)$ and $\mathbf{x}(2)$ be ± 1 values with opposing signs if H separates the two vectors and with same signs otherwise. Then $\tilde{E}(1 - \boldsymbol{\chi}_1 \cdot \boldsymbol{\chi}_2) \leq 1.1393 \cdot \tilde{E}(1 - \mathbf{x}(1)\mathbf{x}(2))$ where \tilde{E} denotes the expected value.

By linearity of expectation, the lemma implies that the expected value of the cut produced by the rounding is at least 0.878 times the expected value of the semidefinite program. Using standard conditional probability techniques for derandomizing, Goemans and Williamson show that a deterministic polynomial-time approximation algorithm with the same margin of approximation can be realized. Hence, we have a cut with value at least 0.878 of the maximum cut value.

Remark 13.12

For semidefinite relaxations of mixed integer programs in which the integer variables are restricted to be 0 or 1, Iyengar and Cezik (2002) develop methods for generating Gomory–Chavatal and disjunctive cutting planes that extends the work of Balas et al. (1993). Ye (2000) shows that strengthened semidefinite

relaxations and mixed rounding methods achieve superior performance guarantee for some discrete optimization problems. A recent survey of SDP and applications is in Wolkowicz et al. (2000).

13.7.4 Neighborhood Search

A combinatorial optimization problem may be written succinctly as

$$\min\{f(x) : x \in X\}$$

The traditional neighborhood method starts at a feasible point x_0 (in X), and iteratively proceeds to a neighborhood point that is better in terms of the objective function $f(\cdot)$ until a specified termination condition is attained. While the concept of neighborhood $N(x)$ of a point x is well defined in calculus, the specification of $N(x)$ is itself a matter of consideration in combinatorial optimization. For instance, for the travelling salesman problem, the so-called *k-opt heuristic* (see Lin and Kernighan, 1973) is a neighborhood search method which for a given tour considers “neighborhood tours” in which k variables (edges) in the given tour are replaced by k other variables such that a tour is maintained. This search technique has proved to be effective though it is quite complicated to implement when k is larger than 3.

A neighborhood search method leads to a local optimum in terms of the neighborhood chosen. Of course, the chosen neighborhood may be large enough to ensure a global optimum, but such a procedure is typically not practical in terms of searching the neighborhood for a better solution. Recently Orlin (2000) has presented very large scale neighborhood search algorithms in which the neighborhood is searched using network flow or dynamic programming methods. Another method advocated by Orlin (2000) is to define the neighborhood in such a manner that the search process becomes a polynomially solvable special case of a hard combinatorial problem.

To avoid getting trapped at a local optimum solution, different strategies such as Tabu Search (see for instance Glover and Laguna, 1997), simulated annealing (see, for instance, Aarts and Korst, 1989), genetic algorithms (see, for instance, Whitley, 1993), and neural networks have been developed. Essentially, these methods allow for the possibility of sometimes moving to an inferior solution in terms of the objective function or even to an infeasible solution. While there is no guarantee of obtaining a global optimal solution, computational experience in solving several difficult combinatorial optimization problems has been very encouraging. However, a drawback of these methods is that performance guarantees are not typically available.

13.7.5 Lagrangian Relaxation

We end our discussion of approximation methods for combinatorial optimization with the description of Lagrangian relaxation. This approach has been widely used for about two decades now in many practical applications. Lagrangian relaxation, like linear programming relaxation, provides bounds on the combinatorial optimization problem being relaxed (i.e., lower bounds for minimization problems).

Lagrangian relaxation has been so successful because of a couple of distinctive features. As was noted earlier, in many hard combinatorial optimization problems, we usually have embedded some nice tractable subproblems which have efficient algorithms. Lagrangian relaxation gives us a framework to *jerry-rig* an approximation scheme that uses these efficient algorithms for the subproblems as subroutines. A second observation is that it has been empirically observed that well-chosen Lagrangian relaxation strategies usually provide very tight bounds on the optimal objective value of integer programs. This is often used to great advantage within partial enumeration schemes to get very effective pruning tests for the search trees.

Practitioners also have found considerable success with designing heuristics for combinatorial optimization by starting with solutions from Lagrangian relaxations and constructing good feasible solutions via so-called *dual ascent* strategies. This may be thought of as the analogue of rounding strategies for linear programming relaxations (but with no performance guarantees, other than empirical ones).

Consider a representation of our combinatorial optimization problem in the form

$$(P) \quad z = \min\{\mathbf{c}\mathbf{x} : \mathbf{A}\mathbf{x} \geq \mathbf{b}, \mathbf{x} \in X \subseteq \mathfrak{R}^n\}$$

Implicit in this representation is the assumption that the explicit constraints ($\mathbf{A}\mathbf{x} \geq \mathbf{b}$) are *small* in number. For convenience, let us also assume that X can be replaced by a finite list $\{\mathbf{x}^1, \mathbf{x}^2, \dots, \mathbf{x}^T\}$.

The following definitions are with respect to (P):

- Lagrangian. $L(\mathbf{u}, \mathbf{x}) = \mathbf{u}(\mathbf{A}\mathbf{x} - \mathbf{b}) + \mathbf{c}\mathbf{x}$ where \mathbf{u} are the Lagrange multipliers.
- Lagrangian-dual function. $\mathcal{L}(\mathbf{u}) = \min_{\mathbf{x} \in X} \{L(\mathbf{u}, \mathbf{x})\}$.
- Lagrangian-dual problem. (D) $d = \max_{\mathbf{u} \geq 0} \{\mathcal{L}(\mathbf{u})\}$.

It is easily shown that (D) satisfies a weak duality relationship with respect to (P), that is, $z \geq d$. The discreteness of X also implies that $\mathcal{L}(\mathbf{u})$ is a piecewise linear and concave function (see Shapiro, 1979). In practice, the constraints X are chosen such that the evaluation of the Lagrangian dual function $\mathcal{L}(\mathbf{u})$ is easily made (i.e., the *Lagrangian subproblem* $\min_{\mathbf{x} \in X} \{L(\mathbf{u}, \mathbf{x})\}$ is easily solved for a fixed value of \mathbf{u}).

Example 13.3 Traveling salesman problem (TSP).

For an undirected graph G , with costs on each edge, the TSP is to find a minimum cost set H of edges of G such that it forms a Hamiltonian cycle of the graph. H is a Hamiltonian cycle of G if it is a simple cycle that spans all the vertices of G . Alternatively, H must satisfy: (1) exactly two edges of H are adjacent to each node, and (2) H forms a connected, spanning subgraph of G .

Held and Karp (1970) used these observations to formulate a Lagrangian relaxation approach for TSP that relaxes the degree constraints (1). Notice that the resulting subproblems are minimum spanning tree problems which can be easily solved.

The most commonly used general method of finding the optimal multipliers in Lagrangian relaxation is subgradient optimization (cf. Held et al., 1974). Subgradient optimization is the non-differentiable counterpart of steepest descent methods. Given a dual vector \mathbf{u}^k , the iterative rule for creating a sequence of solutions is given by:

$$\mathbf{u}^{k+1} = \mathbf{u}^k + t_k \boldsymbol{\gamma}(\mathbf{u}^k)$$

where t_k is an appropriately chosen step size, and $\boldsymbol{\gamma}(\mathbf{u}^k)$ is a subgradient of the dual function \mathcal{L} at \mathbf{u}^k . Such a subgradient is easily generated by

$$\boldsymbol{\gamma}(\mathbf{u}^k) = \mathbf{A}\mathbf{x}^k - \mathbf{b}$$

where \mathbf{x}^k is a maximizer of $\min_{\mathbf{x} \in X} \{L(\mathbf{u}^k, \mathbf{x})\}$.

Subgradient optimization has proven effective in practice for a variety of problems. It is possible to choose the step sizes $\{t_k\}$ to guarantee convergence to the optimal solution. Unfortunately, the method is not finite, in that the optimal solution is attained only in the limit. Further, it is not a pure descent method. In practice, the method is heuristically terminated and the best solution in the generated sequence is recorded. In the context of nondifferentiable optimization, the ellipsoid algorithm was devised by Shor (1970) to overcome precisely some of these difficulties with the subgradient method.

The ellipsoid algorithm may be viewed as a scaled subgradient method in much the same way as variable metric methods may be viewed as scaled steepest descent methods (cf. Akgul, 1984). And if we use the ellipsoid method to solve the Lagrangian dual problem, we obtain the following as a consequence of the polynomial-time equivalence of optimization and separation.

Theorem 13.8

The Lagrangian dual problem is polynomial-time solvable if and only if the Lagrangian subproblem is. Consequently, the Lagrangian dual problem is \mathcal{NP} -hard if and only if the Lagrangian subproblem is.

The theorem suggests that, in practice, if we set up the Lagrangian relaxation so that the subproblem is tractable, then the search for optimal Lagrangian multipliers is also tractable.

13.8 Prospects in Integer Programming

The TSP has been the subject of considerable research in terms of developing specialized software incorporating several theoretical results. The largest problem, in terms of the number of cities, that has been solved is a 85,900 cities problem that arises in the process of making a computer chip, see Cook (2012).

The current emphasis in software design for integer programming is in the development of shells (for example, CPLEX 6.5 [1999], MINTO [Savelsbergh et al., 1994], and OSL [1991]) wherein a general purpose solver like B-and-C is the driving engine. Problem-specific codes for generation of cuts and facets can be easily interfaced with the engine. Recent computational results (Bixby et al., 2001) suggests that it is now possible to solve relatively large size integer programming problems using general purpose codes. Bixby and his team have gone on to create a new optimization engine called GUROBI (GUROBI, 2013) which appears to be the new benchmark. We believe that this trend will eventually lead to the creation of general purpose problem-solving languages for combinatorial optimization akin to AMPL (Fourer et al., 1993) for linear and nonlinear programming.

A promising line of research is the development of an empirical science of algorithms for combinatorial optimization (Hooker, 1993). Computational testing has always been an important aspect of research on the efficiency of algorithms for integer programming. However, the standards of test designs and empirical analysis have not been uniformly applied. We believe that there will be important strides in this aspect of integer programming and more generally of algorithms. Hooker argues that it may be useful to stop looking at algorithmics as purely a deductive science and start looking for advances through repeated application of “hypothesize and test” paradigms, that is, through empirical science. Hooker and Vinay (1995) develop a science of selection rules for the Davis–Putnam–Loveland scheme of theorem proving in propositional logic by applying the empirical approach.

The integration of logic-based methodologies and mathematical programming approaches is evidenced in the recent emergence of CLP systems (Borning, 1994; Saraswat and Van Hentenryck, 1995) and logico-mathematical programming (Jeroslow, 1989; Chandru and Hooker, 1991). In CLP, we see a structure of Prolog-like programming language in which some of the predicates are constraint predicates whose truth values are determined by the solvability of constraints in a wide range of algebraic and combinatorial settings. The solution scheme is simply a clever orchestration of constraint solvers in these various domains and the role of conductor is played by resolution. The clean semantics of logic programming is preserved in CLP. A bonus is that the output language is symbolic and expressive. An orthogonal approach to CLP is to use constraint methods to solve inference problems in logic. Imbeddings of logics in mixed integer programming sets were proposed by Williams (1987) and Jeroslow (1989). Efficient algorithms have been developed for inference algorithms in many types and fragments of logic, ranging from Boolean to predicate to belief logics (Chandru and Hooker, 1999).

A persistent theme in the integer programming approach to combinatorial optimization, as we have seen, is that the representation (formulation) of the problem deeply affects the efficacy of the solution methodology. A proper choice of formulation can therefore make the difference between a successful solution of an optimization problem and the more common perception that the problem is insoluble and one must be satisfied with the best that heuristics can provide. Formulation of integer programs has been treated more as an art form than a science by the mathematical programming community. (See Jeroslow (1989) for a refreshingly different perspective on representation theories for mixed integer programming.) We believe that progress in representation theory can have an important influence on the future of integer programming as a broad-based problem solving methodology in combinatorial optimization.

Key Terms

Column generation: A scheme for solving linear programs with a huge number of columns.

Cutting plane: A valid inequality for an integer polyhedron that separates the polyhedron from a given point outside it.

Extreme point: A corner point of a polyhedron.

Fathoming: Pruning a search tree.

Integer polyhedron: A polyhedron, all of whose extreme points are integer valued.

Linear program: Optimization of a linear function subject to linear equality and inequality constraints.

Mixed integer linear program: A linear program with the added constraint that some of the decision variables are integer valued.

Packing and covering: Given a finite collection of subsets of a finite ground set, to find an optimal sub-collection that is pairwise disjoint (packing) or whose union covers the ground set (covering).

Polyhedron: The set of solutions to a finite system of linear inequalities on real-valued variables. Equivalently, the intersection of a finite number of linear half-spaces in \Re^n .

Relaxation: An enlargement of the feasible region of an optimization problem. Typically, the relaxation is considerably easier to solve than the original optimization problem.

ρ -Approximation: An approximation method that delivers a feasible solution with an objective value within a factor ρ of the optimal value of a combinatorial optimization problem.

14.1 Introduction

Graph drawing addresses the problem of visualizing information by constructing geometric representations of conceptual structures that are modeled by graphs, networks, or hypergraphs. Graphs may be used to represent any information that can be modeled as objects and connections between those objects. The area of graph drawing has grown significantly in the recent years motivated mostly by applications in information visualization and in key computer technologies, including software engineering (call graphs, class hierarchies), visual interfaces, database systems (entity-relationship diagrams), digital libraries and World Wide Web authoring and browsing (hypermedia documents), VLSI (symbolic layout), electronic systems (block diagrams, circuit schematics), project management (PERT diagrams, organization charts), telecommunications (ring covers of networks), business, and social sciences (social network analysis).

14.2 Underlying Principles

A graph is drawn in two or three dimensions. Usually, the nodes are represented by circles or boxes, and the edges are represented by simple open curves between the nodes. A graph $G = (V, E)$ consists of a set V of nodes and a set E of edges, that is, unordered pairs of nodes. Given a graph G , the number of nodes is denoted by n and the number of edges is denoted by m .

The objective of a graph drawing algorithm is to take a graph and produce a nice drawing of it. In order to define the requirements for a nice drawing, Di Battista et al. [28] distinguish three different concepts: (i) drawing conventions, (ii) aesthetics, and (iii) constraints. In the following, we give a brief overview of them.

14.2.1 Drawing Conventions

Various drawing standards have been proposed for drawing graphs, depending on the application. Drawing conventions provide the basic rules that the drawing must satisfy to be admissible. These rules deal with representation and placement of nodes and edges. Examples of drawing conventions are the following:

Straight-line drawing: Each edge is represented as a straight-line segment.

Polyline drawing: Each edge is represented as a polygonal chain.

Orthogonal drawing: Each edge is drawn as a sequence of alternating horizontal and vertical line segments.

Grid drawing: Nodes, edges, and edge bends have integer coordinates.

Planar drawing: No two edges cross each other.

Upward drawing: Edges are drawn as curves that are monotonically nondecreasing in the vertical direction. A drawing is strictly upward if each edge is drawn as a curve strictly increasing in the vertical direction.

14.2.2 Aesthetics

One of the fundamental characteristics of a graph drawing is its readability, that is, the capability of conveying clearly the information associated with the graph. Readability issues are expressed by means of aesthetics, which can be formulated as optimization goals for the graph drawing algorithms. Some aesthetic criteria are general, others depend on the drawing convention adopted and on the particular class of graphs considered.

Further information on aesthetics can be found in [21,98,99,119,122]. It should be noted that aesthetics are subjective and may need to be tailored to suit personal preferences, applications, traditions, and culture. Next, we present some of the most important aesthetics:

Area: The area of a drawing is the area of the smallest rectangle that encloses the drawing and should be minimized.

Aspect ratio: The ratio of the longest to the shortest side of the smallest rectangle enclosing the drawing should be balanced.

Bends: The number of edge bends especially for orthogonal drawings should be minimized.

Edge crossings: The number of crossings in a drawing should be minimized.

Edge length: The total length of all edges, the maximum length of a single edge, or the variance of the lengths of the edges should be minimized.

Convexity: Faces of planar drawings should be drawn as convex polygons.

Symmetry: The symmetries of a graph must be displayed in the drawing.

Angular resolution: The angle between any two consecutive edges of a node should be maximized.

It is not generally possible to fulfill all aesthetics simultaneously. For example, in Figure 14.1, two embeddings of K_4 are displayed, the one on the left minimizes the number of edge crossings, whereas

FIGURE 14.1 Drawings of a K_4 graph.

the one on the right maximizes the display of symmetries. Additionally, it is hard to achieve optimum results since most of the problems described earlier are computationally hard. For example, the following problems related to aesthetics are NP-complete or NP-hard: drawing a graph with the minimum number of crossings [55], embedding a graph in a grid of prescribed size [47,75], determining the minimum number of bends for orthogonal drawings [56], and drawing a graph symmetrically [81,82].

14.2.3 Constraints

While drawing conventions and aesthetics apply to an entire drawing, drawing constraints only apply to specific parts. They usually emphasize semantic aspects of a graph (e.g., by placing related nodes close to each other) and are given as additional input to the layout algorithm. Some examples of drawing constraints are the following:

Center: Place a given node near the center of the drawing.

External: Place a given node at the boundary of the drawing.

Cluster: Place a given subset of nodes close to each other.

Shape: Draw a subgraph with a given shape.

Sequence: Place a given subset of nodes along a straight line.

Order: Place a given node to the left, right, top, or bottom of another given node.

Position: Place a given node at a given position.

Direction: Draw a given subset of edges monotonically in a prescribed direction.

14.3 Graph Drawing Algorithms

Graph drawing algorithms may be classified according to the style of drawing they generate (e.g., hierarchical, orthogonal, force-directed, and circular), the methodology on which they are based (e.g., planarization, and divide, and conquer), and the class of graphs they can be applied to (e.g., planar, directed acyclic, and trees).

Many algorithmic techniques have been devised in order to draw graphs. Due to space restrictions, the main concepts of the most important techniques are presented here. A detailed description of graph drawing algorithms can be found in the literature, see for example [28,71].

14.3.1 Graph Drawing Layout Styles

There are algorithms that produce drawings that attempt to highlight hierarchy, symmetry, grouping structure, or orthogonality. Next, we present the most interesting techniques with respect to the flavor of the resulting layout of a graph drawing.

14.3.1.1 Hierarchical Layout

The hierarchical layout is ideal for displaying hierarchies. Directed graphs that contain an inherent hierarchy are drawn using hierarchical layout algorithms. This layout style is used in a variety of applications, for example, in PERT diagrams, organization charts, scheduling and logistic diagrams, and class hierarchies in software engineering. Figure 14.2 shows an example of a hierarchical drawing.

The basic method for hierarchical graph drawings is presented in [113], upon which all other methods are based. It accepts, as input, a directed graph and produces, as output, a layered drawing, that is, a representation where the nodes are placed on horizontal layers, and the edges are drawn as polygonal chains connecting their end nodes. In hierarchical drawings preferably most edges flow

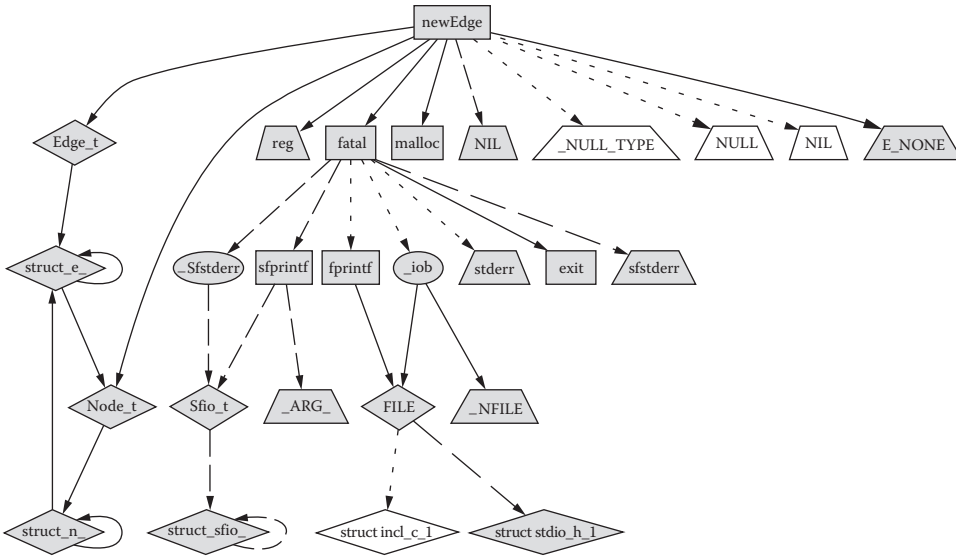

FIGURE 14.2 A hierarchical drawing that displays the reachability analysis of the C function `newEdge`. (Courtesy of R. Chen, E. Koutsofios, and S. North, AT&T Research Labs.)

in the same direction, for example, from top to bottom. The methodology based on this hierarchical layout algorithm consists of the following steps:

Cycle removal: If the input graph contains directed cycles, then the cycles are removed by temporarily reversing the direction of some edges.

Layer assignment: The nodes are assigned to layers such that edges point from lower to higher layers. Dummy nodes are inserted along the edges that cross layers, so that each edge in the resulting digraph connects nodes in consecutive layers.

Crossing reduction: The nodes are ordered on each layer to reduce the number of edge crossings.

Horizontal coordinate assignment: The nodes (original and dummy) are assigned coordinates such that we get only few bend points and short edges.

Reversing the minimum number of edges in order to *remove cycles* is an NP-hard problem. We can perform a Depth-First-Search (DFS) of the graph and reverse all back edges to remove cycles. This simple approach removes all cycles; however, in the worst case this may reverse as many as $m - n - 1$ edges. In [40], a greedy approach guarantees the reversal of at most $m/2 - n/6$ edges.

In most applications, the nodes need to be *assigned to layers*. The longest path layering algorithm is the most commonly used [38]. All sources are assigned to the lowest level L_0 ; each remaining node v is assigned to level L_p where p is the length of the longest path from any source to v . This algorithm runs in linear time and produces the minimum number of layers. However, it tends to produce drawings that are wide towards the bottom. It is NP-hard [38] to minimize both the number of layers and the number of nodes on each layer. For more work on layer assignment see [18,54,104].

The number of *edge crossings* depends on the ordering of the nodes within each layer. This problem is NP-hard even if we restrict it to bipartite (two-layered) graphs [55]. It remains NP-hard even if there are only two layers and the permutation of the nodes on one of them is fixed [39]. Several heuristics for the crossing minimization problem have been proposed (e.g., [62,88,110]).

The *horizontal coordinate assignment* reduces the number of bends by positioning the nodes on each layer without changing their order established in the crossing reduction step. This is an optimization problem and the goal is to minimize the total amount by which an edge deviates from being a straight line [9,15,54].

14.3.1.2 Force-Directed Layout

Force-directed layout produces graph drawings that are aesthetically pleasing, exhibit (i) symmetries and (ii) clustered structure of the underlying graphs. It is a popular choice for drawing general graphs, because it produces good drawings (well-balanced distribution of nodes and few edge crossings) and is relatively easy to understand and implement. However, force-directed drawings are suboptimal and often unpredictable; in addition, there is no performance guarantee and the running time of this technique is typically high. It has applications in many areas of visualization of complex structures, such as bioinformatics, enterprise networking, knowledge representation, system management, WWW visualization, and Mesh visualization. Figure 14.3 shows an example of a force-directed drawing.

In general, a force-directed layout algorithm simulates a system of forces defined on an input graph, and outputs a locally minimum energy configuration. This approach consists of two basic steps:

- A model consisting of physical objects (representing the elements of the graph) and interactions between these objects
- An algorithm for finding a locally minimum energy configuration

In a seminal paper, Eades [35] presented the first force-directed graph drawing algorithm. A graph is modeled as a physical system where the nodes are rings and the edges are springs that connect pairs of rings. The rings are placed in some initial layout and the spring forces move the system to a local minimum of energy. Attractive forces are calculated using a logarithmic function in place of Hooke's law for spring forces and are applied only between pairs of adjacent nodes. Repulsive forces act between every pair of nodes in order to avoid node overlaps. A node will move to its new location based on the sum of those attractive and repulsive forces applied to the node. Most force-directed algorithms adopt the physical model of [35] and propose variants of the definition of the forces [23,50,52,69,112]. For example, in [112], the concept of magnetic springs is introduced to control the orientation of the edges in the drawing. Edges are modeled with three types of springs: non-magnetic springs, unidirectional magnetic springs, and bidirectional magnetic springs. Various magnetic fields are considered: three standard magnetic fields, namely, parallel, polar, and concentric, and two compound magnetic fields, namely, orthogonal and polar-concentric. This model is suited for drawing directed graphs, trees, and graphs with more than one type of edges. In [52], attractive forces take into account the optimal distance between nodes in the drawing which is defined as a function of the number of nodes in the graph and the size of the drawing window. In [69], the forces are chosen so that the Euclidean distance between any two nodes in the drawing is proportional to the graph-theoretic distance between the corresponding nodes in the graph. In [23], the drawing of a graph is formulated as an optimization problem and the solution is found

FIGURE 14.3 A random drawing of a graph and a drawing of the same graph produced by a force-directed algorithm.

using simulated annealing. The goal is to minimize a cost function that is a linear combination of energy functions, each defined to optimize a certain aesthetic criterion, such as uniform distribution of nodes, uniform distribution of edge lengths, number of edge-crossings, and distance between nodes and edges.

14.3.1.3 Circular Layout

Circular layout produces graph drawings that emphasize group structures that are either inherent in a graph's topology or user-defined. Circular layout has many applications, for example, in social networking (organization charts, citation networks, and collaboration networks), security (case information diagrams, fraud networks, and felony event flow diagrams), network management (telecommunication and computer networks, LAN diagrams, and traffic visualization), WWW visualization (visitor movement graphs and internet traffic), and eCommerce. A circular graph drawing (see Figures 14.4 and 14.5 for examples) is a visualization of a graph with the following characteristics:

- The graph is partitioned into groups.
- The nodes of each group are placed onto the circumference of an embedding circle.
- Each edge is drawn as a straight line.

FIGURE 14.4 A random drawing of a graph and a drawing of the same graph produced by a circular layout algorithm [107].

FIGURE 14.5 A user-grouped circular drawing [106].

Node partitions are created by either analyzing the connectivity structure of the underlying graph, or are user-defined. The partitioning of the graph into clusters can show structural information such as biconnectivity, or the clusters can highlight semantic qualities of the graph. An example of an application in which user-grouped circular drawing would be useful is a computer network management system. It would be very helpful to allow the user to group the computers by IP addresses, IP subnet masks, or other criteria.

It is essential that the number of edge crossings within each cluster remain low in order to reduce the visual complexity of the resulting drawings. However, the problem of finding a minimum crossing embedding such that all the nodes are placed onto the circumference of a circle and all edges are represented with straight lines is NP-complete [84].

A technique for producing circular drawings of biconnected graphs on a single embedding circle is presented in [105]. In order to produce circular drawings with few crossings, the algorithm tends to place edges toward the outside of the embedding circle. Also, nodes are placed near their neighbors. In fact, this algorithm tries to maximize the number of edges appearing toward the periphery of the embedding circle. It selectively removes some edges and then builds a DFS based node ordering of the resulting graph. This technique visits the nodes in a wave-like fashion, looking for pairs of edges (edges incident to two nodes which share at least one neighbor) which are then removed. Sometimes, triangulation edges are added to aid this process. It is the selective edge removal that causes many edges to be placed toward the periphery of the embedding circle. Subsequent to the edge removal, a DFS is performed on the reduced graph. The longest path of the resulting DFS tree is placed on the embedding circle and the remaining nodes are nicely merged into this ordering. The worst-case time requirement of this technique is $O(m)$ (recall that m is the number of edges). An important property of this technique is the guarantee that if a zero-crossing drawing exists for a given biconnected graph then this technique will produce it. An alternative approach where selected edges are drawn outside the embedding circle is described in [53].

The earlier presented algorithm can be extended in order to produce circular drawings of nonbiconnected graphs on a single embedding circle. Given a nonbiconnected graph, it can be decomposed into its biconnected components. The algorithm layouts the resulting block-cutpoint tree on a circle and then it layouts each biconnected component.

A framework for producing circular drawings of nonbiconnected graphs on multiple circles is presented in [107]. It decomposes a nonbiconnected graph into biconnected components in $O(m)$ time. Next, it produces a layout of the block-cutpoint tree using a radial layout technique [28,36] (see also Section 14.3.1.5). Finally, each biconnected component of the graph is drawn on a single embedding circle with the circular layout style.

A circular graph drawing technique is presented in [106] where the node grouping is user-defined. It draws each group of nodes efficiently and effectively, and visualizes the superstructure well. This technique produces drawings in which the user-defined groupings are highly visible, each group is laid out with a low number of edge crossings, and the number of crossings between intragroup and intergroup edges is low. First, it produces a layout of the superstructure graph of the input graph by using a basic force-directed technique (see Section 14.3.1.2 for details). Each group of nodes of the input graph is a node in the superstructure and for each edge of the input graph, which is incident to nodes in two different node groups, there is an edge between nodes representing the respective groups in the superstructure graph. Next, each group of nodes is drawn on a single embedding circle with the circular layout style. Finally, in order to reduce the number of intragroup and intergroup edge crossings, a specialized force-directed algorithm is applied, in which the nodes are restricted to appear on circular tracks.

Several linear time algorithms for the visualization of survivable telecommunication networks were introduced in [120]. Given the ring covers of a network, these algorithms create circular drawings such that the survivability of the network is very visible.

An interesting application of circular graph drawings was presented in [76]. The tool InFlow is used to visualize human networks and produces diagrams and statistical summaries to pinpoint the strengths

and weaknesses within an organization. The usually unvisualized characteristics of self-organization, emergent structures, knowledge exchange, and network dynamics can be seen in the drawings of InFlow. Resource bottlenecks, unexpected work flows, and gaps within the organization are clearly visible in circular drawings.

A circular drawing technique and tool for network management was presented in [70]. In [32], an advanced version of this technique was introduced. It partitions nodes into groups based on a pre-defined method, such as biconnectivity of the graph or it is user-defined. Each group of nodes is placed on radiating circles based on their logical interconnection.

Much work (e.g., [4,53,72,114]) has been done on circular layouts where all nodes are placed on a single embedding circle.

14.3.1.4 Orthogonal Layout

An orthogonal drawing is a polyline drawing that maps each edge into a chain of horizontal and vertical segments. Orthogonal drawings are widely used for visualizing diagrams, such as Entity-Relationship and Data-Flow diagrams in database conceptual design, circuit schematics in VLSI design, and UML diagrams in software engineering. Figure 14.6 shows an example of an orthogonal drawing.

A popular and effective technique for computing an orthogonal drawing of a graph is the so-called topology-shape-metrics approach [28]. This technique is well suited for medium-sized sparse graphs. It produces compact drawings with no overlaps, few crossings, and few bends. The topology-shape-metrics approach consists of three phases:

Planarization: Determines the topology of the drawing which is described by a planar embedding. If the input graph is not planar, a set of dummy nodes is added to replace edge crossings. This transforms the input not planar graph to an augmented planar graph.

Orthogonalization: An orthogonal representation H of the graph is computed within the planar embedding found in the planarization step.

Compaction: The final drawing that preserves the orthogonal representation of the second phase is computed by assigning integer coordinates to nodes and bends. Finally, the inserted dummy nodes are removed.

The distinct phases of the topology-shape-metrics approach have been extensively studied in the literature. The first phase is explained in detail in the planarization graph drawing technique, which is presented in the following section.

In the second phase, an orthogonal representation is computed from the planar representation of the previous phase. The goal is to keep the number of bends as small as possible. In [115], a very elegant

FIGURE 14.6 An orthogonal drawing.

network-flow method for constructing an orthogonal representation of an embedded planar graph with nodes having at most four incident edges is presented. It guarantees the minimum number of bends and runs in $O(n^2 \log n)$ time. In [118], a heuristic guarantees a constant number of bends on each edge and runs in linear time.

During the compaction phase, most approaches try to minimize the area and the total edge length of the drawing. However, compacting an orthogonal representation in such a way that it has either minimum area or minimum total edge length is an NP-hard problem [97]. The compaction problem has been studied extensively especially in the context of circuit design [78]. Compaction heuristics in the context of graph drawing can be found in [13,73,115].

A pairing technique for producing orthogonal drawings with maximum degree 4 is presented in [93]. It is the first orthogonal drawing algorithm that produces drawings with less than n^2 area. The drawing is constructed incrementally. The nodes of the graph are grouped into pairs. Then, node pairs are inserted into the drawing according to an st-numbering of the graph. Nodes of the same pair are placed on the same row or column. This technique runs in linear time, requires provably $0.76n^2$ area, and produces drawings with a linear number of bends and at most two bends per edge. A similar approach has been taken in [6].

In [108], a postprocessing technique is introduced that refines and significantly improves aesthetic qualities of a given orthogonal graph drawing such as area, bends, crossings, and total edge length.

For more work on orthogonal drawings see [8,27,29,48,92,118].

14.3.1.5 Tree Layout

Trees are a special case of planar graphs that are commonly used in many applications. Tree layouts have applications in algorithm animation, circuit design, visualization of class hierarchies, flowcharts, project management diagrams, and syntax trees.

The most popular method for drawing a rooted tree is presented in [100]. It draws binary trees in the hierarchical layout style, nodes are placed on horizontal layers, and it is based on the divide and conquer principle. The idea is to recursively draw the left and right subtrees independently in a bottom-up manner, then shift the two drawings in the x -direction as close to each other as possible, and center the parent of the two subtrees between their roots. This method runs in linear time, requires $O(n^2)$ area, and produces drawings with a high degree of symmetry (identical subtrees are drawn identically). In addition, the width of the drawing is relatively small. This algorithm can be easily extended to general rooted trees. Figure 14.7a shows an example of a tree drawing produced by this technique.

Hierarchical layout algorithms can be used to draw trees, since trees are acyclic graphs with edges pointing away from the root. However, the resulting drawings are wide and the parent nodes are not necessarily centered with respect to their subtrees [28].

Another way of drawing trees is the so-called radial layout [28,36]. In the radial layout, the root of the tree is placed at the center and all descendant nodes are placed on concentric circles according to their depth in the tree. To avoid crossings between subtrees, a sector called annulus wedge is assigned to every subtree. In principle, these sectors are proportional in size to the number of nodes in the subtree.

FIGURE 14.7 Three representations of a tree: (a) layered (hierarchical) drawing, (b) radial drawing, and (c) HV drawing.

Algorithms for constructing hierarchical drawings can be adapted to draw trees radially. Figure 14.7b shows an example of the radial layout.

Figure 14.7c represents the drawing of a tree in the HV-drawing style. The HV method (HV stands for horizontal-vertical) can be used on both binary and general trees. A divide and conquer strategy is used to recursively construct an HV drawing of a tree. The root of the tree is placed on the top-left corner, and the drawings of its left and right subtrees are placed one next to the other (horizontal drawing) or one below the other (vertical drawing). Each subtree is assigned its own area so that no overlapping occurs.

14.3.2 Graph Drawing Techniques

The following techniques are frequently used to implement graph drawing algorithms [28]:

Planarization: The planarization approach is motivated by the availability of many efficient graph drawing algorithms for planar graphs. If the graph is nonplanar, it is transformed into a planar graph by introducing dummy nodes at edge crossings. Then, graph drawing algorithms for planar graphs can be used to draw the transformed nonplanar graph.

In [61], a linear time algorithm tests if a graph is planar. A planar embedding of a planar graph can be found in linear time [16,85]. Finding the minimum number of crossings [55] or a maximum planar subgraph [80] are NP-hard problems. Hence, heuristics are used to solve the planarization problem. A natural approach to this problem is to first determine a large planar subgraph and then insert the remaining edges, while trying to keep a minimal number of crossings. An annotated bibliography on planarization techniques is presented in [79].

The orthogonal drawing algorithm (topology-shape-metrics approach), presented in the previous section, is based on the planarization technique.

Divide and conquer: Graphs are broken down into smaller components for which smaller layouts are computed recursively. The smaller layouts are assembled to form the overall layout [28]. This technique is often used when drawing trees.

Flow methods: Bend minimization in orthogonal drawings can efficiently be solved by reduction to a network flow problem, at least if the topology of the embedding is fixed [115]. The same techniques can be used to maximize angles between edges [28].

Visibility approach: The visibility approach is a general purpose technique for producing polyline drawings of graphs and it is based on the visibility representation of planar graphs. Linear time algorithms for producing visibility representations of planar graphs were presented in [103,117].

In a visibility representation of a planar graph, nodes are represented as horizontal segments and edges as vertical segments such that each edge segment has its endpoints on the segments associated with its incident nodes and does not cross any other node segment. A visibility representation can be considered to be a skeleton or a sketch of the final drawing. In [25], a technique is presented, which constructs visibility representations so that some prespecified edges are vertically aligned. These visibility representations, called constrained visibility representations, can be used as starting points for obtaining drawings of graphs with interesting properties. An example of a visibility representation of a planar graph is given in Figure 14.8.

The visibility approach consists of three phases [24,25,28]:

Planarization: This is the same as in the topology-shape-metrics approach presented earlier.

Visibility: The visibility representation of the planar graph, produced in the planarization phase, is computed.

Replacement: Constructs the final polyline drawing by replacing each horizontal line by its node and the vertical lines by polylines connecting the nodes.

In the replacement phase, there are several strategies in order to construct planar polyline drawings from a visibility representation [28]. In [118], a linear time algorithm is presented for constructing

FIGURE 14.8 (a) A planar graph, (b) its visibility representation, (c) a preliminary orthogonal drawing derived from a visibility representation, and (d) the final orthogonal drawing after modifications.

orthogonal drawings which is based on the visibility approach. In the replacement phase of this algorithm, the visibility representation of the graph is transformed into an orthogonal grid embedding. A number of local transformations are applied to the orthogonal representation of the grid embedding in order to reduce the number of bends. Finally, an orthogonal grid embedding with at most $2.4n + 2$ bends is computed from the orthogonal representation. Figure 14.8 shows the steps of this algorithm.

14.3.2.1 Interactive (Dynamic) Drawings

Many applications require the layout of dynamic graphs, representing changing relational information over time. Examples of applications include software engineering visualizations, changing Internet usage, and changes in social network structures. Dynamic graph drawing involves laying out graphs which evolve over time by continuously adding or deleting nodes and edges. The challenge in dynamic graph drawing is to preserve the mental map of the drawing each time we perform an addition or deletion. The notion of the mental map of a drawing has been introduced in [86]. By preserving the user’s mental map of a drawing, we generally mean that a user that has studied a drawing will not have to reinvest significant effort to visualize or understand the resulting drawing after some changes.

Traditional (static) layout techniques may not be suited for drawing dynamic graphs. When static layout algorithms are employed, insertion or deletion of even one node or edge can significantly change the layout and thus alter the user’s mental map of the drawing.

Many algorithms address the problem of offline dynamic graph drawing, where the entire sequence of graphs to be drawn is known in advance. This gives the layout algorithm information about future changes in the graph, which allows it to optimize the layouts generated across the entire sequence. For example, the algorithm can reserve place in order to accommodate a node that appears later in the sequence. In [30], a meta-graph built, using information from the entire graph sequence, is used in order to maintain the mental map. In [77], an abstracted version of the graph is used. The nodes are topologically sorted into a tree structure in order to expose interesting features. An offline force-directed algorithm is used in [44] in order to create two-dimensional (2D) and three-dimensional (3D) animations of evolving graphs.

The more interesting problem of online dynamic graph drawing where the graph sequence is not known in advance has been studied in depth. Sophisticated incremental algorithms for orthogonal graph drawings are presented in [7,12,94,96]. An efficient incremental algorithm for online hierarchical graph drawings is presented in [90]. An algorithm for visualizing dynamic social networks is

discussed in [87]. An approach based on Bayesian networks is described in [10]. An algorithm for producing online layouts of general graphs is presented in [51]. The work in [19] presents data structures for dynamic graph drawings.

14.3.2.2 3D Drawings

3D graph drawings have been extensively studied since they have applications in information visualization, VLSI circuit design, and software engineering. One of the earliest approaches in 3D graph drawing is the cone tree algorithm [102], where each subtree is associated with a cone, such that the vertex at the root of the subtree is placed at the apex of the cone, and its children are circularly arranged around the base of the cone. This technique displays trees in 3D mostly for artistic purposes. Empirical studies suggest that displaying a graph in three dimensions is better than in two [101,124]. The extra dimension gives greater flexibility for placing the nodes and edges of a graph and crossings can be always avoided. However, producing efficient 3D graph drawings is quite a challenging problem due to the occlusion and navigation problems involved. The interest of the 3D graph drawing community has been mainly devoted to straight-line drawings and to orthogonal drawings.

Straight-line drawings map nodes to points and edges to straight-line segments. In [20], it is shown that every graph admits a straight-line, crossing-free 3D drawing on an integer grid of $O(n^3)$ volume, and proved that this is asymptotically optimal. It distributes the nodes of the graph along a “momentum curve,” so that there are not crossings among the edges. In [45], it is shown that all outerplanar graphs can be drawn in a restricted integer 3D grid of $O(n)$ volume consisting of three parallel lines at distance 1 from each other. In [34], it is shown that all planar graphs can be drawn with an upper bound of $O(n^{\frac{3}{2}})$ volume. A technique for drawing 3D hierarchical graph drawings that combines 2D drawings with a lifting transformation is presented in [57]. First, a 2D non-upward representation of a directed acyclic graph is created and then the nodes are lifted along a third dimension. The lifting height of the nodes reflects the hierarchy. Force-directed techniques have been extended to create 3D graph drawing (e.g., [14,22,91]). 3D visibility representations of graphs have been studied in [3,58,109].

Orthogonal drawings map nodes to points and edges to polygonal chains composed of segments that are parallel to the axes. In [5], a linear time algorithm is presented that draws a graph in $O(n^2)$ volume with at most 14 bends per edge. The drawing is obtained by placing all the nodes on a certain horizontal plane and by assigning a further horizontal plane to every edge. In [41], a $O(n^{\frac{3}{2}})$ running time algorithm is proposed that is based on augmenting the graph to an Eulerian graph. The algorithm produces drawings that have $O(n^{\frac{3}{2}})$ volume and at most 16 bends per edge. The algorithm in [42] requires $O(n^{\frac{3}{2}})$ time and volume and introduces at most seven bends per edge. In the same paper, a second algorithm is presented whose complexity is linear, while its volume is $27n^3$, and at most three bends per edge are introduced. In [95], a linear time algorithm is presented that draws a graph of maximum degree 6 in $O(n^3)$ volume with at most three bends per edge. It is incremental and can be extended to draw graphs with nodes of arbitrary degree. The construction starts from a first pair of adjacent nodes, and then it adds one node at a time with its incident edges. In [125], an algorithm for maximum degree 5 graphs that requires $O(n^3)$ volume and at most two bends per edge is presented.

In [11,60,123], a different approach has been taken to construct 3D drawings. More specifically, this framework divides a graph into a set of subgraphs, and then draws the subgraphs in different parallel planes, using well-known 2D drawing algorithms, but with interdependent layouts.

14.3.2.3 Labeling

An important aspect of graph drawing is the automatic placement of text or symbol labels corresponding to nodes and edges of a drawing. Labels are textual descriptions which convey information or clarify

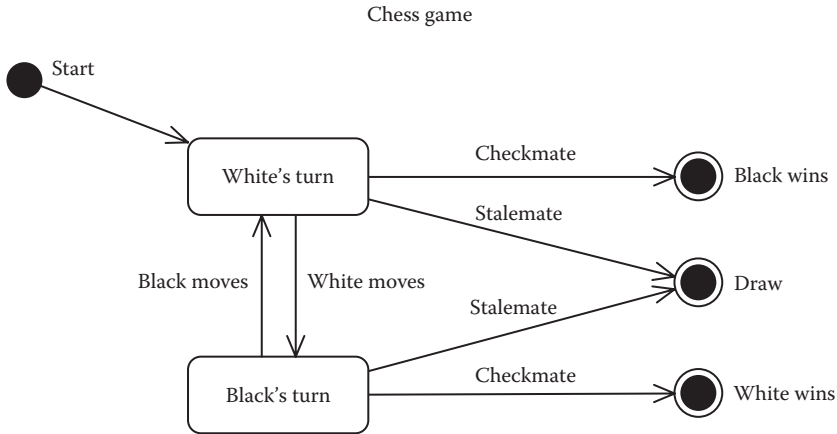

FIGURE 14.9 A UML state diagram that makes use of labels for states and transitions as well as the title of the diagram [33].

the meaning of the elements of a drawing. The problem of positioning labels corresponding to graphical objects of drawings is called automatic label placement or simply graph labeling. The need for displaying node or edge labels is essential in many applications, for example in online Geographic Information Systems, Internet-based map search, UML diagrams, and engineering diagrams.

Labeling of edges, nodes, and graphs themselves aims to communicate the attributes of these graph objects in the most convenient way. This requires that labels be positioned in the most appropriate places and follows some basic rules [66]. It is worth noting that the problems of labeling nodes [83] and edges [65] are NP-hard. Because automatic labeling is a very difficult problem, we rely on heuristics to provide practical solutions for real world problems.

Most of the research on labeling addresses the problem of assigning labels to a set of points or nodes [17,46,59,126]. The problem of assigning labels to a set of lines or edges has been studied in [33,64,121]. For the general labeling problem (i.e., the labeling of nodes, edges, and graphs), most labeling algorithms are based on local and exhaustive search algorithms [1,31,43,49].

In [66], the general labeling problem is transformed into a matching problem. The general framework of this techniques is flexible and can be adjusted for particular labeling requirements. In Figure 14.9, the labeling assignment is produced by this technique. The basic steps for this labeling technique are the following:

1. A set of discrete potential label solutions for each object is carefully selected.
2. This set of labels is reduced by removing heavily overlapping labels. The remaining labels are assigned to groups, such that if two labels overlap, then they belong to the same group.
3. Finally, labels are assigned by solving a variant of the matching problem, where at most one label position from each group is part of the solution.

In many practical applications, each graphical feature may have more than one label. The need for assigning multiple labels is necessary not only when objects are large or long, but also when it is necessary to display different attributes of an object. This problem has been addressed in [49,67].

Since we rely on heuristics to solve the labeling problem, there are cases where the best methods available do not always produce an overlap free label assignment. In order to resolve label overlaps, one may modify minimally the drawing. An algorithm that modifies an orthogonal drawing of a graph, while preserving the orthogonal representation of the drawing, in order to resolve label overlaps is presented in [68]. It remains an open problem, for the other layout styles, how one can modify a drawing to resolve label overlaps.

14.4 Impact on Practice

The industrial need for graph drawing algorithms arose in the late 1960s when a large number of elements in complex circuit designs made hand-drawing too complicated [89]. Many algorithms were developed to aid circuit design [78]. Graph drawing is an active area in computer science. Graphs and their visualizations are essential in data exploration and understanding, particularly for those applications that need to manage, process, and analyze huge quantities of data. Graph drawing has applications in almost all branches of science and technology, we mention just a few:

Web: Site maps, browsing history diagrams, presentation and refinement of query results, product catalogs, visitor movement graphs, and Internet traffic diagrams.

Software engineering: UML diagrams, subroutine call graphs, data-flow diagrams, and object-oriented class hierarchies.

Database systems: Entity-relationship diagrams, database queries, ontology of semantic graphs, dependency graphs, and database schema diagrams.

Real-time systems: Petri nets and state-transition diagrams.

Networking: Telecommunication and computer network management, network visualization, network analysis, and LAN diagrams.

Engineering: Circuit schematics, CAD, and finite state diagrams.

Social Sciences: Social networks, citation networks, co-authorship networks, and collaboration networks.

Business: Business process diagrams, organization charts, event-driven process chains, and scheduling charts.

Biomedical technology: Gene regulatory networks, metabolic networks, protein-protein interaction networks, evolutionary trees, phylogenetic trees, molecular maps, genetic maps, biochemical pathways, and neuronal networks.

Security: Criminal networks, fraud networks, felony event flow diagrams, case information diagrams, attack trees, network monitoring, Internet traffic control, traffic visualization, and traffic analysis.

14.5 Research Issues and Summary

Current research in graph drawing addresses both theoretical and applied issues. On the theoretical side, researchers have investigated issues ranging from combinatorial properties of graphs to algorithms that produce drawings with provably good upper bounds on the area, number of bends, etc., to lower bounds. On the systems side, there are several graph drawing tools and commercial software products (e.g., GraphViz from AT&T, GDToolkit, AGD, Graphlet, Tom Sawyer Software, yWorks, and ILOG). For a compilation of results in graph drawing in excellent tabular exposition, see [116].

Peter Eades [37] points out that the scale problem currently drives much of Computer Science. Data sets are growing at a faster rate than the human ability to understand them. A challenge for the graph drawing community is to explore more efficient ways to draw large graphs. Three approaches have been proposed to solve the scale problem. (i) Dynamic drawings: View only part of the drawing, (ii) Cluster drawings: View an abstraction of the drawing, and (iii) 3D drawings: Spread the drawing over a third dimension. The first two approaches have the drawback that present part of the data in order to reduce visual complexity. Graph drawing algorithms for 3D layouts have mostly failed to untangle the complexity of large graphs [37]. Promising approaches for 3D drawings, which need further investigation, have been presented in [11,60,123]. In [74], a new approach in drawing 3D orthogonal drawings is presented. It combines dominance and row/column reuse and simplifies the visual confirmation of the

existence of an edge and/or path between any two nodes. This is a promising technique for producing simple drawings of large graphs that needs further investigation.

Many open graph drawing problems originating in applied bioinformatics and network biology are presented in [2]. Traditional graph drawing techniques do not adhere to the special drawing conventions of the life science community. Thus, there is a need for specialized layout and visualization algorithms to present, explore, evaluate, and compare biological network data.

Key Terms

Acyclic digraph: A digraph without directed cycles.

Biconnected component: A maximal biconnected subgraph.

Biconnected graph: A graph with the property that for every three distinct nodes u , v , and w there is a path from u to w not containing v .

Binary tree: A rooted tree where each node has at most two children.

Connected component: A maximal connected subgraph.

Connected graph: An undirected graph that has a path between every pair of nodes.

Digraph: A graph where the edges have a direction associated with them (also called *directed* graph).

Embedded graph: A planar graph with a prespecified topological embedding (i.e., set of faces), which must be preserved in the drawing.

Face: A planar drawing of a graph divides the plane into regions called *faces*. The unbounded region is called the **external face**.

Orthogonal representation: A representation of an orthogonal drawing in terms of bends along each edge and angles around each node.

Outerplanar graph: A planar graph which admits an embedding such that all the nodes are on the same face.

Rooted tree: A directed tree with a distinguished node, the *root*, such that each node lies on a directed path to the root.

Sink node: A node of a digraph without outgoing edges (also called *target* node).

Source node: A node of a digraph without incoming edges.

St-digraph: An acyclic digraph with exactly one source and one sink, which are joined by an edge (also called *bipolar digraph*).

Tree: A connected graph without cycles.

Further Information

Three books have been published in the area of graph drawing [28,71,111], one book on Graph Drawing Software [63], and one book on Planar Graph Drawing [89]. A comprehensive bibliography on graph drawing algorithms [26] cites more than 300 papers written before 1994. An International Symposium on Graph Drawing is being held annually and the proceedings are published by Springer-Verlag. *The Journal of Graph Algorithms and Applications (JGAA)* is an online journal which publishes graph drawing-related work. In addition, journals in the area of Computational Geometry (Computational Geometry: Theory and Applications, Algorithmica, etc.) are of particular interest, since graph drawing has strong relationships with computational geometry. Online graph drawing resources can be found in: (i) <http://graphdrawing.org> (a collection of resources mostly related to the annual International Symposium on Graph Drawing), (ii) <http://gdea.informatik.uni-koeln.de> (an electronic repository and archive for research materials on the topic of graph drawing), and (iii) <http://www.ics.uci.edu/eppstein/gina/gdraw.html> (the section of the Geometry in Action pages devoted to graph drawing and maintained by David Eppstein).

15.1 Processing Texts Efficiently

This present chapter describes a few standard algorithms used for processing texts. They apply, for example, to the manipulation of texts (text editors), to the storage of textual data (text compression), and to data retrieval systems. The algorithms of this chapter are interesting in different respects. First, they are basic components used in the implementation of practical software. Second, they introduce programming methods that serve as paradigms in other fields of computer science (system or software design). Third, they play an important role by providing challenging problems in theoretical computer science.

Although data are stored in various ways, text remains the main form of exchanging information. This is particularly evident in literature or linguistics where data are composed of huge corpora and dictionaries.

This applies as well to computer science where a large amount of data are stored in linear files. And this is also the case in molecular biology where biological molecules can often be approximated as sequences of nucleotides or amino acids. Moreover, the quantity of available data in these fields tends to double every 18 months. This is the reason why algorithms should be efficient even if the speed of computers increases at a steady pace.

Pattern matching is the problem of locating a specific pattern inside raw data. The pattern is usually a collection of strings described in some formal language. Two kinds of textual patterns are presented: single strings and approximated strings. Two algorithms for matching patterns in images that are extensions of string-matching algorithms are also presented.

In several applications, texts need to be structured before being searched. Even if no further information is known about their syntactic structure, it is possible and indeed extremely efficient to build a data structure that supports searches. From among several existing data structures equivalent to represent indexes, suffix trees and suffix arrays are presented, along with their construction algorithms.

The comparison of strings is implicit in the approximate pattern searching problem. Since it is sometimes required to compare just two strings (files or molecular sequences), a basic method based on longest common subsequences is discussed.

Finally, the chapter includes two classical text compression algorithms. Variants of these algorithms are implemented in practical compression software, in which they are often combined together or with other elementary methods. An example of mixing different methods is presented.

The efficiency of algorithms is assessed by their asymptotic running times, and sometimes by the amount of memory space they require at run time as well.

15.2 String-Matching Algorithms

String matching is the problem of finding one or, more generally, all the **occurrences** of a pattern in a text. The pattern and the text are both strings built over a finite alphabet (a finite set of symbols). Each algorithm of this section outputs all occurrences of the pattern in the text. The pattern is denoted by $x = x[0 \dots m - 1]$; its length is equal to m . The text is denoted by $y = y[0 \dots n - 1]$; its length is equal to n . The alphabet is denoted by Σ and its size is equal to σ .

String-matching algorithms of the present section work as follows: they first align the left ends of the pattern and the text, then compare the aligned symbols of the text and the pattern—this specific task is called an attempt or a scan—and after a whole match of the pattern or after a mismatch they shift the pattern to the right. They repeat the same procedure again until the right end of the pattern goes beyond the right end of the text. This is called the scan and shift mechanism. Each attempt is associated with the position j in the text, when the pattern is aligned with $y[j \dots j + m - 1]$.

The brute force algorithm consists in checking, at all positions in the text between 0 and $n - m$, whether an occurrence of the pattern starts there or not. Then, after each attempt, it shifts the pattern exactly one position to the right. This is the simplest algorithm, which is described in Figure 15.1.

The time complexity of the brute force algorithm is $O(mn)$ in the worst case, but its behavior in practice is often linear on specific data.

```

BF( $x, m, y, n$ )
1  ▷ Searching
2  for  $j \leftarrow 0$  to  $n - m$ 
3      do  $i \leftarrow 0$ 
4          while  $i < m$  and  $x[i] = y[i + j]$ 
5              do  $i \leftarrow i + 1$ 
6          if  $i \geq m$ 
7              then OUTPUT( $j$ )

```

FIGURE 15.1 Brute force string-matching algorithm. Symbol ▷ introduces comments.

15.2.1 Karp–Rabin Algorithm

Hashing provides a simple method for avoiding a quadratic number of symbol comparisons in most practical situations. Instead of checking at each position of the text whether the pattern occurs, it seems to be more efficient to check only if the portion of the text aligned with the pattern “looks like” the pattern. In order to check the resemblance between these portions a hashing function is used. To be helpful for the string-matching problem, the hashing function should have the following properties:

- Efficiently computable
- Highly discriminating for strings
- $hash(y[j + 1 \dots j + m])$ must be easily computable from $hash(y[j \dots j + m - 1])$
 $hash(y[j + 1 \dots j + m]) = REHASH(y[j], y[j + m], hash(y[j \dots j + m - 1]))$

For a word w of length k , its symbols can be considered as digits, and function $hash(w)$ is defined by

$$hash(w[0..k - 1]) = (w[0] \times 2^{k-1} + w[1] \times 2^{k-2} + \dots + w[k - 1]) \bmod q$$

where q is a large number. Then, REHASH has a simple expression

$$REHASH(a, b, h) = ((h - a \times d) \times 2 + b) \bmod q$$

where $d = 2^{k-1}$ and q are the computer word-size (see Figure 15.2).

During the search for the pattern x , $hash(x)$ is compared with $hash(y[j - m + 1 \dots j])$ for $m - 1 \leq j \leq n - 1$. If an equality is found, it is still necessary to check the equality $x = y[j - m + 1 \dots j]$ symbol by symbol.

In the algorithms of Figures 15.2 and 15.3 all multiplications by 2 are implemented by shifts (operator \ll). Furthermore, the computation of the modulus function is avoided by using the implicit modular arithmetic given by the hardware that forgets carries in integer operations. Thus, q is chosen as the maximum value of an integer of the system.

The worst-case time complexity of the Karp–Rabin algorithm is quadratic (as it is for the brute force algorithm), but its expected running time is $O(m + n)$.

Example 15.1

Let $x = \mathbf{ing}$. Then $hash(x) = 105 \times 2^2 + 110 \times 2 + 103 = 743$ (symbols are assimilated with their ASCII codes).

y	=	s	t	r	i	n	g												
$hash$	=			806	797	776	743	678	585	443	746	719	766	709	736	743			

15.2.2 Knuth–Morris–Pratt Algorithm

This section presents the first discovered linear-time string-matching algorithm. Its design follows a tight analysis of the brute force algorithm, and especially of the way this latter algorithm wastes the information gathered during the scan of the text.

```
REHASH(a, b, h)
1 return ((h - a * d) << 1) + b
```

FIGURE 15.2 Function REHASH.

```

KR( $x, m, y, n$ )
1  ▷ Preprocessing
2   $d \leftarrow 1$ 
3  for  $i \leftarrow 1$  to  $m - 1$ 
4      do  $d \leftarrow d \ll 1$ 
5   $h_x \leftarrow 0$ 
6   $h_y \leftarrow 0$ 
7  for  $i \leftarrow 0$  to  $m - 1$ 
8      do  $h_x \leftarrow (h_x \ll 1) + x[i]$ 
9           $h_y \leftarrow (h_y \ll 1) + y[i]$ 
10 ▷ Searching
11 if  $h_x = h_y$  and  $x = y[0 \dots m - 1]$ 
12     then OUTPUT(0)
13  $j \leftarrow m$ 
14 while  $j < n$ 
15     do  $h_y \leftarrow \text{REHASH}(y[j - m], y[j], h_y)$ 
16         if  $h_x = h_y$  and  $x = y[j - m + 1 \dots j]$ 
17             then OUTPUT( $j - m + 1$ )
18          $j \leftarrow j + 1$ 

```

FIGURE 15.3 Karp–Rabin string-matching algorithm.

Let us look more closely at the brute force algorithm. It is possible to improve the length of shifts and simultaneously remember some portions of the text that match the pattern. This saves comparisons between characters of the text and of the pattern, and consequently increases the speed of the search.

Consider an attempt at position j , that is, when the pattern $x[0 \dots m - 1]$ is aligned with the segment $y[j \dots j + m - 1]$ of the text. Assume that the first mismatch (during a left to right scan) occurs between symbols $x[i]$ and $y[i + j]$ for $0 \leq i < m$. Then, $x[0 \dots i - 1] = y[j \dots i + j - 1] = u$ and $a = x[i] \neq y[i + j] = b$. When shifting, it is reasonable to expect that a **prefix** v of the pattern matches some **suffix** of the portion u of the text. Moreover, if one wants to avoid another immediate mismatch, the letter following the prefix v in the pattern must be different from a . (Indeed, it should be expected that v matches a suffix of ub , but elaborating along this idea goes beyond the scope of the chapter.) The longest such prefix v is called the **border** of u (it occurs at both ends of u). This introduces the notation: let $next[i]$ be the length of the longest (proper) border of $x[0 \dots i - 1]$ followed by a character c different from $x[i]$. Then, after a shift, the comparisons can resume between characters $x[next[i]]$ and $y[i + j]$ without missing any occurrence of x in y and having to backtrack on the text (see Figure 15.4).

FIGURE 15.4 Shift in the Knuth–Morris–Pratt algorithm (v suffix of u).

Example 15.2

Here

$y =$. . . <u>a</u> <u>b</u> <u>a</u> <u>b</u> <u>a</u> <u>a</u> <u>b</u>
$x =$ <u>a</u> <u>b</u> <u>a</u> <u>b</u> <u>a</u> <u>b</u> <u>a</u>
$x =$ <u>a</u> <u>b</u> <u>a</u> <u>b</u> <u>a</u> <u>b</u> <u>a</u>

Compared symbols are underlined. Note that the empty string is the suitable border of **ababa**. Other borders of **ababa** are **aba** and **a**.

The Knuth–Morris–Pratt (KMP) algorithm is displayed in Figure 15.5. The table *next* it uses is pre-computed in $O(m)$ time before the search phase, applying the same searching algorithm to the pattern itself, as if $y = x$ (see Figure 15.6). The worst-case running time of the algorithm is $O(m + n)$ and it requires $O(m)$ extra space. These quantities are independent of the size of the underlying alphabet.

```

KMP( $x, m, y, n$ )
1  ▷ Preprocessing
2   $next \leftarrow \text{PREKMP}(x, m)$ 
3  ▷ Searching
4   $i \leftarrow 0$ 
5   $j \leftarrow 0$ 
6  while  $j < n$ 
7      do while  $i > -1$  and  $x[i] \neq y[j]$ 
8          do  $i \leftarrow next[i]$ 
9           $i \leftarrow i + 1$ 
10          $j \leftarrow j + 1$ 
11         if  $i \geq m$ 
12             then OUTPUT( $j - i$ )
13          $i \leftarrow next[i]$ 
    
```

```

PREKMP( $x, m$ )
1   $i \leftarrow -1$ 
2   $j \leftarrow 0$ 
3   $next[0] \leftarrow -1$ 
4  while  $j < m$ 
5      do while  $i > -1$  and  $x[i] \neq x[j]$ 
6          do  $i \leftarrow next[i]$ 
7           $i \leftarrow i + 1$ 
8           $j \leftarrow j + 1$ 
9          if  $x[i] = x[j]$ 
10             then  $next[j] \leftarrow next[i]$ 
11             else  $next[j] \leftarrow i$ 
12  return  $next$ 
    
```

FIGURE 15.6 Preprocessing phase of the Knuth–Morris–Pratt algorithm: computing *next*.

15.2.3 Boyer–Moore Algorithm

The Boyer–Moore (BM) algorithm is considered the most efficient string-matching algorithm in usual applications. A simplified version of it, or the entire algorithm, is often implemented in text editors for the search and substitute commands.

The algorithm scans the characters of the pattern from right to left beginning with the rightmost symbol. In case of a mismatch (or a complete match of the whole pattern), it uses two precomputed functions to shift the pattern to the right. These two shift functions are called the *bad-character shift* and the *good-suffix shift*. They are based on the following observations.

Assume that a mismatch occurs between the character $x[i] = a$ of the pattern and the character $y[i + j] = b$ of the text during an attempt at position j . Then, $x[i + 1 \dots m - 1] = y[i + j + 1 \dots j + m - 1] = u$ and $x[i] \neq y[i + j]$. The good-suffix shift consists in aligning the **segment** $y[i + j + 1 \dots j + m - 1]$ with its rightmost occurrence in x that is preceded by a character different from $x[i]$ (see Figure 15.7). If there exists no such segment, the shift consists in aligning the longest suffix v of $y[i + j + 1 \dots j + m - 1]$ with a matching prefix of x (see Figure 15.8).

Example 15.3

$y =$.	.	.	a	b	b	a	a	b	b	a	b	b	a	.	.	.
$x =$	a	b	b	a	a	b	<u>b</u>	<u>a</u>	<u>b</u>	<u>b</u>	<u>a</u>						
$x =$				<u>a</u>	<u>b</u>	<u>b</u>	<u>a</u>	<u>a</u>	<u>b</u>	<u>b</u>	<u>a</u>	<u>b</u>	<u>b</u>	<u>a</u>			

The shift is driven by the suffix **abba** of x found in the text. After the shift, the segment **abba** in the middle of y matches a segment of x as in Figure 15.7. The same mismatch does not recur.

Example 15.4

$y =$.	.	.	a	b	b	a	a	b	b	a	b	b	a	b	b	a	.	.	.
$x =$				<u>b</u>	<u>b</u>	<u>a</u>	<u>b</u>	<u>a</u>	<u>b</u>	<u>b</u>	<u>a</u>									
$x =$									<u>b</u>	<u>b</u>	<u>a</u>	<u>b</u>	<u>b</u>	<u>a</u>	<u>b</u>	<u>b</u>	<u>a</u>			

The segment **abba** found in y partially matches a prefix of x after the shift, as in Figure 15.8.

FIGURE 15.7 The good-suffix shift, when u reappears preceded by a character different from a .

FIGURE 15.8 The good-suffix shift, when the situation of Figure 15.7 does not happen. Only a suffix of u reappears as a prefix of x .

FIGURE 15.9 The bad-character shift, b appears in x .

FIGURE 15.10 The bad-character shift, b does not appear in x (except possibly at $m - 1$).

The bad-character shift consists in aligning the text character $y[i + j]$ with its rightmost occurrence in $x[0 \dots m - 2]$ (see Figure 15.9). If $y[i + j]$ does not appear in the pattern x , no occurrence of x in y can overlap the symbol $y[i + j]$, then the left end of the pattern is aligned with the character at position $i + j + 1$ (see Figure 15.10).

Example 15.5

The shift aligns the symbol a in x with the mismatch symbol a in the text y (Figure 15.9).

Example 15.6

The shift positions the left end of x right after the symbol a of y (Figure 15.10).

The BM algorithm is shown in Figure 15.11. For shifting the pattern, it applies the maximum between the bad-character shift and the good-suffix shift. More formally, the two shift functions are defined as follows. The bad-character shift is stored in a table bc of size σ and the good-suffix shift is stored in a table gs of size $m + 1$. For $a \in \Sigma$

$$bc[a] = \begin{cases} \min\{i \mid 1 \leq i < m \text{ and } x[m - 1 - i] = a\} & \text{if } a \text{ appears in } x, \\ m & \text{otherwise.} \end{cases}$$

```

BM( $x, m, y, n$ )
1  ▷ Preprocessing
2   $gs \leftarrow \text{PREGS}(x, m)$ 
3   $bc \leftarrow \text{PREBC}(x, m)$ 
4  ▷ Preprocessing
5   $j \leftarrow 0$ 
6  while  $j \leq n - m$ 
7      do  $i \leftarrow m - 1$ 
8          while  $i \geq 0$  and  $x[i] = y[i + j]$ 
9              do  $i \leftarrow i - 1$ 
10             if  $i < 0$ 
11                 then  $\text{OUTPUT}(j)$ 
12              $j \leftarrow \max\{gs[i + 1], bc[y[i + j] - m + i + 1]\}$ 

```

FIGURE 15.11 BM string-matching algorithm.

Let us define two conditions,

$$\begin{cases} \text{cond}_1(i, s): & \text{for each } k \text{ such that } i < k < m, s \geq k \text{ or } x[k - s] = x[k], \\ \text{cond}_2(i, s): & \text{if } s < i \text{ then } x[i - s] \neq x[i]. \end{cases}$$

Then, for $0 \leq i < m$,

$$gs[i + 1] = \min\{s > 0 \mid \text{cond}_1(i, s) \text{ and } \text{cond}_2(i, s) \text{ hold}\}$$

and $gs[0]$ is defined as the length of the smallest period of x .

To compute the table gs , a table $suff$ is used. This table can be defined as follows: for $i = 0, 1, \dots, m - 1$,

$$suff[i] = \text{longest common suffix between } x[0 \dots i] \text{ and } x.$$

It is computed in linear time and space by the function SUFFIXES (see Figure 15.12).

```

SUFFIXES( $x, m$ )
1   $suff[m - 1] \leftarrow m$ 
2   $g \leftarrow m - 1$ 
3  for  $i \leftarrow m - 2$  downto 0
4      do if  $i > g$  and  $suff[i + m - 1 - f] \neq i - g$ 
5          then  $suff[i] \leftarrow \min\{suff[i + m - 1 - f], i - g\}$ 
6          else if  $i < g$ 
7              then  $g \leftarrow i$ 
8               $f \leftarrow i$ 
9              while  $g \geq 0$  and  $x[g] = x[g + m - 1 - f]$ 
10                 do  $g \leftarrow g - 1$ 
11                  $suff[i] \leftarrow f - g$ 
12  return  $suff$ 

```

FIGURE 15.12 Computation of the table $suff$.

```

PREBC( $x, m$ )
1  for  $a \leftarrow$  firstLetter to lastLetter
2      do  $bc[a] \leftarrow m$ 
3  for  $i \leftarrow 0$  to  $m - 2$ 
4      do  $bc[x[i]] \leftarrow m - 1 - i$ 
5  return  $bc$ 

```

FIGURE 15.13 Computation of the bad-character shift.

```

PREGS( $x, m$ )
1   $gs \leftarrow$  SUFFIXES( $x, m$ )
2  for  $i \leftarrow 0$  to  $m - 1$ 
3      do  $gs[i] \leftarrow m$ 
4   $j \leftarrow 0$ 
5  for  $i \leftarrow m - 1$  downto  $-1$ 
6      do if  $i = -1$  or  $suff[i] = i + 1$ 
7          then while  $j < m - 1 - i$ 
8              do if  $gs[j] = m$ 
9                  then  $gs[j] \leftarrow m - 1 - i$ 
10                  $j \leftarrow j + 1$ 
11 for  $i \leftarrow 0$  to  $m - 2$ 
12     do  $gs[m - 1 - suff[i]] \leftarrow m - 1 - i$ 
13 return  $gs$ 

```

FIGURE 15.14 Computation of the good-suffix shift.

Tables bc and gs can be precomputed in time $O(m + \sigma)$ before the search phase and require an extra space in $O(m + \sigma)$ (see Figures 15.13 and 15.14). The worst-case running time of the algorithm is quadratic. However, on large alphabets (relative to the length of the pattern), the algorithm is extremely fast. Slight modifications of the strategy yield linear-time algorithms (see the References Section). When searching for a^m in $(a^{m-1}b)^{n/m}$ the algorithm makes only $O(n/m)$ comparisons, which is the absolute minimum for any string-matching algorithm in the model where the pattern only is preprocessed.

15.2.4 Quick Search Algorithm

The bad-character shift used in the BM algorithm is not very efficient for small alphabets, but when the alphabet is large compared with the length of the pattern, as it is often the case with the ASCII table and ordinary searches made under a text editor, it becomes very useful. Using it alone produces a very efficient algorithm (in practice) that is described now.

After an attempt where x is aligned with $y[j \dots j + m - 1]$, the length of the shift is at least equal to one. Thus, the character $y[j + m]$ is necessarily involved in the next attempt, and thus can be used for the bad-character shift of the current attempt. In the present algorithm, the bad-character shift is slightly modified to take into account the observation as follows ($a \in \Sigma$):

$$bc[a] = 1 + \begin{cases} \min\{i \mid 0 \leq i < m \text{ and } x[m - 1 - i] = a\} & \text{if } a \text{ appears in } x, \\ m & \text{otherwise.} \end{cases}$$

Indeed, the comparisons between text and pattern characters during each attempt can be done in any order. The algorithm of Figure 15.15 performs the comparisons from left to right. It was called Quick Search (QS) by its inventor and has a quadratic worst-case time complexity but good practical behavior.

Example 15.7

```

y=  s  t  r  i  n  g  -  m  a  t  c  h  i  n  g
x=  i  n  g
x=           i  n  g
x=                   i  n  g
x=                             i  n  g
x=                                   i  n  g

```

The QS algorithm makes only nine comparisons to find the two occurrences of **ing** inside the text of length 15.

15.2.5 Experimental Results

Figures 15.16 and 15.17 present the running times of three string-matching algorithms: the BM algorithm, the QS algorithm, and the Backward Oracle Matching (BOM) algorithm. The BOM algorithm can be viewed as a variation of the BM algorithm where factors (segments) rather than suffixes of the pattern are recognized. The BOM algorithm uses a data structure to store all the factors of the reversed pattern: a factor oracle but a suffix automaton or a **suffix tree** (see section 15.4) can also be used.

Tests have been performed on various types of texts. Figure 15.16 shows the results when the text is a DNA sequence on the four-letter alphabet of nucleotides **A, C, G, T**. In Figure 15.17, English text is considered.

For each pattern length, a large number of searches with random patterns were run. The average time according to the length is shown in the two figures. The running times of both preprocessing

```

QS(x, m, y, n)
1  ▷ Preprocessing
2  for a ← firstLetter to lastLetter
3      do bc[a] ← m + 1
4  for i ← 0 to m - 1
5      do bc[x[i]] ← m - i
6  ▷ Searching
7  j ← 0
8  while j ≤ n - m
9      do i ← 0
10     while i ≥ 0 and x[i] = y[i + j]
11         do i ← i + 1
12     if i ≥ m
13         then OUTPUT(j)
14     j ← bc[y[j + m]]

```

FIGURE 15.15 QS string-matching algorithm.

FIGURE 15.16 Running times for a DNA sequence.

FIGURE 15.17 Running times for an English text.

and searching phases are added. The three algorithms are implemented in a homogeneous way in order to keep the comparison significant.

For the genome, as expected, the QS algorithm is the best for short patterns. But for long patterns, it is eventually less efficient than the BM algorithm. In this latter case, the BOM algorithm achieves the best results. For rather large alphabets, the three algorithms have similar behaviors; however, the QS is always faster.

15.2.6 Aho–Corasick Algorithm

The UNIX operating system provides standard text (or file) facilities. Among them is the series of **grep** commands that locate patterns in files. The algorithm underlying the **fgrep** command of UNIX is described in this section. It searches files for a finite set of strings, and can, for instance, output lines containing at least one of the strings.

If one is interested in searching for all occurrences of all patterns taken from a finite set of patterns, a first solution consists in repeating some string-matching algorithm for each pattern. If the set contains k patterns, this search runs in time $O(kn)$. The solution described in the present section and designed by Aho and Corasick runs in time $O(n \log \sigma)$. The algorithm is a direct extension of the KMP algorithm, and the running time is independent of the number of patterns.

Let $X = \{x_0, x_1, \dots, x_{k-1}\}$ be the set of patterns, and let $|X| = |x_0| + |x_1| + \dots + |x_{k-1}|$ be the total size of the set X . The Aho–Corasick algorithm first builds a **trie** $T(X)$, a digital tree recognizing the patterns of X .

```

PREAC( $X, k$ )
1  Create a new node  $root$ 
2  ▷ creates a loop on the root of the trie
3  for  $a \in \Sigma$ 
4      do  $child(root, a) \leftarrow root$ 
5  ▷ enters each pattern in the trie
6  for  $i \leftarrow 0$  to  $k - 1$ 
7      do ENTER( $X[i], root$ )
8  ▷ completes the trie with failure links
9  COMPLETE( $root$ )
10 return  $root$ 

```

FIGURE 15.18 Preprocessing phase of the Aho–Corasick algorithm.

The trie $T(X)$ is a tree in which edges are labeled by letters and in which branches spell the patterns of X . A node p in the trie $T(X)$ is identified with the unique word w spelled by the path of $T(X)$ from its root to p . The root itself is identified with the empty word ϵ . Notice that if w is a node in $T(X)$, then w is a prefix of some $x_i \in X$. If w is a node in $T(X)$ and $a \in \Sigma$, then $child(w, a)$ is equal to wa if wa is a node in $T(X)$; it is equal to UNDEFINED otherwise.

The function PREAC in Figure 15.18 returns the trie of all patterns. During the second phase, where patterns are entered in the trie, the algorithm initializes an output function out . It associates the singleton $\{x_i\}$ with the nodes x_i ($0 \leq i < k$), and associates the empty set with all other nodes of $T(X)$ (see Figure 15.19).

Finally, the last phase of function PREAC (Figure 15.18) consists in building the failure link of each node of the trie, and simultaneously completing the output function. This is done by the function COMPLETE in Figure 15.20. The failure function $fail$ is defined on nodes as follows (w is a node):

$$fail(w) = u \text{ where } u \text{ is the longest proper suffix of } w \text{ that belongs to } T(X).$$

Computation of failure links is done during a breadth-first traversal of $T(X)$. Completion of the output function is done while computing the failure function $fail$ using the following rule:

$$\text{if } fail(w) = u \text{ then } out(w) = out(w) \cup out(u).$$

```

ENTER( $x, root$ )
1   $r \leftarrow root$ 
2   $i \leftarrow 0$ 
3  ▷ follows the existing edges
4  while  $i < |x|$  and  $child(r, x[i]) \neq \text{UNDEFINED}$  and  $child(r, x[i]) \neq root$ 
5      do  $r \leftarrow child(r, x[i])$ 
6           $i \leftarrow i + 1$ 
7  ▷ creates new edges
8  while  $i < |x|$ 
9      do Create a new node  $s$ 
10          $child(r, x[i]) \leftarrow s$ 
11          $r \leftarrow s$ 
12          $i \leftarrow i + 1$ 
13   $out(r) \leftarrow \{x\}$ 

```

FIGURE 15.19 Construction of the trie.

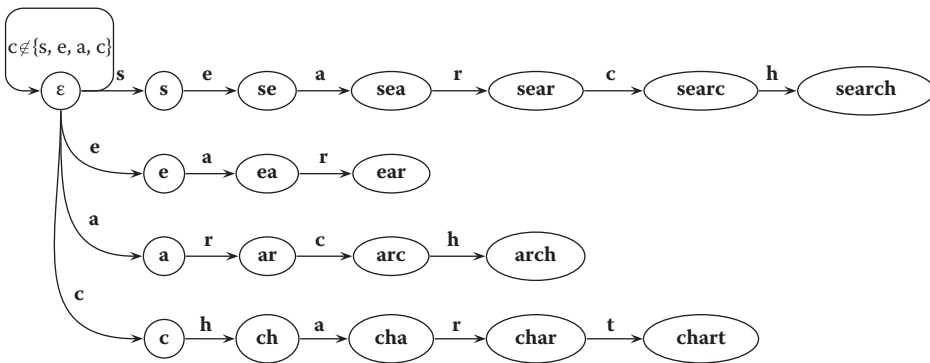

```

COMPLETE(root)
1  q ← empty queue
2  ℓ ← list of the edges (root, a, p) for any character a ∈ Σ
   and any node p ≠ root
3  while the list ℓ is not empty
4    do (r, a, p) ← FIRST(ℓ)
5      ℓ ← NEXT(ℓ)
6      ENQUEUE(q, p)
7      fail(p) ← root
8  while the queue q is not empty
9    do r ← DEQUEUE(q)
10     ℓ ← list of the edges (root, a, p) for any character a ∈ Σ
        and any node p
11     while the list ℓ is not empty
12       do (r, a, p) ← FIRST(ℓ)
13         ℓ ← NEXT(ℓ)
14         ENQUEUE(q, p)
15         s ← fail(r)
16         while child(s, a) = UNDEFINED
17           do s ← fail(s)
18           fail(p) ← child(s, a)
19           out(p) ← out(p) ∪ out(child(s, a))
    
```

5      do while  $\text{child}(r, y[j]) = \text{UNDEFINED}$ 
6          do  $r \leftarrow \text{fail}(r)$ 
7           $r \leftarrow \text{child}(r, y[j])$ 
8          if  $\text{out}(r) \neq \emptyset$ 
9              then  $\text{OUTPUT}(\text{out}(r), j)$ 

```

FIGURE 15.21 Complete Aho–Corasick algorithm.

To stop going back with failure links during the computation of the failure links, and also to overpass text characters for which no transition is defined from the root, a loop is added on the root of the trie for these symbols. This is done at the first phase of function `PREAC`.

After the preprocessing phase is completed, the searching phase consists in parsing all the characters of the text y with $T(X)$. This starts at the root of $T(X)$ and uses failure links whenever a character in y does not match any label of outgoing edges of the current node. Each time a node with a nonempty output is encountered, this means that the patterns of the output have been discovered in the text, ending at the current position. Then, the position is output.

An implementation of the Aho–Corasick algorithm from the previous discussion is shown in Figure 15.21. Note that the algorithm processes the text in an online way, so that the buffer on the text can be limited to only one symbol. Also, note that the instruction $r \leftarrow \text{fail}(r)$ in Figure 15.21 is the exact analogue of instruction $i \leftarrow \text{next}[i]$ in Figure 15.5. A unified view of both algorithms exists but is beyond the scope of the chapter.

The entire algorithm runs in time $O(|X| + n)$ if the *child* function is implemented to run in constant time. This is the case for any fixed alphabet. Otherwise a $\log \sigma$ multiplicative factor comes from access to the children nodes.

15.3 Two-Dimensional Pattern Matching Algorithms

In this section, only two-dimensional arrays are considered. Arrays may be thought of as bit map representations of images, where each cell of arrays contains the codeword of a pixel. The string-matching problem finds an equivalent formulation in two dimensions (and even in any number of dimensions), and algorithms of Section 15.2 can be extended to operate on arrays.

The problem now is to locate all occurrences of a two-dimensional pattern $X = X[0 \dots m_1 - 1, 0 \dots m_2 - 1]$ of size $m_1 \times m_2$ inside a two-dimensional text $Y = Y[0 \dots n_1 - 1, 0 \dots n_2 - 1]$ of size $n_1 \times n_2$. The brute force algorithm for this problem is given in Figure 15.22. It consists in checking at all positions of $Y[0 \dots n_1 - m_1, 0 \dots n_2 - m_2]$ if the pattern occurs. This algorithm has a quadratic (with respect to the size of the problem) worst-case time complexity in $O(m_1 m_2 n_1 n_2)$. In the next sections, two more efficient algorithms are presented. The first one is an extension of the Karp–Rabin algorithm (previous section). The second one solves the problem in linear time on a fixed alphabet; it uses both the Aho–Corasick and the KMP algorithms.

15.3.1 Zhu–Takaoka Algorithm

As for one-dimensional string matching, it is possible to check if the pattern occurs in the text only if the *aligned* portion of the text looks like the pattern. To do that, the idea is to use vertically the hash

2  for  $j_1 \leftarrow 0$  to  $n_1 - m_1$ 
3      do for  $j_2 \leftarrow 0$  to  $n_2 - m_2$ 
4          do  $i \leftarrow 0$ 
5              while  $i < m_1$ 
6                  and  $x[i, 0 \dots m_2 - 1] = y[j_1 + i, j_2 \dots j_2 + m_2 - 1]$ 
7                      do  $i \leftarrow i + 1$ 
8                  if  $i \geq m_1$ 
9                      then OUTPUT( $j_1, j_2$ )

```

FIGURE 15.22 Brute force two-dimensional pattern matching algorithm.

function method proposed by Karp and Rabin. To initialize the process, the two-dimensional arrays X and Y are translated into one-dimensional arrays of numbers x and y . The translation from X to x is done as follows ($0 \leq i < m_2$):

$$x[i] = \text{hash}(X[0,i]X[1,i] \cdots X[m_1 - 1,i])$$

and the translation from Y to y is done by ($0 \leq i < m_2$):

$$y[i] = \text{hash}(Y[0,i]Y[1,i] \cdots Y[m_1 - 1,i]).$$

The fingerprint y helps to find occurrences of X starting at row $j = 0$ in Y . It is then updated for each new row in the following way ($0 \leq i < m_2$):

$$\begin{aligned} & \text{hash}(Y[j + 1,i]Y[j + 2,i] \cdots Y[j + m_1,i]) \\ &= \text{REHASH}(Y[j,i], Y[j + m_1,i], \text{hash}(Y[j,i]Y[j + 1,i] \cdots Y[j + m_1 - 1,i])) \end{aligned}$$

(functions *hash* and REHASH are described in Section 15.2.1).

Next value of y is

681	681	681	680	684	683	685
-----	-----	-----	-----	-----	-----	-----

. The occurrence of x at position 1 on y corresponds to an occurrence of X at position $(1, 1)$ on Y .

Since the alphabet of x and y is large, searching for x in y must be done by a string-matching algorithm for which the running time is independent of the size of the alphabet: the KMP suits this application perfectly. Its adaptation is shown in Figure 15.23.

When an occurrence of x is found in y , then one still has to check if an occurrence of X starts in Y at the corresponding position. This is done naively by the procedure of Figure 15.24.

The Zhu–Takaoka algorithm as explained is displayed in Figure 15.25. The search for the pattern is performed row by row starting at row 0 and ending at row $n_1 - m_1$.

15.3.2 Bird–Baker Algorithm

The algorithm designed independently by Bird and Baker for the two-dimensional pattern matching problem combines the use of the Aho–Corasick algorithm and the KMP algorithm. The pattern X is divided into its m_1 rows $R_0 = X[0, 0 \dots m_2 - 1]$ to $R_{m_1-1} = x[m_1 - 1, 0 \dots m_2 - 1]$. The rows are preprocessed into a trie as in the Aho–Corasick algorithm described earlier.

19      do KMP-IN-LINE( $X, m_1, m_2, Y, n_1, n_2, x, y, next, j_2$ )
20          if  $j_1 < n_1 - 1$ 
21              then for  $j_2 \leftarrow 0$  to  $n_2 - 1$ 
22                  do  $y[j_2] \leftarrow \text{REHASH}(Y[j_1 - m_1 + 1, j_2],$ 
23                       $Y[j_1 + 1, j_2], y[j_2])$ 

```

FIGURE 15.25 Zhu-Takaoka two-dimensional pattern matching algorithm.

Example 15.10

Pattern X and the trie of its rows:

$X =$

b	a	a
a	b	b
b	a	a

The search proceeds as follows. The text is read from the upper left corner to the bottom right corner, row by row. When reading the character $Y[j_1, j_2]$ the algorithm checks whether the portion $Y[j_1, j_2 - m_2 + 1 \dots j_2] = R$ matches any of R_0, \dots, R_{m_1-1} using the Aho–Corasick machine. An additional one-dimensional array a of size n_1 is used as follows: $a[j_2] = k$ means that the $k - 1$ first rows R_0, \dots, R_{k-2} of the pattern match,

respectively, the portions of the text: $Y[j_1 - k + 1, j_2 - m_2 + 1 \dots j_2], \dots, Y[j_1 - 1, j_2 - m_2 + 1 \dots j_2]$. Then, if $R = R_{k-1}, a[j_2]$ is incremented to $k + 1$. If not, $a[j_2]$ is set to $s + 1$ where s is the maximum i such that

$$R_0 \cdots R_i = R_{k-s+1} \cdots R_{k-2} R.$$

The value s is computed using the KMP algorithm vertically (in columns). If there exists no such s , $a[j_2]$ is set to 0. Finally, if at some point $a[j_2] = m_1$ an occurrence of the pattern appears at position $(j_1 - m_1 + 1, j_2 - m_2 + 1)$ in the text.

The Bird-Baker algorithm is presented in Figures 15.26 and 15.27. It runs in time $O((n_1 n_2 + m_1 m_2) \log \sigma)$.

```

```

FIGURE 15.27 Bird-Baker two-dimensional pattern matching algorithm.

15.4 Suffix Trees

The suffix tree $S(y)$ of a string y is a trie (as described earlier) containing all the suffixes of the string, and having the properties described subsequently. This data structure serves as an index on the string: it provides a direct access to all segments of the string, and gives the positions of all their occurrences in the string.

Once the suffix tree of a text y is built, searching for x in y remains to spell x along a branch of the tree. If this walk is successful, the positions of the pattern can be output. Otherwise, x does not occur in y .

Any kind of trie that represents the suffixes of a string can be used to search it. But the suffix tree has additional features which imply that its size is linear. The suffix tree of y is defined by the following properties:

- All branches of $S(y)$ are labeled by all suffixes of y .
- Edges of $S(y)$ are labeled by strings.
- Internal nodes of $S(y)$ have at least two children (when y is not empty).
- Edges outgoing an internal node are labeled by segments starting with different letters.
- The preceding segments are represented by their starting positions on y and their lengths.

Moreover, it is assumed that y ends with a symbol occurring nowhere else in it (the dollar sign is used in examples). This avoids marking nodes, and implies that $S(y)$ has exactly n leaves (number of nonempty suffixes). The other properties then imply that the total size of $S(y)$ is $O(n)$, which makes it possible to design a linear-time construction of the trie. The algorithm described in the present section has this time complexity provided the alphabet is fixed, or with an additional multiplicative factor $\log \sigma$ otherwise.

The algorithm inserts all nonempty suffixes of y in the data structure from the longest to the shortest suffix, as shown in Figure 15.28. Two definitions to explain how the algorithm works are introduced:

- $head_j$ is the longest prefix of $y[j \dots n - 1]$ which is also a prefix of $y[i \dots n - 1]$ for some $i < j$.
- $tail_j$ is the word such that $y[j \dots n - 1] = head_j tail_j$.

The strategy to insert the i th suffix in the tree is based on these definitions and described in Figure 15.29.

The second step of the insertion (Figure 15.29) is clearly performed in constant time. Thus, finding the node h is critical for the overall performance of the algorithm. A brute-force method to find it consists in spelling the current suffix $y[j \dots n - 1]$ from the root of the tree, giving an $O(|head_j|)$ time complexity for the insertion at step j , and an $O(n^2)$ running time to build $S(y)$. Adding short-cut links leads to an overall $O(n)$ time complexity, although there is no guarantee that insertion at step j is realized in constant time.

```

SUFFIX-TREE( $y, n$ )
1   $T_{-1} \leftarrow$  one node tree
2  for  $j \leftarrow 0$  to  $n - 1$ 
3      do  $T_j \leftarrow$  INSERT( $T_{j-1}, y[j \dots n - 1]$ )
4  return  $T_{n-1}$ 
    
```

FIGURE 15.28 Construction of a suffix tree for y .

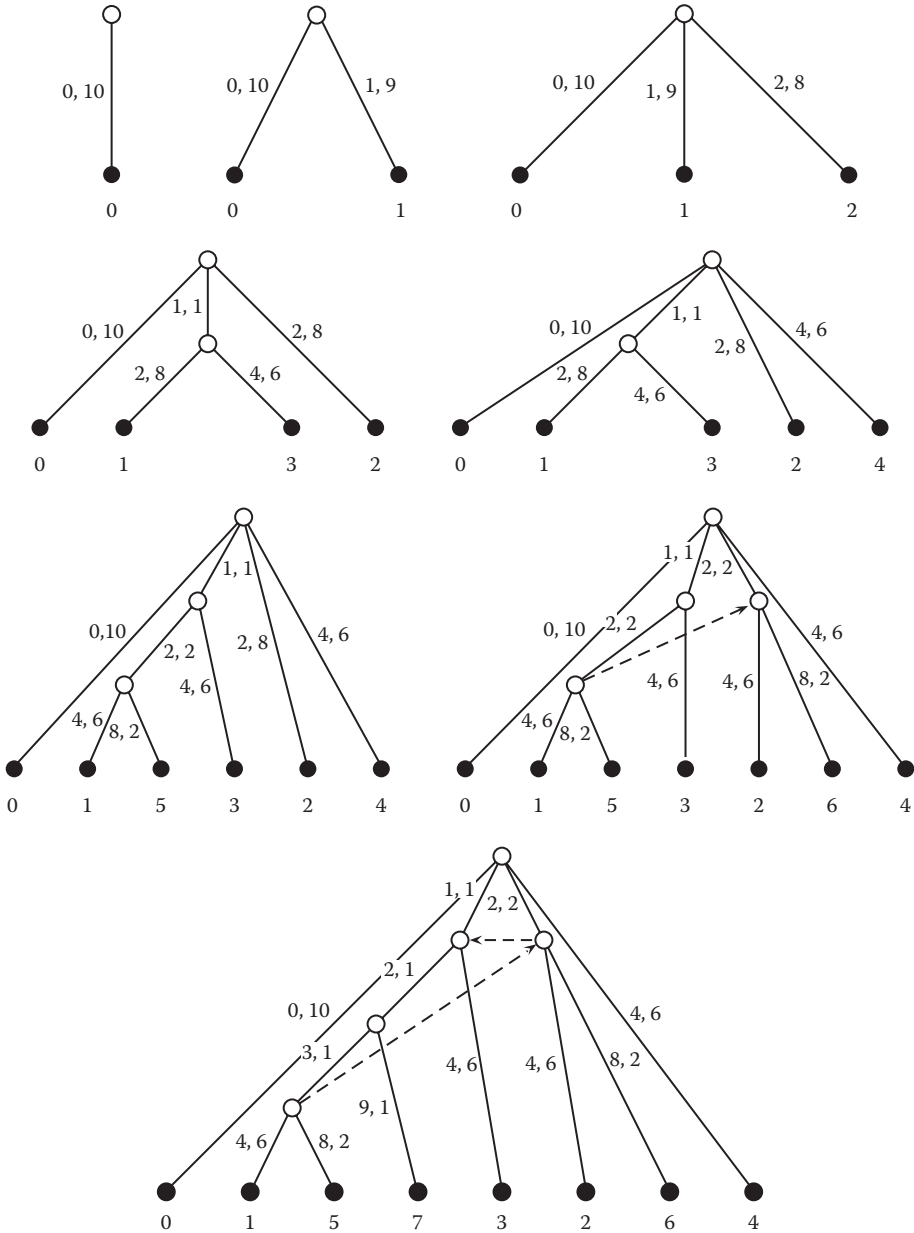

```

INSERT( $T_{j-1}, y[j \dots n - 1]$ )
1  locate the node  $h$  associated with  $head_j$  in  $T_{j-1}$ , possibly breaking an edge
2  add a new edge labeled  $tail_j$  from  $h$  to a new leaf representing  $y[j \dots n - 1]$ 
3  return the modified tree
    
```

FIGURE 15.29 Insertion of a new suffix in the tree.

Example 15.11

The different tries during the construction of the suffix tree of $y = \mathbf{CAGATAGAG}$. Leaves are black and labeled by the position of the suffix they represent. Plain arrows are labeled by pairs: the pair (j, ℓ) stands for the segment $y[j \dots j + \ell - 1]$. Dashed arrows represent the nontrivial suffix links.

15.4.1 McCreight Algorithm

The key to get an efficient construction of the suffix tree $S(y)$ is to add links between nodes of the tree: they are called *suffix links*. Their definition relies on the relationship between $head_{j-1}$ and $head_j$: if $head_{j-1}$ is of the form az ($a \in \Sigma, z \in \Sigma^*$), then z is a prefix of $head_j$. In the suffix tree, the node associated with z is linked to the node associated with az . The suffix link creates a shortcut in the tree that helps with finding the next head efficiently. The insertion of the next suffix, namely, $head_j tail_j$, in the tree reduces to the insertion of $tail_j$ from the node associated with $head_j$.

The following property is an invariant of the construction: in T_j , only the node h associated with $head_j$ can fail to have a valid suffix link. This effectively happens when h has just been created at step j . The procedure to find the next head at step j is composed of two main phases:

A Rescanning: Assume that $head_{j-1} = az$ ($a \in \Sigma, z \in \Sigma^*$) and let d' be the associated node. If the suffix link on d' is defined, it leads to a node d from which the second step starts. Otherwise, the suffix link on d' is found by rescanning as follows. Let c' be the parent of d' , and let (j, ℓ) be the label of edge (c', d') . For the ease of the description, assume that $az = av(y[j \dots j + \ell - 1])$ (it may happen that $az = y[j \dots j + \ell - 1]$). There is a suffix link defined on c' and going to some node c associated with v . The crucial observation here is that $y[j \dots j + \ell - 1]$ is the prefix of the label of some branch starting at node c . Then, the algorithm rescans $y[j \dots j + \ell - 1]$ in the tree: let e be the child of c along that branch, and let (k, m) be the label of edge (c, e) . If $m < \ell$, then a recursive rescan of $q = y[j + m \dots j + \ell - 1]$ starts from node e . If $m > \ell$, the edge (c, e) is broken to insert a new node d ; labels are updated correspondingly. If $m = \ell$, d is simply set to e . If the suffix link of d' is currently undefined, it is set to d .

B Scanning: A downward search starts from d to find the node h associated with $head_j$. The search is dictated by the characters of $tail_{j-1}$ one at a time from left to right. If necessary, a new internal node is created at the end of the scanning.

After the two phases A and B are executed, the node associated with the new head is known, and the tail of the current suffix can be inserted in the tree.

To analyze the time complexity of the entire algorithm, one mainly has to evaluate the total time of all scannings, and the total time of all rescannings. Assume that the alphabet is fixed, so that branching from a node to one of its children can be implemented to take constant time. Thus, the time spent for

```

M(y, n)
1  root ← INIT(y, n)
2  head ← root
3  tail ← child(root, y[0])
4  n ← n - 1
5  while n > 0
6      do if head = root                                ▷ Phase A (rescanning)
7          then d ← root
8              (j, ℓ) ← label(tail)
9              γ ← (j + 1, ℓ - 1)
10         else γ ← label(tail)
11             if link(head) ≠ UNDEFINED
12                 then d ← link(head)
13                 else (j, ℓ) ← label(head)
14                 if parent(head) = root
15                     then d ← RESCAN(root, j + 1, ℓ - 1)
16                     else d ← RESCAN(link(parent(head)), j, ℓ)
17                 link(head) ← d
18         (head, γ) ← SCAN(d, γ)                            ▷ Phase B (scanning)
19         create a new node tail
20         parent(tail) ← head
21         label(tail) ← γ
22         (j, ℓ) ← γ

24         n ← n - 1
25  return root

```

FIGURE 15.30 Suffix tree construction.

all scannings is linear because each letter of y is scanned only once. The same holds true for rescannings because each step downward (through node e) increases strictly the position of the segment of y considered there, and this position never decreases.

An implementation of McCreight's algorithm is shown in Figure 15.30. The next figures (Figures 15.31 through 15.34) give the procedures used by the algorithm, especially procedures RESCAN and SCAN.

The following notation will be used:

- $parent(c)$ is the parent node of the node c .
- $label(c)$ is the pair (i, l) if the edge from the parent node of c to c itself is associated with the factor $y[i \dots i + l - 1]$.
- $child(c, a)$ is the only node that can be reached from the node c with the character a .
- $link(c)$ is the suffix node of the node c .

15.5 Suffix Arrays

Suffix trees are very powerful; however, they are very space consuming. In most cases, they can be replaced by suffix arrays that are more space economical. The technique involves binary search in the sorted list of the text suffixes. In this section, we show how to lexicographically sort the suffixes of a string y of length n . The resulting permutation, as an array, constitutes the suffix array of the string. It is usually enhanced with the LCP array described further in the section to get an efficient string searching algorithm.

The goal of the sorting is to compute a permutation p of the indices on y that satisfies the condition

$$y[p[0]..n-1] < y[p[1]..n-1] < \dots < y[p[n-1]..n-1]. \quad (15.1)$$

Note that the inequalities are strict since two suffixes occurring at distinct positions cannot be identical.

The implementation of a standard lexicographic sorting method (repeated radix sort) leads to an algorithm whose execution time is $O(n^2)$ since the sum of the lengths of the suffixes of y is quadratic.

Actually, the ordering is not entirely sufficient to get an efficient search. The precomputation and the utilization of common prefixes to the suffixes are extra elements that make the technique very efficient. The search for a string of length m in a string length n then takes $O(m + \log n)$ time.

To describe the sorting algorithm, for $u \in \Sigma^*$, we denote by

$$\text{first}_k(u) = \begin{cases} u & \text{if } |u| \leq k, \\ u[0..k-1] & \text{otherwise,} \end{cases}$$

the beginning of order k of the string u .

15.5.1 Kärkkäinen–Sanders Algorithm

In this section, the alphabet of y is assumed to be a bounded segment of integers, as it can be considered in most real applications. With this condition, not only letters can be sorted in linear time but suffixes of y as well.

The present algorithm for sorting the suffixes proceeds in four steps as follows, where k is an appropriate nonnegative integer.

Step 1 Positions i on the input string y are sorted for two-third of them, namely for $i = 3k$ or $i = 3k + 1$, according to $\text{first}_3(y[i \dots n - 1])$.

Let $t[i]$ be the rank of i in the sorted list.

Step 2 Suffixes of the $2/3$ -shorter word $z = t[0]t[3] \dots t[3k] \dots t[1]t[4] \dots t[3k + 1] \dots$ are recursively sorted.

Let $s[i]$ be the rank of suffix at position i on y in the sorted list of them derived from the sorted list of suffixes of z .

Step 3 Suffixes $y[j \dots n - 1]$, for j of the form $3k + 2$, are sorted using the table s .

Step 4 The final step consists in merging the ordered lists obtained at the second and third steps.

A careful implementation of the algorithm leads to a linear running time. It relies on the following elements. The first step can be executed in linear time by using a mere radix sort. Since the order of suffixes $y[j + 1 \dots n - 1]$ is already known from s , the third step can be done in linear time by just radix sorting pairs $(y[j], s[j + 1])$. Comparing suffixes at positions i ($i = 3k$ or $i = 3k + 1$ for the first list) and j ($j = 3k + 2$ for the second list) remains to compare pairs of the form $(y[i], s[i + 1])$ and $(y[j], s[j + 1])$ if $i = 3k$ or pairs of the form $(y[i]y[i + 1], s[i + 2])$ and $(y[j]y[j + 1], s[j + 2])$ if $i = 3k + 1$. This is done in constant time and then the merge at the fourth step can thus be realized in linear time.

An example of a run of the algorithm is shown in Figure 15.35: (1) String $y = \mathbf{abaaabaaabb}$ and its two sets of positions P_{01} and P_2 . (2) Step 1. Strings $\text{first}_3(y[i \dots n - 1])$ for $i \in P_{01}$ and their ranks: $t[i]$ is the

i	0	1	2	3	4	5	6	7	8	9	10

FIGURE 15.35 Building the suffix array of $y = \mathbf{abaabaaabb}$.

rank of i in the sorted list. (3) Step 2. Positions in P_{01} sorted according to their associated suffixes in z , resulting in L_{01} and the table of ranks s . (4) Step 3. Positions j in P_2 sorted according to pairs $(y[j], s[j+1])$ resulting in L_2 . (5) Step 4. Pairs used for comparing positions when merging the sorted lists L_{01} and L_2 . (6) Permutation p corresponding to the sorted suffixes of y .

The algorithm SKEW-SUFFIX-SORT (Figure 15.36) describes the method presented above in a more precise way. To shorten the presentation of the algorithm, the definition of s (see Line 11) is extended to positions n and $n + 1$ that are considered Lines 12 and 13 (call to COMP, Figure 15.37).

The recursivity of the algorithm (Line 8) yields the recurrence relation $T(n) = T(2n/3) + O(n)$, for $n > 3$, and $T(n) = O(1)$, for $n \leq 3$, because all other lines execute in constant time, that is, $O(n)$ time. The recurrence has solution $T(n) = O(n)$, Algorithm SKEW-SUFFIX-SORT computes the suffix array of a string of length n in time $O(n)$.

15.5.2 Substring Search

Searching for a pattern x of length m in the string y using its suffix array can be done by a simple binary search (see Figure 15.38). It returns:

- $(-1, 0)$ if $x < y[p[0] \dots n - 1]$.
- $(n - 1, n)$ if $x > y[p[n - 1] \dots n - 1]$.
- i if x is a prefix of $x[p[i] \dots n - 1]$.
- $(i, i + 1)$ if $y[p[i] \dots n - 1] < x < y[p[i + 1] \dots n - 1]$.

6      if  $k = m$ 
7        then return  $i$ 
8      elseif  $x \leq y[p[i] \dots n - 1]$ 
9        then  $r \leftarrow i$ 
10     else  $\ell \leftarrow i$ 
11  return  $(\ell, r)$ 

```

FIGURE 15.38 Binary search of x in the suffix array of y .

The loop line 3 iterates at most $\log n$ times and each test line 8 can perform at most m character comparisons. Thus the time complexity of algorithm is $O(m \times \log n)$.

15.5.3 Longest Common Prefixes

In this section, the second element that constitutes a suffix array is described: the array LCP storing the maximal lengths of prefixes common to suffixes in the sorted list. We first introduce the following notation for two strings $u, v \in \Sigma^*$:

$$lcp(u, v) = \text{longest common prefix of } u \text{ and } v.$$

We start by the first half of the array LCP storing the maximal lengths of prefixes common to consecutive suffixes in the sorted list. It is defined as follows, for $1 \leq i \leq n - 1$:

$$LCP[i] = lcp(y[p[i-1] \dots n-1], y[p[i] \dots n-1]).$$

A direct computation using letter by letter comparisons leads to an execution time in $O(n^2)$ since the sum of lengths of the suffixes is quadratic.

We describe an algorithm that performs the computation in linear time. Indeed, the suffixes of y are not independent of each other. This dependence allows to reduce the computation time by the mean of a quite simple algorithm, based on the following property: let i, j, i' be positions on y for which $j = p[i]$ and $j - 1 = p[i']$, then $LCP[i'] - 1 \leq LCP[i]$.

Using this result, in order to compute $LCP[i]$, that is, the length of the longest common prefix between $y[p[i] \dots n - 1]$ and $y[p[i - 1] \dots n - 1]$ when $0 < i \leq n$, one can start the letter by letter comparison exactly at the position at which stops the previous computation, the one of $LCP[i']$. Knowing that, it is sufficient to proceed by considering the suffixes from the longest to the shortest, and not in the lexicographic order that seems more natural. This is what Algorithm DEF-HALF-LCP (see Figure 15.39) realizes. It computes the values $LCP[i]$ for $0 \leq i \leq n$. Note that to determine the position i associated with position j , the algorithm uses the reverse of permutation p which is computed in the first step (Lines 1–2). This function is represented by the table called *Rank* since it indicates the rank of each suffix in the sorted list of suffixes of y .

```

DEF-HALF-LCP( $y, n, p$ )
1  for  $i \leftarrow 0$  to  $n - 1$ 
2      do  $Rank[p[i]] \leftarrow i$ 
3   $\ell \leftarrow 0$ 
4  for  $j \leftarrow 0$  to  $n - 1$ 
5      do  $\ell \leftarrow \max\{0, \ell - 1\}$ 
6          $i \leftarrow Rank[j]$ 
7         if  $i \neq 0$ 
8             then  $j' \leftarrow p[i - 1]$ 
9                 while  $j + \ell < n$  and  $j' + \ell < n$ 
                    and  $y[j + \ell] = y[j' + \ell]$ 
10                    do  $\ell \leftarrow \ell + 1$ 
11                else  $\ell \leftarrow 0$ 
12                 $LCP[i] \leftarrow \ell$ 
13  return  $LCP$ 

```

FIGURE 15.39 Linear computation of the first LCP values.

FIGURE 15.40 Pairs considered during the binary search in a string of length 11.

Applied to string y of length n and to the permutation p of its suffixes, Algorithm DEF-HALF-LCP computes the LCP array in time $O(n)$.

The number of pairs (ℓ, r) considered by algorithm BINARY-SEARCH(y, n, p, x, m) is bounded by $2n + 1$: there are $n + 1$ pairs of the form $(i, i + 1)$ that constitute the leaves of a binary tree; thus, there are at most n internal nodes. Figure 15.40 shows an example for a string of length 11. Small numbers close to pairs (ℓ, r) are $i = \lfloor (\ell + r)/2 \rfloor$.

It is thus possible to extend array LCP as follows:

$$LCP[n + 1 + i] = lcp(p[\ell] \dots n - 1, y[p[r] \dots n - 1])$$

where $i = \lfloor (\ell + r)/2 \rfloor$.

The length of the longest common prefix between $y[p[\ell] \dots n - 1]$ and $y[p[r] \dots n - 1]$ when $\ell < r - 1$ is equal to the minimum value among all $LCP[i]$ where $\ell < i \leq r$. Then these values can be computed by a call to the algorithm DEF-LCP($y, 0, n - 1, LCP$) (see Figure 15.41).

15.5.4 Substring Search with the Length of the Common Prefixes

Let ℓ, r, i be three integers, $0 \leq \ell < i < r < n$. If $y[p[\ell] \dots n - 1] < x < y[p[r] \dots n - 1]$ let $lb = |lcp(x, y[p[\ell] \dots n - 1])|$ and $le = |lcp(x, y[p[r] \dots n - 1])|$ satisfying $lb \leq le$. We then have:

$$|lcp(y[p[i] \dots n - 1], y[p[r] \dots n - 1])| < le \text{ implies } y[p[i] \dots n - 1] < x < y[p[r] \dots n - 1]$$

```

DEF-LCP( $y, \ell, r, LCP$ )
1   ▷  $\ell < r$ 
2   if  $\ell + 1 = r$ 
3       then return  $LCP[r]$ 
4   else  $i \leftarrow \lfloor (\ell + r)/2 \rfloor$ 
5        $LCP[n + 1 + i] \leftarrow \min\{\text{DEF-LCP}(y, \ell, i, LCP),$ 
         $\text{DEF-LCP}(y, i, r, LCP)\}$ 
6   return  $LCP[n + 1 + i]$ 

```

FIGURE 15.41 Linear computation of the last LCP values.

```

SEARCH( $y, n, p, LCP, x, m$ )
1  ( $\ell, lb$ )  $\leftarrow (-1, 0)$ 
2  ( $r, le$ )  $\leftarrow (n, 0)$ 
3  while  $\ell + 1 < r$ 
4      do  $i \leftarrow \lfloor (\ell + r)/2 \rfloor$ 
5          if  $\ell + 1 = i$ 
6              then  $g \leftarrow LCP[i]$ 
7              else  $g \leftarrow LCP[n + 1 + \lfloor (\ell + i)/2 \rfloor]$ 
8          if  $i + 1 = r$ 
9              then  $h \leftarrow LCP[r]$ 
10             else  $h \leftarrow LCP[n + 1 + \lfloor (i + r)/2 \rfloor]$ 
11             if  $lb \leq h$  and  $h < le$ 
12                 then ( $\ell, lb$ )  $\leftarrow (i, h)$ 
13             elseif  $lb \leq le$  and  $le < h$ 
14                 then ( $r, le$ )  $\leftarrow (i, h)$ 
15             elseif  $le \leq g$  and  $g < lb$ 
16                 then ( $r, le$ )  $\leftarrow (i, g)$ 
17             elseif  $le \leq lb$  and  $lb < g$ 
18                 then ( $\ell, lb$ )  $\leftarrow (i, g)$ 
19             else  $\ell \leftarrow \max\{lb, le\}$ 
20                  $\ell \leftarrow \ell + |lcp(x[\ell \dots m - 1], y[p[i] + [\ell \dots n - 1]])|$ 
21                 if  $\ell = m$ 
22                     then return  $i$ 
23                 elseif  $x < y[p[i] \dots n - 1]$ 
24                     then ( $r, le$ )  $\leftarrow (i, \ell)$ 
25                 else ( $\ell, lb$ )  $\leftarrow (i, \ell)$ 
26 return ( $\ell, r$ )

```

FIGURE 15.42 Search for x in the suffix array of y using the length of the common prefixes.

and

$$|lcp(y[p[i] \dots n - 1], y[p[r] \dots n - 1])| > le \text{ implies } y[p[\ell] \dots n - 1] < x < y[p[i] \dots n - 1].$$

The search can then now be done in $O(m + \log n)$ with the algorithm SEARCH(y, n, p, LCP, x, m) (see Figure 15.42).

15.6 Alignment

Alignments are used to compare strings. They are widely used in computational molecular biology. They constitute a mean to visualize resemblance between strings. They are based on notions of distance or similarity. Their computation is usually done by dynamic programming. A typical example of this method is the computation of the longest common subsequence of two strings. The reduction of the memory space presented on it can be applied to similar problems. Three different kinds of alignment of two strings x and y are considered: global alignment (that consider the whole strings x and y), local alignment (that enable to find the segment of x that is closer to a segment of y), and the longest common subsequence of x and y .

An **alignment** of two strings x and y of length m and n , respectively, consists in aligning their symbols on vertical lines. Formally, an alignment of two strings $x, y \in \Sigma^*$ is a word w on the alphabet $(\Sigma \cup \{\epsilon\}) \times (\Sigma \cup \{\epsilon\}) \setminus \{(\epsilon, \epsilon)\}$ (ϵ is the empty word) whose projection on the first component is x and whose projection of the second component is y .

Thus, an alignment $w = (\bar{x}_0, \bar{y}_0)(\bar{x}_1, \bar{y}_1) \cdots (\bar{x}_{p-1}, \bar{y}_{p-1})$ of length p is such that $x = \bar{x}_0\bar{x}_1 \cdots \bar{x}_{p-1}$ and $y = \bar{y}_0\bar{y}_1 \cdots \bar{y}_{p-1}$ with $\bar{x}_i \in \Sigma \cup \{\epsilon\}$ and $\bar{y}_i \in \Sigma \cup \{\epsilon\}$ for $0 \leq i \leq p - 1$. The alignment is represented as follows:

$$\begin{array}{cccc} \bar{x}_0 & \bar{x}_1 & \cdots & \bar{x}_{p-1} \\ \bar{y}_0 & \bar{y}_1 & \cdots & \bar{y}_{p-1} \end{array}$$

with the symbol—instead of the symbol ϵ .

Example 15.12

A	C	G	-	-	A
A	T	G	C	T	A

is an alignment of ACGA and ATGCTA.

15.6.1 Global Alignment

A global alignment of two strings x and y can be obtained by computing the distance between x and y . The notion of distance between two strings is widely used to compare files. The **diff** command of UNIX operating system implements an algorithm based on this notion, in which lines of the files are treated as symbols. The output of a comparison made by **diff** gives the minimum number of operations (substitute a symbol, insert a symbol, or delete a symbol) to transform one file into the other.

Let us define the edit distance between two strings x and y as follows: it is the minimum number of elementary edit operations that enable to transform x into y . The elementary edit operations are:

- The substitution of a character of x at a given position by a character of y .
- The deletion of a character of x at a given position.
- The insertion of a character of y in x at a given position.

A cost is associated to each elementary edit operation. For $a, b \in \Sigma$:

- $Sub(a, b)$ denotes the cost of the substitution of the character a by the character b .
- $Del(a)$ denotes the cost of the deletion of the character a .
- $Ins(a)$ denotes the cost of the insertion of the character a .

This means that the costs of the edit operations are independent of the positions where the operations occur. The edit distance of two strings x and y can now be defined by

$$edit(x, y) = \min\{\text{cost of } \gamma \mid \gamma \in \Gamma_{x,y}\}$$

where $\Gamma_{x,y}$ is the set of all the sequences of edit operations that transform x into y , and the cost of an element $\gamma \in \Gamma_{x,y}$ is the sum of the costs of its elementary edit operations.

In order to compute $edit(x, y)$ for two strings x and y of length m and n , respectively, a two-dimensional table T of $m + 1$ rows and $n + 1$ columns is used such that

$$T[i, j] = edit(x[i], y[j])$$

for $i = 0, \dots, m - 1$ and $j = 0, \dots, n - 1$. It follows $edit(x, y) = T[m - 1, n - 1]$.

The values of the table T can be computed by the following recurrence formula:

$$\begin{aligned}
 T[-1, -1] &= 0, \\
 T[i, -1] &= T[i - 1, -1] + Del(x[i]), \\
 T[-1, j] &= T[-1, j - 1] + Ins(y[j]), \\
 T[i, j] &= \min \begin{cases} T[i - 1, j - 1] + Sub(x[i], y[j]), \\ T[i - 1, j] + Del(x[i]), \\ T[i, j - 1] + Ins(y[j]), \end{cases}
 \end{aligned}$$

for $i = 0, 1, \dots, m - 1$ and $j = 0, 1, \dots, n - 1$.

The value at position (i, j) in the table T only depends on the values at the three neighbor positions $(i - 1, j - 1)$, $(i - 1, j)$, and $(i, j - 1)$.

The direct application of the recurrence formula mentioned earlier gives an exponential time algorithm to compute $T[m - 1, n - 1]$. However, the whole table T can be computed in quadratic time, technique known as “dynamic programming.” This is a general technique that is used to solve the different kinds of alignments.

The computation of the table T proceeds in two steps. First, it initializes the first column and first row of T ; this is done by a call to a generic function MARGIN which is a parameter of the algorithm and that depends on the kind of alignment that is considered. Second, it computes the remaining values of T ; this is done by a call to a generic function FORMULA which is a parameter of the algorithm and that depends on the kind of alignment that is considered. Computing a global alignment of x and y can be done by a call to GENERIC-DP with the following parameters $(x, m, y, n, \text{MARGIN-GLOBAL}, \text{FORMULA-GLOBAL})$ (see Figures 15.43 through 15.45). The computation of all the values of the table T can thus be done in quadratic space and time: $O(m \times n)$.

```

GENERIC-DP( $x, m, y, n, \text{MARGIN}, \text{FORMULA}$ )
1  MARGIN( $T, x, m, y, n$ )
2  for  $j \leftarrow 0$  to  $n - 1$ 
3      do for  $i \leftarrow 0$  to  $m - 1$ 
4          do  $T[i, j] \leftarrow \text{FORMULA}(T, x, i, y, j)$ 
5  return  $T$ 
    
```

FIGURE 15.43 Computation of the table T by dynamic programming.

```

MARGIN-GLOBAL( $T, x, m, y, n$ )
1   $T[-1, -1] \leftarrow 0$ 
2  for  $i \leftarrow 0$  to  $m - 1$ 
3      do  $T[i, -1] \leftarrow T[i - 1, -1] + Del(x[i])$ 
4  for  $j \leftarrow 0$  to  $n - 1$ 
5      do  $T[-1, j] \leftarrow T[-1, j - 1] + Ins(y[j])$ 
    
```

```

FORMULA-GLOBAL( $T, x, i, y, j$ )
1  return min  $\begin{cases} T[i - 1, j - 1] + Sub(x[i], y[j]) \\ T[i - 1, j] + Del(x[i]) \\ T[i, j - 1] + Ins(y[j]) \end{cases}$ 
    
```

FIGURE 15.45 Computation of $T[i, j]$ for a global alignment.

```

ONE-ALIGNMENT( $T, x, i, y, j$ )
1  if  $i = -1$  and  $j = -1$ 
2      then return  $(\epsilon, \epsilon)$ 
3  else if  $i = -1$ 
4      then return ONE-ALIGNMENT( $T, x, -1, y, j - 1$ )  $\cdot (\epsilon, y[j])$ 
5  elseif  $j = -1$ 
6      then return ONE-ALIGNMENT( $T, x, i - 1, y, -1$ )  $\cdot (x[i], \epsilon)$ 
7  else if  $T[i, j] = T[i - 1, j - 1] + \text{Sub}(x[i], y[j])$ 
8      then return ONE-ALIGNMENT( $T, x, i - 1, y, j - 1$ )
           $(x[i], y[j])$ 
9  elseif  $T[i, j] = T[i - 1, j] + \text{Del}(x[i])$ 
10     then return ONE-ALIGNMENT( $T, x, i - 1, y, j$ )
           $(x[i], \epsilon)$ 
11     else return ONE-ALIGNMENT( $T, x, i, y, j - 1$ )
           $(\epsilon, y[j])$ 

```

FIGURE 15.46 Recovering an optimal alignment.

An optimal alignment (with minimal cost) can then be produced by a call to the function

$$\text{ONE-ALIGNMENT}(T, x, m - 1, y, n - 1)$$

(see Figure 15.46). It consists in tracing back the computation of the values of the table T from position $[m - 1, n - 1]$ to position $[-1, -1]$. At each cell $[i, j]$, the algorithm determines among the three values $T[i - 1, j - 1] + \text{Sub}(x[i], y[j])$, $T[i - 1, j] + \text{Del}(x[i])$, and $T[i, j - 1] + \text{Ins}(y[j])$, which has been used to produce the value of $T[i, j]$. If $T[i - 1, j - 1] + \text{Sub}(x[i], y[j])$ has been used, it adds $(x[i], y[j])$ to the optimal alignment and proceeds recursively with the cell at $[i - 1, j - 1]$. If $T[i - 1, j] + \text{Del}(x[i])$ has been used, it adds $(x[i], -)$ to the optimal alignment and proceeds recursively with cell at $[i - 1, j]$. If $T[i, j - 1] + \text{Ins}(y[j])$ has been used it adds $(-, y[j])$ to the optimal alignment and proceeds recursively with cell at $[i, j - 1]$. Recovering all the optimal alignments can be done by a similar technique.

Example 15.13

T	j	-1	0	1	2	3	4	5
i		$y[j]$	A	T	G	C	T	A
-1	$x[i]$	0	1	2	3	4	5	6
0	A	1	0	1	2	3	4	5
1	C	2	1	1	2	2	3	4
2	G	3	2	2	1	2	3	4
3	A	4	3	3	2	2	3	3

The values of the above table have been obtained with the following unitary costs: $\text{Sub}(a, b) = 1$ if $a \neq b$ and $\text{Sub}(a, a) = 0$, $\text{Del}(a) = \text{Ins}(a) = 1$ for $a, b \in \Sigma$.

15.6.2 Local Alignment

A local alignment of two strings x and y consists in finding the segment of x that is closer to a segment of y . The notion of distance used to compute global alignments cannot be used in that case since the segments of x closer to segments of y would only be the empty segment or individual characters. This is why a notion of similarity is used based on a scoring scheme for edit operations.

A score (instead of a cost) is associated to each elementary edit operation. For $a, b \in \Sigma$:

- $Sub_s(a, b)$ denotes the score of substituting the character b for the character a .
- $Del_s(a)$ denotes the score of deleting the character a .
- $Ins_s(a)$ denotes the score of inserting the character a .

This means that the scores of the edit operations are independent of the positions where the operations occur. For two characters a and b , a positive value of $Sub_s(a, b)$ means that the two characters are close to each other, and a negative value of $Sub_s(a, b)$ means that the two characters are far apart.

The edit score of two strings x and y can now be defined by

$$sco(x, y) = \max\{\text{score of } \gamma \mid \gamma \in \Gamma_{x,y}\}$$

where $\Gamma_{x,y}$ is the set of all the sequences of edit operations that transform x into y and the score of an element $\sigma \in \Gamma_{x,y}$ is the sum of the scores of its elementary edit operations.

In order to compute $sco(x, y)$ for two strings x and y of length m and n , respectively, a two-dimensional table T of $m + 1$ rows and $n + 1$ columns is used such that

$$T[i, j] = sco(x[i], y[j])$$

for $i = 0, \dots, m - 1$ and $j = 0, \dots, n - 1$. Therefore $sco(x, y) = T[m - 1, n - 1]$.

The values of the table T can be computed by the following recurrence formula:

$$\begin{aligned} T[-1, -1] &= 0, \\ T[i, -1] &= 0, \\ T[-1, j] &= 0, \\ T[i, j] &= \max \begin{cases} T[i - 1, j - 1] + Sub_s(x[i], y[j]), \\ T[i - 1, j] + Del_s(x[i]), \\ T[i, j - 1] + Ins_s(y[j]), \\ 0, \end{cases} \end{aligned}$$

for $i = 0, 1, \dots, m - 1$ and $j = 0, 1, \dots, n - 1$.

Computing the values of T for a local alignment of x and y can be done by a call to GENERIC-DP with the following parameters ($x, m, y, n, \text{MARGIN-LOCAL}, \text{FORMULA-LOCAL}$) in $O(mn)$ time and space complexity (see Figures 15.43, 15.47, and 15.48). Recovering a local alignment can be done in a way similar to what is done in the case of a global alignment (see Figure 15.46) but the trace back procedure must start at a position of a maximal value in T rather than at position $[m - 1, n - 1]$.

```

MARGIN-LOCAL( $T, x, m, y, n$ )
1   $T[-1, -1] \leftarrow 0$ 
2  for  $i \leftarrow 0$  to  $m - 1$ 
3      do  $T[i, -1] \leftarrow 0$ 
4  for  $j \leftarrow 0$  to  $n - 1$ 
5      do  $T[-1, j] \leftarrow 0$ 
    
```

FIGURE 15.47 Margin initialization for computing a local alignment.

```

FORMULA-LOCAL( $T, x, i, y, j$ )
1 return  $\max \begin{cases} T[i - 1, j - 1] + Sub_S(x[i], y[j]) \\ T[i - 1, j] + Del_S(x[i]) \\ T[i, j - 1] + Ins_S(y[j]) \\ 0 \end{cases}$ 
    
```

FIGURE 15.48 Recurrence formula for computing a local alignment.

Example 15.14

Computation of an optimal local alignment of

$x = \mathbf{EAWACQGKL}$ and $y = \mathbf{ERDAWCQPGKWY}$ with scores:

$Sub_S(a, a) = 1, Sub_S(a, b) = -3$ and $Del_S(a) = Ins_S(a) = -1$ for $a, b \in \Sigma, a \neq b$.

T	j	-1	0	1	2	3	4	5	6	7	8	9	10	11
i		$y[j]$	E	R	D	A	W	C	Q	P	G	K	W	Y
-1	$x[i]$	0	0	0	0	0	0	0	0	0	0	0	0	0
0	E	0	1	0	0	0	0	0	0	0	0	0	0	0
1	A	0	0	0	0	1	0	0	0	0	0	0	0	0
2	W	0	0	0	0	0	2	1	0	0	0	0	1	0
3	A	0	0	0	0	1	1	0	0	0	0	0	0	0
4	C	0	0	0	0	0	0	2	1	0	0	0	0	0
5	Q	0	0	0	0	0	0	1	3	2	1	0	0	0
6	G	0	0	0	0	0	0	0	2	1	3	2	1	0
7	K	0	0	0	0	0	0	0	1	0	2	4	3	2
8	L	0	0	0	0	0	0	0	0	0	1	3	2	1

The corresponding optimal local alignment is

```

A  W  A  C  Q  -  G  K
A  W  -  C  Q  P  G  K
    
```

15.6.3 Longest Common Subsequence of Two Strings

A subsequence of a word x is obtained by deleting zero or more characters from x . More formally $w[0 \dots i - 1]$ is a subsequence of $x[0 \dots m - 1]$ if there exists an increasing sequence of integers $(k_j \mid j = 0, \dots, i - 1)$ such that for $0 \leq j \leq i - 1, w[j] = x[k_j]$. A word is an **lcs**(x, y) if it is a **longest common subsequence**

```

FORMULA-LCS( $T, x, i, y, j$ )
1  if  $x[i] = y[j]$ 
2     then return  $T[i - 1, j - 1] + 1$ 
3     else return  $\max\{T[i - 1, j], T[i, j - 1]\}$ 

```

FIGURE 15.49 Recurrence formula for computing an *lcs*.

of the two words x and y . Note that two strings can have several longest common subsequences. Their common length is denoted by $\text{llcs}(x, y)$.

A brute-force method to compute an $\text{lcs}(x, y)$ would consist in computing all the subsequences of x , checking if they are subsequences of y , and keeping the longest one. The word x of length m has 2^m subsequences, and so this method could take $O(2^m)$ time, which is impractical even for fairly small values of m .

However, $\text{llcs}(x, y)$ can be computed with a two-dimensional table T by the following recurrence formula:

$$\begin{aligned}
 T[-1, -1] &= 0, \\
 T[i, -1] &= 0, \\
 T[-1, j] &= 0, \\
 T[i, j] &= \begin{cases} T[i - 1, j - 1] + 1 & \text{if } x[i] = y[j], \\ \max(T[i - 1, j], T[i, j - 1]) & \text{otherwise,} \end{cases}
 \end{aligned}$$

for $i = 0, 1, \dots, m - 1$ and $j = 0, 1, \dots, n - 1$. Then $T[i, j] = \text{llcs}(x[0 \dots i], y[0 \dots j])$ and $\text{llcs}(x, y) = T[m - 1, n - 1]$.

Computing $T[m - 1, n - 1]$ can be done by a call to `GENERIC-DP` with the following parameters ($x, m, y, n, \text{MARGIN-LOCAL}, \text{FORMULA-LCS}$) in $O(mn)$ time and space complexity (see Figures 15.43, 15.47, and 15.49).

It is possible afterward to trace back a path from position $[m - 1, n - 1]$ in order to exhibit an $\text{lcs}(x, y)$ in a similar way as for producing a global alignment (see Figure 15.46).

Example 15.15

The value $T[4, 8] = 4$ is $\text{llcs}(x, y)$ for $x = \text{AGCGA}$ and $y = \text{CAGATAGAG}$. String **AGGA** is an *lcs* of x and y .

T	j	-1	0	1	2	3	4	5	6	7	8
i		$y[j]$	C	A	G	A	T	A	G	A	G
-1	$x[i]$	0	0	0	0	0	0	0	0	0	0
0	A	0	0	1	1	1	1	1	1	1	1
1	G	0	0	1	2	2	2	2	2	2	2
2	C	0	1	1	2	2	2	2	2	2	2
3	G	0	1	1	2	2	2	2	3	3	3
4	A	0	1	2	2	3	3	3	3	4	4

15.6.4 Reducing the Space: Hirschberg Algorithm

If only the length of an $\text{lcs}(x, y)$ is required, it is easy to see that only one row (or one column) of the table T needs to be stored during the computation. The space complexity becomes $O(\min(m, n))$ as can be checked on the algorithm of Figure 15.50. Indeed, the Hirschberg algorithm computes an $\text{lcs}(x, y)$ in linear space and not only the value $\text{llcs}(x, y)$. The computation uses the algorithm of Figure 15.50.

Let us define

$$T^*[i, n] = T^*[m, j] = 0, \text{ for } 0 \leq i \leq m \text{ and } 0 \leq j \leq n$$

$$T^*[m-i, n-j] = \text{llcs}((x[i \dots m-1])^R, (y[j \dots n-1])^R)$$

$$\text{for } 0 \leq i \leq m-1 \text{ and } 0 \leq j \leq n-1$$

and

$$M(i) = \max_{0 \leq j < n} \{T[i, j] + T^*[m-i, n-j]\}.$$

where the word w^R is the reverse (or mirror image) of the word w . The following property is the key observation to compute an $\text{lcs}(x, y)$ in linear space:

$$M(i) = T[m-1, n-1], \text{ for } 0 \leq i < m.$$

In the algorithm shown in Figure 15.51, the integer j is chosen as $n/2$. After $T[i, j-1]$ and $T^*[m-i, n-j]$ ($0 \leq i < m$) are computed, the algorithm finds an integer k such that $T[i, k] + T^*[m-i, n-k] = T[m-1, n-1]$. Then, recursively, it computes an $\text{lcs}(x[0 \dots k-1], y[0 \dots j-1])$ and an $\text{lcs}(x[k \dots m-1], y[j \dots n-1])$, and concatenates them to get an $\text{lcs}(x, y)$.

The running time of the Hirschberg algorithm is still $O(mn)$, but the amount of space required for the computation becomes $O(\min(m, n))$ instead of being quadratic when computed by dynamic programming.

```

LLCS( $x, m, y, n$ )
1  for  $i \leftarrow -1$  to  $m-1$ 
2      do  $C[i] \leftarrow 0$ 
3  for  $j \leftarrow 0$  to  $n-1$ 
4      do  $last \leftarrow 0$ 
5      for  $i \leftarrow -1$  to  $m-1$ 
6          do if  $last > C[i]$ 
7              then  $C[i] \leftarrow last$ 
8              elseif  $last < C[i]$ 
9                  then  $last \leftarrow C[i]$ 
10             elseif  $x[i] = y[j]$ 
11                 then  $C[i] \leftarrow C[i] + 1$ 
12                      $last \leftarrow last + 1$ 
13  return  $C$ 

```

FIGURE 15.50 $O(m)$ -space algorithm to compute $\text{llcs}(x, y)$.

```

HIRSCHBERG( $x, m, y, n$ )
1  if  $m = 0$ 
2    then return  $\varepsilon$ 
3  else if  $m = 1$ 
4    then if  $x[0] \in y$ 
5      then return  $x[0]$ 
6      else return  $\varepsilon$ 
7    else  $j \leftarrow \lfloor n/2 \rfloor$ 
8       $C \leftarrow \text{LLCS}(x, m, y[0 \dots j-1], j)$ 
9       $C^* \leftarrow \text{LLCS}(x^R, m, y[j \dots n-1]^R, n-j)$ 
10      $k \leftarrow m-1$ 
11      $M \leftarrow C[m-1] + C^*[m-1]$ 
12     for  $j \leftarrow -1$  to  $m-2$ 
13       do if  $C[j] + C^*[j] > M$ 
14         then  $M \leftarrow C[j] + C^*[j]$ 
15          $k \leftarrow j$ 
16     return  $\text{HIRSCHBERG}(x[0 \dots k-1], k, y[0 \dots j-1], j)$ .
            $\text{HIRSCHBERG}(x[k \dots m-1], m-k,$ 
            $y[j \dots n-1], n-j)$ 

```

FIGURE 15.51 $O(\min(m, n))$ -space computation of $\text{lcs}(x, y)$.

15.7 Approximate String Matching

Approximate string matching is the problem of finding all approximate occurrences of a pattern x of length m in a text y of length n . Approximate occurrences of x are segments of y that are close to x according to a specific distance: the distance between segments and x must be not greater than a given integer k . Two distances are considered in this section: the **Hamming distance** and the **Levenshtein distance**.

With the Hamming distance, the problem is also known as approximate string matching with k mismatches. With the Levenshtein distance (or edit distance), the problem is known as approximate string matching with k differences.

The Hamming distance between two words w_1 and w_2 of the same length is the number of positions with different characters. The Levenshtein distance between two words w_1 and w_2 (not necessarily of the same length) is the minimal number of differences between the two words. A difference is one of the following operations:

- A substitution: a character of w_1 corresponds to a different character in w_2 .
- An insertion: a character of w_1 corresponds to no character in w_2 .
- A deletion: a character of w_2 corresponds to no character in w_1 .

The *Shift-Or algorithm* of the next section is a method that is both very fast in practice and very easy to implement. It solves the Hamming distance and the Levenshtein distance problems. The method for the exact string-matching problem is initially described and then it is presented how to handle the cases of k mismatches and of k differences. The method is flexible enough to be adapted to a wide range of similar approximate matching problems.

15.7.1 Shift-Or Algorithm

An algorithm to solve the exact string-matching problem is first presented that uses a technique different from those developed in Section 15.2, but which extends readily to the approximate string-matching problem.

FIGURE 15.52 Meaning of vector \mathbf{R}_j^0 .

Let \mathbf{R}^0 be a bit array of size m . Vector \mathbf{R}_j^0 is the value of the entire array \mathbf{R}^0 after text character $y[j]$ has been processed (see Figure 15.52). It contains information about all matches of prefixes of x that end at position j in the text. It is defined, for $0 \leq i \leq m - 1$, by

$$\mathbf{R}_j^0[i] = \begin{cases} 0 & \text{if } x[0..i] = y[j-i..j], \\ 1 & \text{otherwise.} \end{cases}$$

Therefore, $\mathbf{R}_j^0[m-1] = 0$ is equivalent to saying that an (exact) occurrence of the pattern x ends at position j in y .

The vector \mathbf{R}_j^0 can be computed after \mathbf{R}_{j-1}^0 by the following recurrence relation:

$$\mathbf{R}_j^0[i] = \begin{cases} 0 & \text{if } \mathbf{R}_{j-1}^0[i-1] = 0 \text{ and } x[i] = y[j], \\ 1 & \text{otherwise,} \end{cases}$$

and

$$\mathbf{R}_j^0[0] = \begin{cases} 0 & \text{if } x[0] = y[j], \\ 1 & \text{otherwise.} \end{cases}$$

The transition from \mathbf{R}_{j-1}^0 to \mathbf{R}_j^0 can be computed very fast as follows. For each $a \in \Sigma$, let S_a be a bit array of size m defined, for $0 \leq i \leq m - 1$, by

$$S_a[i] = 0 \quad \text{iff} \quad x[i] = a.$$

The array S_a denotes the positions of the character a in the pattern x . All arrays S_a are preprocessed before the search starts. And the computation of \mathbf{R}_j^0 reduces to two operations, SHIFT and OR:

$$\mathbf{R}_j^0 = \text{SHIFT}(\mathbf{R}_{j-1}^0) \quad \text{OR} \quad S_{y[j]}.$$

Example 1.16

String $x = \text{GATAA}$ occurs at position 2 in $y = \text{CAGATAAGAGAA}$.

	S_A	S_C	S_G	S_T
	1	1	0	1
	0	1	1	1
	1	1	1	0
	0	1	1	1
	0	1	1	1

	C	A	G	A	T	A	A	G	A	G	A	A
G	1	1	0	1	1	1	1	0	1	0	1	1
A	1	1	1	0	1	1	1	1	0	1	0	1
T	1	1	1	1	0	1	1	1	1	1	1	1
A	1	1	1	1	1	0	1	1	1	1	1	1
A	1	1	1	1	1	1	0	1	1	1	1	1

15.7.2 String Matching with k Mismatches

The Shift-Or algorithm easily adapts to support approximate string matching with k mismatches. To simplify the description, the case where at most one substitution is allowed is presented first.

Arrays \mathbf{R}^0 and S are used as before, and an additional bit array \mathbf{R}^1 of size m . Vector \mathbf{R}_{j-1}^1 indicates all matches with at most one substitution up to the text character $y[j-1]$. The recurrence on which the computation is based splits into two cases:

- There is an exact match on the first i characters of x up to $y[j-1]$ (i.e., $\mathbf{R}_{j-1}^0[i-1] = 0$). Then, substituting $x[i]$ to $y[j]$ creates a match with one substitution (see Figure 15.53). Thus,

$$\mathbf{R}_j^1[i] = \mathbf{R}_{j-1}^0[i-1].$$

- There is a match with one substitution on the first i characters of x up to $y[j-1]$ and $x[i] = y[j]$. Then, there is a match with one substitution of the first $i+1$ characters of x up to $y[j]$ (see Figure 15.54). Thus,

$$\mathbf{R}_j^1[i] = \begin{cases} \mathbf{R}_{j-1}^1[i-1] & \text{if } x[i] = y[j], \\ 1 & \text{otherwise.} \end{cases}$$

FIGURE 15.53 If $\mathbf{R}_{j-1}^0[i-1] = 0$ then $\mathbf{R}_j^1[i] = 0$.

FIGURE 15.54 $\mathbf{R}_j^1[i] = \mathbf{R}_{j-1}^1[i-1]$ if $x[i] = y[j]$.

This implies that R_j^1 can be updated from R_{j-1}^1 by the relation:

$$R_j^1 = (\text{SHIFT}(R_{j-1}^1) \text{ OR } S_{y[j]}) \text{ AND } \text{SHIFT}(R_{j-1}^0).$$

Example 1.17

String $x = \text{GATAA}$ occurs at positions 2 and 7 in $y = \text{CAGATAAGAGAA}$ with no more than one mismatch.

	C	A	G	A	T	A	A	G	A	G	A	A
G	0	0	0	0	0	0	0	0	0	0	0	0
A	1	0	1	0	1	0	0	1	0	1	0	0
T	1	1	1	1	0	1	1	1	1	0	1	0
A	1	1	1	1	1	0	1	1	1	1	0	1
A	1	1	1	1	1	1	0	1	1	1	1	0

15.7.3 String Matching with k Differences

In this section, it is shown how to adapt the Shift-Or algorithm to the case of only one insertion, and then dually to the case of only one deletion. The method is based on the following elements.

One insertion is allowed: here, vector R_{j-1}^1 indicates all matches with at most one insertion up to text character $y[j-1]$. Entry $R_{j-1}^1[i] = 0$ if the first i characters of x ($x[0 \dots i-1]$) match i symbols of the last $i+1$ text characters up to $y[j-1]$. Array R^0 is maintained as before, and array R^1 is maintained as follows. Two cases arise:

- There is an exact match on the first $i+1$ characters of x ($x[0 \dots i]$) up to $y[j-1]$. Then inserting $y[j]$ creates a match with one insertion up to $y[j]$ (see Figure 15.55). Thus,

$$R_j^1[i] = R_{j-1}^0[i].$$

FIGURE 15.55 If $R_{j-1}^0[i] = 0$ then $R_j^1[i] = 0$.

FIGURE 15.56 $R_j^1[i] = R_{j-1}^1[i-1]$ if $x[i] = y[j]$.

- There is a match with one insertion on the i first characters of x up to $y[j - 1]$. Then if $x[i] = y[j]$, there is a match with one insertion on the first $i + 1$ characters of x up to $y[j]$ (see Figure 15.56). Thus,

$$R_j^1[i] = \begin{cases} R_{j-1}^1[i-1] & \text{if } x[i] = y[j], \\ 1 & \text{otherwise.} \end{cases}$$

This shows that R_j^1 can be updated from R_{j-1}^1 with the formula

$$R_j^1 = (\text{SHIFT}(R_{j-1}^1) \text{ OR } S_{y[j]}) \text{ AND } R_{j-1}^0.$$

Example 1.18

GATAAG is an occurrence of $x = \text{GATAA}$ with exactly one insertion in $y = \text{CAGATAAGAGAA}$

	C	A	G	A	T	A	A	G	A	G	A	A
G	1	1	1	0	1	1	1	1	0	1	0	1
A	1	1	1	1	0	1	1	1	1	0	1	0
T	1	1	1	1	1	0	1	1	1	1	1	1
A	1	1	1	1	1	1	0	1	1	1	1	1
A	1	1	1	1	1	1	1	0	1	1	1	1

One deletion is allowed: assume here that R_{j-1}^1 indicates all possible matches with at most one deletion up to $y[j - 1]$. As in the previous solution, two cases arise:

- There is an exact match on the first $i + 1$ characters of x ($x[0 \dots i]$) up to $y[j]$ (i.e., $R_j^0[i] = 0$). Then, deleting $x[i]$ creates a match with one deletion (see Figure 15.57). Thus,

$$R_j^1[i] = R_j^0[i].$$

- There is a match with one deletion on the first i characters of x up to $y[j - 1]$ and $x[i] = y[j]$. Then, there is a match with one deletion on the first $i + 1$ characters of x up to $y[j]$ (see Figure 15.58). Thus,

$$R_j^1[i] = \begin{cases} R_{j-1}^1[i-1] & \text{if } x[i] = y[j], \\ 1 & \text{otherwise.} \end{cases}$$

FIGURE 15.57 If $R_j^0[i] = 0$ then $R_j^1[i] = 0$.

FIGURE 15.58 $R_j^1[i] = R_{j-1}^1[i - 1]$ if $x[i] = y[j]$.

The discussion provides the following formula used to update R_j^1 from R_{j-1}^1 :

$$R_j^1 = (\text{SHIFT}(R_{j-1}^1) \text{ OR } S_{y[j]}) \text{ AND } \text{SHIFT}(R_j^0).$$

Example 1.19

GATA and ATAA are two occurrences with one deletion of $x = \text{GATAA}$ in $y = \text{CAGATAAGAGAA}$

	C	A	G	A	T	A	A	G	A	G	A	A
G	0	0	0	0	0	0	0	0	0	0	0	0
A	1	0	0	0	1	0	0	0	0	0	0	0
T	1	1	1	0	0	1	1	1	0	1	0	1
A	1	1	1	1	0	0	1	1	1	1	1	0
A	1	1	1	1	1	0	0	1	1	1	1	1

15.7.4 Wu–Manber Algorithm

In this section, a general solution for the approximate string-matching problem with at most k differences of the types: insertion, deletion, and substitution is presented. It is an extension of the problems presented above. The following algorithm maintains $k + 1$ bit arrays R^0, R^1, \dots, R^k that are described now. The vector R^0 is maintained similarly as in the exact matching case (Section 15.7.1). The other vectors are computed with the formula ($1 \leq \ell \leq k$)

$$\begin{aligned}
 R_j^\ell &= (\text{SHIFT}(R_{j-1}^\ell) \text{ OR } S_{y[j]}) \\
 &\quad \text{AND } \text{SHIFT}(R_j^{\ell-1}) \\
 &\quad \text{AND } \text{SHIFT}(R_{j-1}^{\ell-1}) \\
 &\quad \text{AND } R_{j-1}^{\ell-1}
 \end{aligned}$$

which can be rewritten into

$$\begin{aligned}
 R_j^\ell &= (\text{SHIFT}(R_{j-1}^\ell) \text{ OR } S_{y[j]}) \\
 &\quad \text{AND } \text{SHIFT}(R_j^{\ell-1} \text{ AND } R_{j-1}^{\ell-1}) \\
 &\quad \text{AND } R_{j-1}^{\ell-1}.
 \end{aligned}$$

```

WM( $x, m, y, n, k$ )
1  for each character  $a \in \Sigma$ 
2      do  $S_a \leftarrow 1^m$ 
3  for  $i \leftarrow 0$  to  $m - 1$ 
4      do  $S_{x[i]}[i] \leftarrow 0$ 
5   $\mathbf{R}^0 \leftarrow 1^m$ 
6  for  $\ell \leftarrow 1$  to  $k$ 
7      do  $\mathbf{R}^\ell \leftarrow \text{SHIFT}(\mathbf{R}^{\ell-1})$ 
8  for  $j \leftarrow 0$  to  $n - 1$ 
9      do  $T \leftarrow \mathbf{R}^0$ 
10      $\mathbf{R}^0 \leftarrow \text{SHIFT}(\mathbf{R}^0) \text{ OR } S_{y[j]}$ 
11     for  $\ell \leftarrow 1$  to  $k$ 
12         do  $T' \leftarrow \mathbf{R}^\ell$ 
13          $\mathbf{R}^\ell \leftarrow (\text{SHIFT}(\mathbf{R}^\ell) \text{ OR } S_{y[j]}) \text{ AND}$ 
14              $(\text{SHIFT}(T \text{ AND } \mathbf{R}^{\ell-1}) \text{ AND } T$ 
15              $T \leftarrow T'$ 
16     if  $\mathbf{R}^k[m - 1] = 0$ 
17         then OUTPUT( $j$ )

```

FIGURE 15.59 Wu–Manber approximate string-matching algorithm.

Example 15.20

$x = \text{GATAA}$ and $y = \text{CAGATAAGAGAA}$ and $k = 1$. The output 5, 6, 7, and 11 corresponds to the segments **GATA**, **GATAA**, **GATAAG**, and **GAGAA** which approximate the pattern **GATAA** with no more than one difference.

	C	A	G	A	T	A	A	G	A	G	A	A
G	0	0	0	0	0	0	0	0	0	0	0	0
A	1	0	0	0	0	0	0	0	0	0	0	0
T	1	1	1	0	0	0	1	1	0	0	0	0
A	1	1	1	1	0	0	0	1	1	1	0	0
A	1	1	1	1	1	0	0	0	1	1	1	0

The method, called the Wu–Manber algorithm, is implemented in Figure 15.59. It assumes that the length of the pattern is no more than the size of the memory word of the machine, which is often the case in applications.

The preprocessing phase of the algorithm takes $O(\sigma m + km)$ memory space, and runs in time $O(\sigma m + k)$. The time complexity of its searching phase is $O(kn)$.

15.8 Text Compression

This section is interested in algorithms that compress texts. Compression serves both to save storage space and to save transmission time. Assume that the uncompressed text is stored in a file. The aim of compression algorithms is to produce another file containing the compressed version of the same text. Methods in this section work with no loss of information, so that decompressing the compressed text restores exactly the original text.

Two main strategies to design the algorithms are applied. The first strategy is a statistical method that takes into account the frequencies of symbols to build a uniquely decipherable code optimal with respect to the compression. The code contains new codewords for the symbols occurring in the text. In this method, fixed-length blocks of bits are encoded by different codewords. *A contrario* the second strategy encodes variable-length segments of the text. To put it simply, the algorithm, while scanning the text, replaces some already read segments just by a pointer to their first occurrences.

Text compression software often use a mixture of several methods. An example of that is given in Section 15.8.3 which contains in particular two classical simple compression algorithms. They compress efficiently only a small variety of texts when used alone. But they become more powerful with the special preprocessing presented there.

15.8.1 Huffman Coding

The Huffman method is an optimal statistical coding. It transforms the original code used for characters of the text (ASCII code on 8 bits, for instance). Coding the text is just replacing each symbol (more exactly each occurrence of it) by its new codeword. The method works for any length of blocks (not only 8 bits), but the running time grows rapidly with the length. In the following, one assumes that symbols are originally encoded on 8 bits to simplify the description.

The Huffman algorithm uses the notion of **prefix code**. A prefix code is a set of words containing no word that is a prefix of another word of the set. The advantage of such a code is that decoding is immediate. Moreover, it can be proved that this type of code does not weaken the compression.

A prefix code on the binary alphabet $\{0, 1\}$ can be represented by a trie (see Section 15.2.6) that is a binary tree. In the present method, codes are complete: they correspond to complete tries (internal nodes have exactly two children). The leaves are labeled by the original characters, edges are labeled by 0 or 1, and labels of branches are the words of the code. The condition on the code implies that codewords are identified with leaves only. The convention is adopted that, from an internal node, the edge to its left child is labeled by 0, and the edge to its right child is labeled by 1.

In the model where characters of the text are given new codewords, the Huffman algorithm builds a code that is optimal in the sense that the compression is the best possible (the length of the compressed text is minimum). The code depends on the text, and more precisely on the frequencies of each character in the uncompressed text. The more frequent characters are given short codewords, whereas the less frequent symbols have longer codewords.

15.8.1.1 Encoding

The coding algorithm is composed of three steps: count of character frequencies, construction of the prefix code, and encoding of the text.

The first step consists in counting the number of occurrences of each character in the original text (see Figure 15.60). A special end marker (denoted by END) is used, which (virtually) appears only once at the end of the text. It is possible to skip this first step if fixed statistics on the alphabet are used. In this case, the method is optimal according to the statistics, but not necessarily for the specific text.

```

COUNT(fin)
1  for each character  $a \in \Sigma$ 
2      do  $freq(a) \leftarrow 0$ 
3  while not end of file fin and  $a$  is the next symbol
4      do  $freq(a) \leftarrow freq(a) + 1$ 
5  END  $\leftarrow 1$ 

```

FIGURE 15.60 Counts the character frequencies.

The second step of the algorithm builds the tree of a prefix code using the character frequency $freq(a)$ of each character a in the following way:

- Create a one-node tree t for each character a , setting $weight(t) = freq(a)$ and $label(t) = a$.
 - Repeat (1), extract the two least-weighted trees t_1 and t_2 (2) Create a new tree t_3 having left subtree t_1 , right subtree t_2 , and weight $weight(t_3) = weight(t_1) + weight(t_2)$.
- until only one tree remains.

The tree is constructed by the algorithm BUILD-TREE in Figure 15.61. The implementation uses two linear lists. The first list contains the leaves of the future tree, each associated with a symbol. The list is sorted in the increasing order of the weight of the leaves (frequency of symbols). The second list contains the newly created trees. Extracting the two least weighted trees consists in extracting the two least weighted trees among the two first trees of the list of leaves and the two first trees of the list of created trees. Each new tree is inserted at the end of the list of the trees. The only tree remaining at the end of the procedure is the coding tree.

After the coding tree is built, it is possible to recover the codewords associated with characters by a simple depth-first search of the tree (see Figure 15.62); $codeword(a)$ is then the binary code associated with the character a .

In the third step, the original text is encoded. Since the code depends on the original text, in order to be able to decode the compressed text, the coding tree and the original codewords of symbols must

```

BUILD-TREE()
1  for each character  $a \in \Sigma \cup \{\text{END}\}$ 
2      do if  $freq(a) \neq 0$ 
3          then create a new node  $t$ 
4               $weight(t) \leftarrow freq(a)$ 
5               $label(t) \leftarrow a$ 
6   $l\text{leaves} \leftarrow$  list of all the nodes in increasing order of weight
7   $l\text{trees} \leftarrow$  empty list
8  while  $LENGTH(l\text{leaves}) + LENGTH(l\text{trees}) > 1$ 
9      do  $(\ell, r) \leftarrow$  extract the two nodes of smallest weight (among the two nodes
           at the beginning of  $l\text{leaves}$  and the two nodes at the beginning of  $l\text{trees}$ )
10         create a new node  $t$ 
11          $weight(t) \leftarrow weight(\ell) + weight(r)$ 
12          $left(t) \leftarrow \ell$ 
13          $right(t) \leftarrow r$ 
14         insert  $t$  at the end of  $l\text{trees}$ 
15  return  $t$ 

```

be stored with the compressed text. This information is placed in a header of the compressed file, to be read at decoding time just before the compressed text. The header is made via a depth-first traversal of the tree. Each time an internal node is encountered a 0 is produced. When a leaf is encountered, a 1 is produced followed by the original code of the corresponding character on 9 b (so that the end marker can be equal to 256 if all the characters appear in the original text). This part of the encoding algorithm is shown in Figure 15.63.

After the header of the compressed file is computed, the encoding of the original text is realized by the algorithm of Figure 15.64.

A complete implementation of the Huffman algorithm, composed of the three steps just described, is given in Figure 15.65.

Example 1.21

$y = \text{CAGATAAGAGAA}$. The length of $y = 12 \times 8 = 96$ bits (assuming an 8-bit code). The character frequencies are

A	C	G	T	END
7	1	3	1	1

The different steps during the construction of the coding tree are

character codewords:

The encoded tree is **0001** binary (END, 9)**01**binary (C, 9)**1**binary(T, 9) **1**binary (G, 9)**1**binary (A, 9), which produces a header of length 54 bits,

0001 100000000 01 001000011 1 001010100 1 001000111 1 001000001

The encoded text

0010 1 01 1 0011 1 1 01 1 01 1 1 000

is of length 24 bits. The total length of the compressed file is 78 bits.

A	C	G	T	END
1	0010	01	0011	000

The construction of the tree takes $O(\sigma \log \sigma)$ time if the sorting of the list of the leaves is implemented efficiently. The rest of the encoding process runs in linear time in the sum of the sizes of the original and compressed texts.

15.8.1.2 Decoding

Decoding a file containing a text compressed by the Huffman algorithm is a mere programming exercise. First, the coding tree is rebuilt by the algorithm of Figure 15.66. Then, the uncompressed text is

```

REBUILD-TREE(fin, t)
1  b ← read a bit from the file fin
2  if b = 1                                ▷ leaf
3    then left(t) ← NIL
4         right(t) ← NIL
5         label(t) ← symbol corresponding to
                       the 9 next bits in the file fin
6  else create a new node ℓ
7         left(t) ← ℓ
8         REBUILD-TREE(fin, ℓ)
9         create a new node r
10        right(t) ← r
11        REBUILD-TREE(fin, r)
    
```

FIGURE 15.66 Rebuilds the tree read from the compressed file.

```

DECODE-TEXT(fin, fout, root)
1  t ← root
2  while label(t) ≠ END
3      do if t is a leaf
4          then label(t) in the file fout
5              t ← root
6          else b ← read a bit from the file fin
7              if b = 1
8                  then t ← right(t)
9                  else t ← left(t)

```

FIGURE 15.67 Reads the compressed text and produces the uncompressed text.

```

DECODING(fin, fout)
1  create a new node root
2  REBUILD-TREE(fin, root)
3  DECODE-TEXT(fin, fout, root)

```

FIGURE 15.68 Complete function for Huffman decoding.

recovered by parsing the compressed text with the coding tree. The process begins at the root of the coding tree and follows a left edge when a 0 is read or a right edge when a 1 is read. When a leaf is encountered, the corresponding character (in fact, the original codeword of it) is produced and the parsing phase resumes at the root of the tree. The parsing ends when the codeword of the end marker is read. An implementation of the decoding of the text is presented in Figure 15.67.

The complete decoding program is given in Figure 15.68. It calls the preceding functions. The running time of the decoding program is linear in the sum of the sizes of the texts it manipulates.

15.8.2 Lempel–Ziv–Welsh (LZW) Compression

Ziv and Lempel designed a compression method using encoding segments. These segments are stored in a dictionary that is built during the compression process. When a segment of the dictionary is encountered later while scanning the original text, it is substituted by its index in the dictionary. In the model where portions of the text are replaced by pointers on previous occurrences, the Ziv–Lempel compression scheme can be proved to be asymptotically optimal (on large enough texts satisfying good conditions on the probability distribution of symbols).

The dictionary is the central point of the algorithm. It has the property of being prefix closed (every prefix of a word of the dictionary is in the dictionary), so that it can be implemented as a tree. Furthermore, a hashing technique makes its implementation efficient. The version described in this section is called the Lempel–Ziv–Welsh (LZW) method after several improvements introduced by Welsh. The algorithm is implemented by the **compress** command existing under the UNIX operating system.

15.8.2.1 Compression Method

The scheme of the compression method is first described. The dictionary is initialized with all the characters of the alphabet. The current situation is when one has just read a segment w in the text. Let a be the next symbol (just following w). Then the methods proceed as follows:

- If wa is not in the dictionary, write the index of w to the output file, and add wa to the dictionary. Then w is reset to a and process the next symbol (following a).
- If wa is in the dictionary, process the next symbol, with segment wa instead of w .

Initially, the segment w is set to the first symbol of the source text.

Example 1.22

Here $y = \text{CAGTAAGAGAA}$

C	A	G	T	A	A	G	A	G	A	A	w	out	added
	↑										C	67	CA, 257
		↑									A	65	AG, 258
			↑								G	71	GT, 259
				↑							T	84	TA, 260
					↑						A	65	AA, 261
						↑					A		
							↑				AG	258	AGA, 262
								↑			A		
									↑		AG		
										↑	AGA	262	AGAA, 262
											A		
												65	
												256	

15.8.2.2 Decompression Method

The decompression method is symmetrical to the compression algorithm. The dictionary is recovered while the decompression process runs. It is basically done in this way:

- Read a code c in the compressed file.
- Write in the output file the segment w which has index c in the dictionary.
- Add to the dictionary the word wa where a is the first letter of the next segment.

In this scheme, a problem occurs if the next segment is the word which is being built. This arises only if the text contains a segment $azax$ for which az belongs to the dictionary but aza does not. During the compression process, the index of az is written into the compressed file, and aza is added to the dictionary. Next, aza is read and its index is written into the file. During the decompression process, the index of aza is read while the word az has not been completed yet: the segment aza is not already in the dictionary. However, since this is the unique case where the situation arises, the segment aza is recovered taking the last segment az added to the dictionary concatenated with its first letter a .

Example 15.23

Here the decoding is 67, 65, 71, 84, 65, 258, 262, 65, 256

read	written	added

18  write code(HASH-SEARCH(D, (-1, END))) on 1 + log(count) bits in fout

```

FIGURE 15.69 LZW compression algorithm.

15.8.2.3 Implementation

For the compression algorithm shown in Figure 15.69, the dictionary is stored in a table D . The dictionary is implemented as a tree; each node z of the tree has the three following components:

- $parent(z)$ is a link to the parent node of z .
- $label(z)$ is a character.
- $code(z)$ is the code associated with z .

The tree is stored in a table that is accessed with a hashing function. This provides fast access to the children of a node. The procedure $HASH-INSERT((D, (p, a, c)))$ inserts a new node z in the dictionary D with $parent(z) = p$, $label(z) = a$, and $code(z) = c$. The function $HASH-SEARCH((D, (p, a)))$ returns the node z such that $parent(z) = p$ and $label(z) = a$.

For the decompression algorithm, no hashing technique is necessary. Having the index of the next segment, a bottom-up walk in the trie implementing the dictionary produces the mirror image of the segment. A stack is used to reverse it. Assume that the function $string(c)$ performs this specific work for a code c . The bottom-up walk follows the parent links of the data structure. The function $first(w)$ gives the first character of the word w . These features are part of the decompression algorithm displayed in Figure 15.70.

The Ziv–Lempel compression and decompression algorithms run both in linear time in the sizes of the files provided a good hashing technique is chosen. Indeed, it is very fast in practice. Its main advantage compared to Huffman coding is that it captures long repeated segments in the source file.

15.8.3 Mixing Several Methods

Simple compression methods, basis of the popular **bzip** software are described and then an example of a combination of several of them.

```

UNCOMPRESS(fin, fout)

23                         write string(d) in fout
24                         c ← d
25                     else break

```

FIGURE 15.70 LZW decompression algorithm.

15.8.3.1 Run Length Encoding

The aim of Run Length Encoding (RLE) is to efficiently encode repetitions occurring in the input data. Let us assume that it contains a good quantity of repetitions of the form $aa \dots a$ for some character a ($a \in \Sigma$). A repetition of k consecutive occurrences of letter a is replaced by $\&ak$, where the symbol $\&$ is a new character ($\& \notin \Sigma$).

The string $\&ak$ that encodes a repetition of k consecutive occurrences of a is itself encoded on the binary alphabet $\{0, 1\}$. In practice, letters are often represented by their ASCII code. Therefore, the code-word of a letter belongs to $\{0, 1\}^k$ with $k = 7$ or 8 . Generally, there is no problem in choosing or encoding the special character $\&$. The integer k of the string $\&ak$ is also encoded on the binary alphabet, but it is not sufficient to translate it by its binary representation, because one would be unable to recover it at decoding time inside the stream of bits. A simple way to cope with this is to encode k by the string $0^\ell \text{bin}(k)$, where $\text{bin}(k)$ is the binary representation of k , and ℓ is the length of it. This works well because the binary representation of k starts with a 1 so there is no ambiguity to recover ℓ by counting during the decoding phase. The size of the encoding of k is thus roughly $2 \log k$. More sophisticated integer representations are possible, but none is really suitable for the present situation. Simpler solution consists in encoding k on the same number of bits as other symbols, but this bounds values of ℓ and decreases the power of the method.

15.8.3.2 Move to Front

The Move To Front (MTF) method may be regarded as an extension of RLE or a simplification of Ziv-Lempel compression. It is efficient when the occurrences of letters in the input text are localized into relatively short segment of it. The technique is able to capture the proximity between occurrences of symbols and to turn it into a short encoded text.

Letters of the alphabet Σ of the input text are initially stored in a list that is managed dynamically. Letters are represented by their rank in the list, starting from 1, rank that is itself encoded as described above for RLE.

Letters of the input text are processed in an online manner. The clue of the method is that each letter is moved to the beginning of the list just after it is translated by the encoding of its rank.

The effect of MTF is to reduce the size of the encoding of a letter that reappears soon after its preceding occurrence.

15.8.3.3 Integrated Example

Most compression software combine several methods to be able to compress efficiently a large range of input data. An example of this strategy, implemented by the UNIX command **bzip**, is presented.

Let $y = y[0]y[1] \dots y[n - 1]$ be the input text. The k -th rotation (or conjugate) of y , $0 \leq k \leq n - 1$, is the string $y_k = y[k]y[k + 1] \dots y[n - 1]y[0]y[1] \dots y[k - 1]$.

The *BW* transformation is defined as $BW(y) = y[p_0]y[p_1] \dots y[p_{n-1}]$, where $p_i + 1$ is such that y_{p_i+1} has rank i in the sorted list of all rotations of y .

It is remarkable that y can be recovered from both $BW(y)$ and a position on it, starting position of the inverse transformation (see Figure 15.71). This is possible due to the following property of the transformation. Assume that $i < j$ and $y[p_i] = y[p_j] = a$. Since $i < j$, the definition implies $y_{p_i+1} < y_{p_j+1}$. Since $y[p_i] = y[p_j]$, transferring the last letters of y_{p_i+1} and y_{p_j+1} to the beginning of these words does not change the inequality. This proves that the two occurrences of a in $BW(y)$ are in the same relative order as in the sorted list of letters of y . Figure 15.71 illustrates the inverse transformation. Top line is $BW(y)$ and bottom line the sorted list of letters of it. Top-down arrows correspond to succession of occurrences in y . Each bottom-up arrow links the same occurrence of a letter in y . Arrows starting from equal letters do not cross. The circular path is associated with rotations of the string y . If the starting point is known, the only occurrence of letter **b** here, following the path, produces the initial string y .

Transformation *BW* obviously does not compress the input text y . But $BW(y)$ is compressed more efficiently with simple methods. This is the strategy applied for the command **bzip**. It is a combination of the *BW* transformation followed by MTF encoding and RLE encoding. Arithmetic coding, a method providing compression ratios slightly better than Huffman coding, may also be used.

Table 15.1 contains a sample of experimental results showing the behavior of compression algorithms on different types of texts from the Calgary Corpus: **bib** (bibliography), **book1** (fiction book), **news** (USENET batch file), **pic** (black and white fax picture), **progC** (source code in C), and **trans** (transcript of terminal session).

FIGURE 15.71 *BW*(baccara).

TABLE 15.1 Compression Results with Three Algorithms: Huffman Coding (**pack**), Ziv–Lempel Coding (**gzip-b**), and Burrows–Wheeler Coding (**bzip2-1**)

Bytes	111, 261	768, 771	377, 109	513, 216	39, 611	93, 695	
Texts	bib	book1	news	pic	progC	trans	Average
pack	5.24	4.56	5.23	1.66	5.26	5.58	4.99
gzip-b	2.51	3.25	3.06	0.82	2.68	1.61	2.69
bzip2-1	2.10	2.81	2.85	0.78	2.53	1.53	2.46

The compression algorithms reported in the table are: the Huffman coding algorithm implemented by **pack**, the Ziv–Lempel algorithm implemented by **gzip-b**, and the compression based on the *BW* transform implemented by **bzip2-1**. Figures give the number of bits used per character (letter). They show that **pack** is the less efficient method and that **bzip2-1** compresses a bit more than **gzip-b**. Additional compression results can be found at <http://corpus.canterbury.ac.nz>.

15.9 Research Issues and Summary

The algorithm for string searching by hashing was introduced by Harrison in 1971, and later fully analyzed by Karp and Rabin (1987).

The linear-time string-matching algorithm of Knuth, Morris, and Pratt is from 1976. It can be proved that, during the search, a character of the text is compared to a character of the pattern no more than $\log_{\Phi}(|x| + 1)$ (where Φ is the golden ratio $(1 + \sqrt{5})/2$). Simon (1993) gives an algorithm similar to the previous one but with a delay bounded by the size of the alphabet (of the pattern x). Hancart (1993) proves that the delay of Simon’s algorithm is, indeed, no more than $1 + \log_2|x|$. He also proves that this is optimal among algorithms searching the text through a window of size 1.

Galil (1981) gives a general criterion to transform searching algorithms of that type into real-time algorithms.

The BM algorithm was designed by Boyer and Moore (1977). The first proof of its linearity when restricted to the search for the first pattern occurrence is by Knuth et al. (1977). Cole (1994) proves that the maximum number of symbol comparisons is bounded by $3n$, and that this bound is tight.

Knuth et al. (1977) consider a variant of the BM algorithm in which all previous matches inside the current window are memorized. Each window configuration becomes the state of what is called the BM automaton. It is still unknown whether the maximum number of states of the automaton is polynomial or not.

Several variants of the BM algorithm avoid the quadratic behavior when searching for all occurrences of the pattern. Among the more efficient in terms of the number of symbol comparisons are: the algorithm of Apostolico and Giancarlo (1986), Turbo–BM algorithm by Crochemore *et al.* (1992) (the two algorithms are analyzed in Lecroq (1995)), and the algorithm of Colussi (1994).

The general bound on the expected time complexity of string matching is $O(|y| \log |x|/|x|)$. The probabilistic analysis of a simplified version of the BM algorithm, similar to the QS algorithm of Sunday (1990) described in the chapter, was studied by several authors.

String searching can be solved by a linear-time algorithm requiring only a constant amount of memory in addition to the pattern and the (window on the) text. This can be proved by different techniques presented in Crochemore and Rytter (2002).

Experimental results presented in this chapter have been realized using SMART (String Matching Algorithms Research Tool, <http://www.dmi.unict.it/~faro/smart/>) by Faro and Lecroq (2011). An exhaustive experimental study can be found in Faro and Lecroq (2010).

The Aho–Corasick algorithm is from Aho and Corasick (1975). It is implemented by the **fgrep** command under the UNIX operating system. Commentz-Walter (1979) has designed an extension of the BM algorithm to several patterns. It is fully described in Aho (1990).

On general alphabets, the two-dimensional pattern matching can be solved in linear time, whereas the running time of the Bird–Baker algorithm (Baker, 1978; Bird, 1977) has an additional $\log \sigma$ factor. It is still unknown whether the problem can be solved by an algorithm working simultaneously in linear time and using only a constant amount of memory space (see Crochemore and Rytter, 2002).

The suffix tree construction of Section 15.4 is by McCreight (1976). An online construction is given by Ukkonen (1995). Other data structures to represent indexes on text files are: direct acyclic word graph (Blumer et al., 1985), suffix automata (Crochemore, 1986), and suffix arrays (Manber and Myers, 1993). All these techniques are presented in Crochemore and Rytter (2002). The Zhu–Takaoka was published in Zhu and Takaoka (1989). The data structures implement full indexes with standard operations, whereas applications sometimes need only incomplete indexes. The design of compact indexes is still unsolved.

The suffix array of a string, with the associated search algorithm based on the knowledge of the common prefixes (Section 15.5), is from Manber and Myers (1993). The suffix array construction in Section 15.5.1 is from Kärkkäinen and Sanders (2003) (see also Kim et al., 2003; Ko and Aluru, 2003). The method used in Section 15.5.3 to compute the longest common prefixes of sorted suffixes is from Kasai et al. (2001).

First algorithms for aligning two sequences are by Needleman and Wunsch (1970) and Wagner and Fischer (1974). Idea and algorithm for local alignment is by Smith and Waterman (1981). Hirschberg (1975) presents the computation of the lcs in linear space. This is an important result because the algorithm is classically run on large sequences. Another implementation is given in Durbin et al. (1998). The quadratic time complexity of the algorithm to compute the Levenshtein distance is a bottleneck in practical string comparison for the same reason.

Approximate string searching is a lively domain of research. It includes, for instance, the notion of regular expressions to represent sets of strings. Algorithms based on regular expression are commonly found in books related to compiling techniques. The algorithms of Section 15.7 are by Baeza-Yates and Gonnet (1992) and Wu and Manber (1992).

The statistical compression algorithm of Huffman (1951) has a dynamic version where symbol counting is done at coding time. The current coding tree is used to encode the next character and then updated. At decoding time, a symmetrical process reconstructs the same tree, so the tree does not need to be stored with the compressed text, see Knuth (1985). The command **compact** of UNIX implements this version.

Several variants of the Ziv and Lempel algorithm exist. The reader can refer to Bell et al. (1990) for a discussion on them (see Welch [1984], for instance). Nelson (1992) presents practical implementations of various compression algorithms. The *BW* transform is from Burrows and Wheeler (1994).

Key Terms

Alignment: An alignment of two strings x and y is a word of the form $(\bar{x}_0, \bar{y}_0)(\bar{x}_1, \bar{y}_1) \cdots (\bar{x}_{p-1}, \bar{y}_{p-1})$ where each $(\bar{x}_i, \bar{y}_i) \in (\Sigma \cup \{\epsilon\}) \times (\Sigma \cup \{\epsilon\}) \setminus \{(\epsilon, \epsilon)\}$ for $0 \leq i \leq p-1$ and both $x = \bar{x}_0 \bar{x}_1 \cdots \bar{x}_{p-1}$ and $y = \bar{y}_0 \bar{y}_1 \cdots \bar{y}_{p-1}$.

Border: A word $u \in \Sigma^*$ is a border of a word $w \in \Sigma^*$ if u is both a prefix and a suffix of w (there exist two words $v, z \in \Sigma^*$ such that $w = vu = uz$). The common length of v and z is a period of w .

Edit distance: The metric distance between two strings that counts the minimum number of insertions and deletions of symbols to transform one string into the other.

Hamming distance: The metric distance between two strings of same length that counts the number of mismatches.

Levenshtein distance: The metric distance between two strings that counts the minimum number of insertions, deletions, and substitutions of symbols to transform one string into the other.

Occurrence: An occurrence of a word $u \in \Sigma^*$, of length m , appears in a word $w \in \Sigma^*$, of length n , at position i if for $0 \leq k \leq m-1$, $u[k] = w[i+k]$.

Prefix: A word $u \in \Sigma^*$ is a prefix of a word $w \in \Sigma^*$ if $w = uz$ for some $z \in \Sigma^*$.

Prefix code: Set of words such that no word of the set is a prefix of another word contained in the set. A prefix code is represented by a coding tree.

Segment: A word $u \in \Sigma^*$ is a segment of a word $w \in \Sigma^*$ if u occurs in w (see occurrence), that is, $w = vuz$ for two words $v, z \in \Sigma^*$ (u is also referred to as a factor or a subword of w).

Subsequence: A word $u \in \Sigma^*$ is a subsequence of a word $w \in \Sigma^*$ if it is obtained from w by deleting zero or more symbols that need not be consecutive (u is sometimes referred to as a subword of w , with a possible confusion with the notion of segment).

Suffix: A word $u \in \Sigma^*$ is a suffix of a word $w \in \Sigma^*$ if $w = vu$ for some $v \in \Sigma^*$.

Suffix tree: Trie containing all the suffixes of a word.

Trie: Tree in which edges are labeled by letters or words.

Further Information

Problems and algorithms presented in the chapter are just a sample of questions related to pattern matching. They share the formal methods used to design solutions and efficient algorithms. A wider panorama of algorithms on texts may be found in a few books such as:

Adjeroh, D., Bell, T., and Mukherjee, A. 2008. *The Burrows-Wheeler Transform: Data Compression, Suffix Arrays, and Pattern Matching*. Springer Verlag, Heidelberg, Germany.

Apostolico, A. and Galil, Z., eds. 1997. *Pattern Matching Algorithms*. Oxford University Press, New York.

Bell, T. C., Cleary, J. G., and Witten, I. H. 1990. *Text Compression*. Prentice-Hall, Englewood Cliffs, NJ.

Crochemore, M., Hancart, C., and Lecroq, T. 2007. *Algorithms on Strings*. Cambridge University Press, Cambridge, U.K.

Crochemore, M. and Rytter, W. 2002. *Jewels of Stringology*. World Scientific, Singapore.

Gusfield D. 1997. *Algorithms on Strings, Trees and Sequences: Computer Science and Computational Biology*. Cambridge University Press, Cambridge, U.K.

Salomon, D. 2000. *Data Compression: The Complete Reference*. Springer Verlag, New York.

Smyth, W. F. 2003. *Computing Patterns in Strings*. Addison-Wesley Longman, Harlow, U.K.

Stephen, G. A. 1994. *String Searching Algorithms*. World Scientific Press, Singapore.

Research papers in pattern matching are disseminated in a few journals, among which are: *Communications of the ACM*, *Journal of the ACM*, *Theoretical Computer Science*, *Algorithmica*, *Journal of Algorithms*, *SIAM Journal on Computing*, *Journal of Discrete Algorithms*.

Finally, three main annual conferences present the latest advances of this field of research: Combinatorial Pattern Matching, which started in 1990. Data Compression Conference, which is regularly held at Snowbird. The scope of SPIRE (String Processing and Information Retrieval) includes the domain of data retrieval.

General conferences in computer science often have sessions devoted to pattern matching algorithms.

Several books on the design and analysis of general algorithms contain chapters devoted to algorithms on texts. Here is a sample of these books:

Cormen, T. H., Leiserson, C. E., and Rivest, R. L. 1990. *Introduction to Algorithms*. MIT Press, Boston, MA.

Gonnet, G. H. and Baeza-Yates, R. A. 1991. *Handbook of Algorithms and Data Structures*. Addison-Wesley, Boston, MA.

Animations of selected algorithms may be found at:

- <http://www-igm.univ-mlv.fr/~lecroq/string/> (Exact String Matching Algorithms),
- <http://www-igm.univ-mlv.fr/~lecroq/seqcomp/> (Alignments).

16.1 Introduction

One of the key trends in computing over the past two decades, both at the level of large-scale and small-scale systems, has been *distribution*. At one extreme, given the advent of new paradigms such as cloud computing, utility computing, and social networks, large-scale software systems are now routinely distributed over several machines or clusters of machines, which can in turn be spread over large geographic regions.

At the other extreme, that is, at the processor level, recent years have shown an industry shift towards *multicore* architectures. In particular, due to technological limitations, processor manufacturers were forced to stop increasing processor clock speeds and instead started providing more processing units or *cores* as part of a single processor. This change, known as the *multicore revolution*, implies that software applications must be designed with parallelism in mind, to exploit the extra computing power of multiple cores.

Given this broad shift toward distributed computing, understanding the power and limitations of computation in a distributed setting is one of the major challenges in modern Computer Science. This challenge has prompted researchers to look for common frameworks to specify distributed algorithms and compare their performance. For classical centralized algorithms such analytical tools have already been in place for decades. This guided the design of efficient algorithms for practical problems and provided an understanding of the inherent limitations of classical computing in terms of lower bounds and NP-completeness.

Research in distributed computing aims to provide the formal models and analytic tools for understanding problems arising when computation is performed on a set of devices, connected through a network or located on the same chip. In particular, distributed computing identifies fundamental problems that appear in practical distributed systems, states them formally, and provides algorithms and lower bounds for these problems.

One of the key differences from centralized computing is that there is no single, universal model of computation for distributed computing. This is because distributed systems vary significantly in terms of the communication primitives or timing guarantees that the system provides. Another important distinction is *fault-tolerance*: In centralized computing, it is generally assumed that the underlying (Turing) machine always functions properly, following its algorithm. On the other hand, distributed algorithms model the fact that single computing agents may be unreliable and are usually designed to deal with crashes of the individual units of computation or even with agents that act maliciously in order to influence the global computation. In some sense, the multiplicity of Turing machines calls for a new notion of computation that tolerates the unreliability of some of these machines.

Even though there may never be a single unified model for distributed computing, there does, however, exist a set of core problems that keep reoccurring in distributed systems, irrespective of their architecture. The focus of research is on the solvability and complexity of such fundamental problems under various timing and failure guarantees.

In this chapter, we give an overview of the core principles of distributed computing and present some of the field's fundamental results. We then survey some of the practical applications of the research and give an overview of the major challenges that the field will face in the near future. Since distributed computing is an extremely active research area, our presentation is not meant to be exhaustive. We just scratch the surface, in the hope that the reader will find it appealing to explore the field in more depth.

16.2 Underlying Principles

Over the past 30 years, distributed computing has emerged as a coherent research field. In general, the style of work follows a pattern: The field first abstracts problems and models relevant for practical systems, then develops algorithms to solve these problems, or proves impossibility results that characterize the feasibility and complexity of the problem at hand. In case the problem is proved to be unsolvable in a given setting, research focuses on ways to circumvent the impossibility by restricting the model or relaxing the problem requirements.

In the rest of this section, we present some of the fundamental notions underlying distributed computing and isolate the key questions that the field aims to answer. We illustrate the pattern of research outlined above by discussing some canonical distributed problems and outline some of the main results and research directions in the area.

16.2.1 Basic Notions

The fundamental concept in distributed computing is the *process*, that is, a sequential computing device, which executes a distributed algorithm.* In particular, a process is the functional equivalent of a sequential Turing machine; by extension, a distributed system can be seen as a collection of communicating Turing machines. In a distributed system, each process runs an instance of a distributed algorithm, with a limited amount of information about the state of the whole system.

Processes communicate with each other and gain information about the system by performing operations on *shared objects*, that is, abstractions that can be accessed by multiple processes. Examples of elementary shared objects are *registers*, that is, units of shared memory holding information, which can be read or written by multiple processes, and *communication channels*, which processes can use to send messages to each other. These basic communication primitives provided by hardware are also called *base objects*. Depending on the type of communication primitives available, distributed systems can be classified as either *shared-memory* or *message-passing* systems.†

* Some texts, for example [80], use the term *processor* instead of process.

† Under certain conditions, shared-memory and message-passing systems can be shown to be computationally equivalent [9].

Processes may be *faulty*, that is, may deviate from their algorithm. Such faulty behavior includes *crash faults*, where the process stops executing the algorithm after a certain point. Failures can also be *Byzantine*, in which case processes may behave arbitrarily; in particular, they might behave maliciously, attempting to manipulate the distributed computation. Research also considers failures of the communication mechanisms, such as message loss or memory corruption.

The timing behavior of processes and their faults are typically assumed to be under the control of an external abstraction called a *scheduler*, which is independent from the processes. In particular, the scheduler decides the order in which processes take steps and the timing of their faults. Since we focus on the correctness and worst-case behavior of algorithms, the scheduler is generally assumed to be *adversarial*. The most general scheduler is *asynchronous*, that is, does not assume any bound on the relative speeds of processes, and thus allows arbitrary interleavings of process steps.

Algorithms that guarantee termination in an asynchronous model in which all but one process may crash are called *wait-free*; such algorithms ensure progress without making any assumptions on the timing behavior of processes. Even though in typical real-world systems it is possible to make stronger timing assumptions, wait-free algorithms have the advantage of being general and portable; in particular, they are guaranteed to run correctly in systems with arbitrary timing guarantees.

16.2.2 Fundamental Questions

Roughly speaking, the key question in distributed computing is that of *computability*:

Given a set of processes communicating through shared objects, what abstractions can be implemented on top of these objects?

In a broad sense, the objective is to raise the level of abstraction that a distributed system can provide, beyond the fundamental message-passing or shared-memory primitives generally available in hardware.* A distributed algorithm typically has at its disposal a set of *base objects* (basic primitives ensured by shared-memory or communication channels) and lower level *shared objects* (in turn, these may be composed of other base and shared objects, and so on). The problem is to correctly implement a higher-level abstraction on top of these objects, in spite of timing anomalies and process faults. This would then allow programmers to use such abstractions to build specific applications.

Once we know what abstractions can be implemented in a distributed system, a second fundamental question is that of *complexity*:

Given a distributed abstraction, what is the minimal cost of implementing it out of a set of lower-level shared objects?

Several cost metrics may be of interest, such as the number of shared object accesses (the counterpart of sequential time complexity) or the number of shared objects that need to be allocated (the counterpart of sequential space complexity). Complexity is characterized by giving algorithms that minimize the cost and lower bounds that demonstrate inherent cost requirements. In general, distributed computing is interested in characterizing *worst-case* complexity, that is, the executions in which the cost is maximized; practical implementations sometimes focus on improving complexity in the average case or in certain common cases.

16.2.3 Fundamental Results

As we pointed out in the previous section, research in distributed computing follows a general pattern. In particular, it isolates models and problems of interest for distributed systems practitioners, abstracts them, and then studies the solvability and complexity of fundamental abstractions in general models. In case an abstraction cannot be implemented, research investigates ways to circumvent the impossibility.

* In the sequential world, the same role is played by data structures such as queues, stacks, sets, etc.

In the following, we illustrate this pattern by considering *state machine replication* and *consensus* as examples of such canonical problems. Along the way, we will describe some of the fundamental techniques and research directions underlying distributed computing.

16.2.3.1 Identifying the Practical Problem

A replicated state machine (RSM) [73,87] is the distributed equivalent of a highly available Turing machine, as it requires a set of processes to maintain a coherent state machine in a distributed, fault-tolerant fashion.

This problem is motivated by the observation that distributed software is often structured in terms of *clients* and *services*. A software service, such as a bank's web service, comprises one or more servers and exports operations that clients invoke by making requests. To ensure availability under high load or failures, multiple servers that fail independently have to be used, maintaining a consistent version of the service via a distributed protocol. These independent servers are called *replicas*, implementing the distributed service that is maintained as a RSM. (See Figure 16.1 for an illustration.)

16.2.3.2 Determining the Fundamental Abstraction

Several fundamental results, for example, [61,73], show that a RSM is computationally equivalent to the *consensus* problem. In this problem, a set of processes, each proposing a value, must *agree* on the same output from the values proposed. Formally, consensus is defined as follows.

Definition 16.1 (Consensus)

The consensus problem exports a propose operation, which takes as input an integer value. Each process p_i calls propose with its proposal value v_i as argument. The consensus object requires every nonfaulty process to eventually output a single output (the termination condition), such that all outputs are equal (the agreement condition). To avoid trivial solutions, the common output decided has to be the input of some process (the validity condition).

The intuition behind the transformation is given in Figure 16.2. The equivalence between RSM and consensus is important, since it suggests that, given consensus, any object representable as a state machine has a distributed implementation.

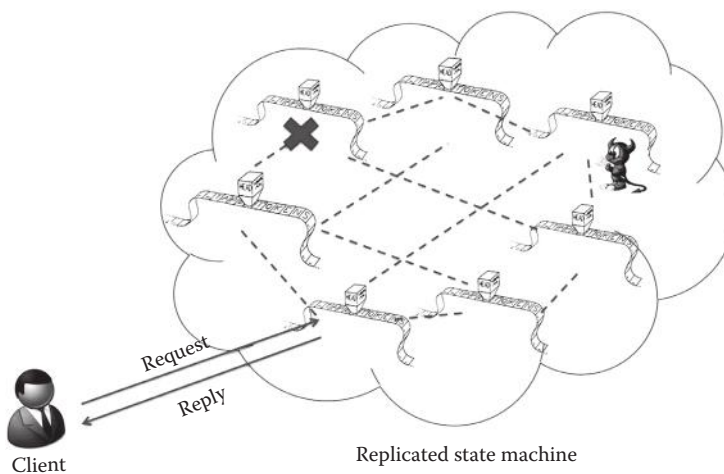

FIGURE 16.1 A distributed Turing machine implemented as a replicated state machine (RSM). The protocol must maintain the illusion of a centralized Turing machine, even though the implementation is distributed over multiple sequential machines, some of which may be subject to crash faults or malicious (Byzantine) faults.

```

Shared Objects:
  Cons, an array of consensus objects
Local Variables: /* at process i */
  Requestsi, a list of requests from clients
  stateMachinei, a state machine
  indexi, a counter variable, initially 0

procedure ReplicatedStateMachine()
  while Requestsi is not empty do
    request ← Requestsi.next()
    repeat
      cons ← Cons[index]
      decision ← cons.propose(request)
      stateMachinei.perform(decision)
      index ← index + 1
    until request = decision

```

FIGURE 16.2 A basic RSM implementation using consensus objects. The replicas receive requests from clients, and use the consensus objects to agree on the order in which requests are committed.

16.2.3.3 Establishing a Fundamental Limitation

On the other hand, surprisingly, consensus cannot be implemented using elementary base objects such as read-write registers or message-passing communication channels in an asynchronous system in which a single process may crash. This result, proved by Fischer, Lynch, and Paterson [47], abbreviated as FLP, is probably the most celebrated result in distributed computing. By reduction, we obtain the same impossibility for implementations of a RSM and for many other abstractions, which can be used to implement consensus.

Theorem 16.1 (FLP [47])

Given an asynchronous message-passing system or an asynchronous shared-memory system with read-write registers, no consensus protocol is totally correct in spite of one crash fault.

The intuition behind the proof is the following. The argument proceeds by contradiction and assumes there exists an algorithm that solves consensus in the given setting. It then builds a valid execution of the algorithm in which no process can decide. The construction relies on two fundamental notions: one is the *bivalence* of an execution, that is, the property that an execution prefix can be continued by arranging process steps in two different ways, where each extension reaches a distinct decision. The second is the notion of *indistinguishability*: two system configurations are *indistinguishable* to a process if the values of all shared variables and the state of the process are the same in both configurations. Both these notions are key for proving lower bounds and impossibility results in distributed computing. The FLP argument starts by proving that any consensus algorithm has a bivalent initial configuration; it then shows that each bivalent configuration can be extended to a configuration that is still bivalent by scheduling an additional process step. Iterating this argument, we obtain an execution of infinite length in which each configuration is bivalent, therefore no process may decide in that execution.

16.2.3.4 Generalizing the Result

Besides the connection to the RSM problem, another strong argument for the centrality of consensus in distributed computing is Herlihy's *consensus hierarchy* [61]. Herlihy showed that every shared object can be assigned a *consensus number*, which is the maximum number of processes for which the object can solve wait-free consensus in an asynchronous system. The resulting hierarchy has a key separation property: No object with consensus number $x + 1$ can be implemented out of objects of consensus number at most x .

TABLE 16.1 Structure of Herlihy's Consensus Hierarchy [61]

Consensus Number	Shared Object
1	Read-write registers
2	Test-and-set, swap, fetch-and-add, queue, stack
⋮	⋮
∞	Augmented queue, compare-and-swap, sticky byte

For example, read-write registers have consensus number 1, since they can solve consensus for one process (trivially) but cannot solve consensus for two processes (by the FLP result). Herlihy also showed that shared objects such as *queues*, *stacks*, and *fetch-and-add* counters have consensus number 2. Shared-memory primitives such as *compare-and-swap* or *sticky bytes* have consensus number ∞ , since they can solve consensus for any number of processes. (See Table 16.1). In turn, consensus is *universal*, that is, it may implement any other shared object wait-free.

This elegant result gives a way of characterizing the computational power of shared objects and suggests that distributed systems should provide universal primitives, which can be used to build wait-free distributed implementations of any sequential object.

16.2.3.5 Circumventing the Impossibility

Given the centrality of consensus in distributed computing, considerable research effort has been invested in understanding the limits of the FLP impossibility.

16.2.3.5.1 More Choices

One approach has been to relax the problem specification from consensus to *k-set agreement*, which allows k distinct decision values from the $n \geq k$ values proposed. This line of work led to a stronger impossibility: for any $k \geq 1$, k -set agreement is impossible in an asynchronous system in which k processes may fail by crashing.

This result was proved concurrently by three independent groups of researchers: Herlihy and Shavit [63], Borowsky and Gafni [19], and Saks and Zaharoglou [86], revealing a deep connection between distributed computing and a branch of mathematics called algebraic topology. This fundamental result has been extended to other models by reduction [6,50,51], while the topological tools have been developed further to characterize the solvability of other fundamental distributed tasks such as *renaming* [22,23,63].

16.2.3.5.2 Stronger Timing Assumptions

Another approach for circumventing the FLP impossibility has been to identify the additional amount of system information needed to solve consensus in a distributed system. This additional information can be provided in through a distinct shared object called a *failure detector* [27]. Whereas, in general, shared objects are used for interprocess communication, a failure detector acts as an oracle, providing extra information about process crashes or their relative speeds. These ideas have been developed into a coherent theory, which allows to identify the minimal amount of synchronization, that is, weakest failure detector, needed to implement abstractions such as consensus [26] or set agreement [52].

The FLP result holds in an *asynchronous* system, in which processes may be delayed for arbitrarily long periods of time. Real systems, however, exhibit bounded delays in most executions and unbounded delays only in the worst case. It is therefore natural to ask whether one can mitigate the impossibility of consensus by designing an algorithm that decides quickly when the system behaves well and maintains correctness (does not break agreement) in executions with failures or asynchrony. This idea was exploited by Dwork et al. [41], who showed that if the maximum delay between two process steps becomes bounded eventually, then consensus can be solved once this delay is respected. Further research, for example [12,39], extended this idea to other distributed problems and introduced frameworks for exploiting periods with bounded delays.

FIGURE 16.3 The message pattern in a failure-free execution of the Paxos protocol [74]. In the absence of failures, the protocol solves consensus among the replicas within two message delays.

16.2.3.5.3 Randomization

An important tool for circumventing the FLP impossibility is the use of *randomization*. The idea is to allow processes to flip coins during the execution and bias their decisions based on the results of the coin flips. The resulting probability space assigns weight to particular executions. One can then relax the problem specification to allow processes to terminate *with probability 1*—therefore, nonterminating executions are still possible in theory, but occur with probability 0. The other correctness properties must be preserved in every execution. Ben-Or [17] was the first to use this approach to show that randomized consensus can be solved in an fault-prone asynchronous system. Further research characterized the expected complexity of asynchronous consensus, for example [8,11], and applied randomization to other distributed problems, such as renaming [4,5,84] or concurrent data structures, for example [89].

16.2.3.6 Complexity of Consensus

The research described above aimed to isolate the minimal set of assumptions needed to solve consensus in a distributed system. On the other hand, another aspect of the quest for understanding the limitations of the FLP result has been understanding the *complexity* of consensus in a practical setting, for example [13,32,37,40,45].

A key approach in this direction has been to design *speculative* distributed algorithms, which decide quickly in well-behaved executions, for example, in which processes are relatively synchronous or there are no crashes and delay decision during periods with crashes or delays. The classic example is the *Paxos* protocol, for example [33,74,75], which solves consensus in a constant number of message delays if the system is well behaved (see Figure 16.3 for an illustration). Paxos does not contradict the FLP impossibility, since there exist worst-case executions in which it is prevented from terminating indefinitely. However, the protocol performs well in practice, since worst-case executions occur very rarely, and maintains correctness in all executions.

16.2.4 More Abstractions

To illustrate the pattern of work in distributed computing, we have considered consensus and state machine replication as examples of fundamental distributed abstractions. Of course, research in the field goes beyond these canonical problems and explores a wide variety of other research directions: for example, problems related to concurrent data structures, for example [7,42,46,68], distributed graph algorithms, for example [16,72,79], mutual exclusion, for example [14,18,91], distributed information dissemination, for example [30,36,69], clock synchronization, for example [44,78], distributed storage, for example [3,35], distributed task allocation, for example [20,71], distributed knowledge, for example [43,58], or issues related to decidability and checkability in a distributed setting, for example [48,49].

16.3 Impact on Practice

Distributed computing research constitutes an elegant mathematical theory for distributed systems. However, the field goes beyond being just mathematical theory: the research results can be applied back to the original practical problems that inspire distributed computing abstractions. In particular, algorithms can be engineered for practical use in real systems, while impossibility results can suggest to system designers when to stop trying to build a certain kind of system or point to the requirements that need to be relaxed to gain efficiency. In the following, we give a few examples of the impact of the field on practical aspects of computer systems.

16.3.1 Fault-Tolerant Computing

Chronologically, one of the first prominent practical applications of distributed computing results has been the *state machine replication* approach for large-scale distributed systems [73,87]. State machine replication is a general method of implementing a fault-tolerant distributed service by replicating servers and coordinating the interactions between replicas and clients. Lamport was the first to propose this approach in a seminal 1984 paper [73]; the approach was later elaborated by Schneider [87].

The Paxos family of protocols, for example [74,75], is at the core of many RSM implementations. The original protocol was proposed by Lamport [74] as a means to reach consensus among a set of servers in an asynchronous system. Although no deterministic consensus algorithm may solve consensus in an asynchronous system with faults [47], Paxos guarantees safety (no two processes decide distinct values) and may delay termination under asynchrony or failures, conditions that occur relatively rarely in practice [74,76].

Several variants of the original protocol were developed, tailored to different contexts such as disk storage [53] or fault-tolerant distributed databases [25]. Google uses the Paxos algorithm in the Chubby distributed lock service [25]; in turn, Chubby is used by BigTable, a high performance data storage system employed by several Google applications such as Gmail, Google Maps, or Youtube and available externally through the Google App Engine [29]. Microsoft also uses Paxos in the Autopilot cluster management service of the Bing search engine [67].

The Paxos protocol was generalized by Castro and Liskov in the context of malicious (Byzantine) failures among the replicas, to obtain a high-performance Byzantine fault-tolerant algorithm [24]. Their protocol has been later refined in terms of performance [57,70] and in terms of fault-tolerance [31]. Elements of Byzantine fault-tolerant protocols are used in the Bitcoin online currency system [55].

16.3.2 Concurrent Programming

The wide-spread introduction of multicore processors has brought problems related to concurrency in a distributed system at the forefront of software design. Even though the code executed by a single processor core may have few lines, the fact that many cores execute the program in parallel, with arbitrary interleavings of steps, implies that there is a variety of ways in which the program may behave, even given the same inputs. This makes concurrent programming an exceedingly difficult task. Further, classic interprocess synchronization primitives, such as locks or barriers, are increasingly believed not to be suitable for widespread use in large-scale multicore systems, for example [88].

Given the practical need for efficient concurrent code and the challenges posed by the use of classic synchronization primitives, significant research effort went into devising abstractions that make concurrent programming easier, while ensuring scalability of the software in a multicore environment.

16.3.2.1 Transactional Memory

One of the most promising solutions to this problem is *transactional memory* (TM). First introduced by Herlihy and Moss [62], the idea behind this abstraction is to enable processes to execute concurrently

through the use of lightweight, in-memory *transactions*. A transaction is a sequence of operations that should be executed atomically, similarly to the code in the critical section of a conventional lock. Unlike locks, transactions may *abort*, in which case their operations are rolled back and invisible to any other processes. To gain performance, transactions only *appear* to have executed sequentially, while they might in fact execute concurrently.

TM is easy to use, since the programmer should simply convert the blocks of code that have to be executed atomically into transactions. The burden of executing the code correctly and efficiently is taken by the TM implementation, whose contention management mechanisms are hidden from the programmer. TM can be seen as an adaptation of the notion of database transaction [54] to handle concurrency in multicore systems.

Since its introduction in 1993 [62], significant research effort has gone into implementing efficient TM systems and formalizing its properties. Particular attention has been given to *software* TM [90], that is, implementations where contention management is performed in software, without additional architectural support, for example [34,38]; hardware TM implementations also exist, for example [65,82].

TM is currently migrating from being a research construct to adoption in production environments. In particular, Intel has recently announced that its new Haswell microprocessor architecture will feature Transactional Synchronization Extensions [66]. IBM's BlueGene/Q processor, used in the Sequoia supercomputer, will also support TM [65]. The Rock processor by Oracle also has hardware support for TM [82]. Practical software TM implementations include the Glasgow Haskell Compiler [2].

16.3.2.2 Concurrent Data Structures

A related research direction is the design of efficient *concurrent* versions of practical data structures, such as stacks, queues, sets, or hash tables. Research has focused on *lock-free* versions of these data structures, which generally employ read-modify-write hardware primitives such as *compare-and-swap* instead of locks. The key property of such implementations is that they guarantee *system-wide progress*; in particular, by contrast to lock-based techniques, the suspension of one or more processes does not prevent the whole system from making progress. Efficient lock-free implementations of many practical data structures, such as queues [81], lists [60,89], or counters [42], have been developed. Lock-free implementations of these data structures are available through several libraries [1,83].

16.4 Research Issues

We presented a few fundamental results in the area, which only scratch the surface of a deeper theory for distributed computation. As such, distributed computing will be more and more a field of intense research activity, stimulated by the proliferation of distributed systems in the context of large-scale Internet services and multicore architectures.

16.4.1 Unified Theory

Given the wide variety of models and abstractions for distributed computing, a major research challenge is isolating a core set of fundamental models, abstractions, and results for the field. Such results should express fundamental notions and limitations of distributed computing and could be extended to new settings introduced by new architectures or new programming paradigms. A growing body of evidence points to *wait-free computation* in asynchronous systems as being such a fundamental abstraction: Several central results proved for wait-free asynchronous computation can be extended to yield new lower bounds in other models. For example, it has been shown that the impossibility of asynchronous set agreement [19,63,86] can be extended through simulation to yield time complexity lower bounds in synchronous [50,51] and eventually synchronous models [6]. Identifying such fundamental notions and developing them into a unified theory of distributed computation remain a major open question.

16.4.2 Understanding Speculation

Another important research question is the structured understanding of *algorithmic speculation* in the context of distributed systems. As noted before, many distributed algorithms are based on the idea of taking advantage of common well-behaved executions, while covering worst-case scenarios via several intricate backup procedures. This is the case of several protocols of practical interest, such as *Paxos* [74] or *PBFT* [24]. However, due to their ad hoc structure, such algorithms are exceedingly difficult to design, implement, and analyze, for example, [25,57]. Thus, a key challenge is to develop a structured approach for building and analyzing such algorithms. Given a specific problem, such approaches should identify common scenarios in which the algorithm has to speculate and provide a framework for composing speculative algorithmic modules with the fail-safe backup protocols correctly and efficiently. Questions such as the inherent complexity overhead of speculation or formally specifying algorithmic composition are still not well understood and present interesting research opportunities.

Furthermore, significant research effort has been invested in characterizing the complexity of *wait-free* implementations of fundamental abstractions. Together with practical observations, this research suggests that wait-free deterministic implementations of many common objects may have prohibitive cost in the worst case and even in the average case. On the other hand, the per-thread progress ensured by wait-free implementations may not be necessary in all situations; implementations that guarantee *global* progress, such as *lock-free (nonblocking)* implementations, may suffice in many practical scenarios. However, the complexity requirements of such implementations are not known for many fundamental abstractions.

16.4.3 Consistency Conditions and Randomization

With the advent of large-scale distribution, research started exploring *relaxed consistency conditions* for shared object implementations. The goal of such an approach is to obtain a gain in performance by weakening some of the formal requirements for object implementations. A simple example of this approach is the use of *unordered* pool or hash map data structures in concurrent programs [88], instead of queue or stack data structures, which do maintain a precise order between elements, but have been shown to have high complexity overhead [5,46,68].

A related research direction is the use of *randomization* in shared object implementations to ensure good performance with high probability. The use of relaxed consistency conditions and randomization appears promising for some implementations; however, a major open question is to fully exploit the benefits of these approaches for practical use and to characterize their limitations in the context of distributed computation.

16.4.4 New Computing Paradigms

Finally, a major challenge that the field faces periodically is adapting to new trends in distributed computation, dictated by new computing paradigms and new architectures. Currently, such changes are brought about by developments such as the pervasiveness of mobile wireless devices, new distributed computing paradigms such as *big data* processing, the advent of social networks and crowdsourcing, or the introduction of new architectures and programming paradigms for mass-produced microprocessors.

16.5 Summary

In this chapter, we have given an overview of some basic principles and fundamental results that underlie the study of distributed algorithms. In particular, we considered consensus and state machine replication as examples of fundamental abstractions and gave an overview of the core results and research

directions in distributed computing, together with some practical applications of results in the field. Given the continuing trend toward distribution, both at the macrolevel, through large-scale distributed services, and at the microlevel, through multicore processor architectures, we predict that distributed computing will be an area of intense research activity for years to come.

Key Terms

Adversary: The interleaving of process steps and the failures of the processes in a distributed system are assumed to be under the control of an entity called *adversary* or *scheduler*. It is assumed that the goal of the adversary is to maximize the cost of the algorithm (under a given cost metric), leading to worst-case executions of the distributed algorithm.

Asynchronous system: A system is said to be *asynchronous* if there are no bounds on the speeds at which processes take steps. In particular, processes may take steps in arbitrary order and at arbitrary relative speeds.

Byzantine failure: A process failure is said to be *Byzantine* [77] if the process stops following its prescribed algorithm and instead may behave arbitrarily. In particular, the process may behave maliciously, attempting to influence the global computation.

Consensus: Consensus [77,85] is a fundamental problem in distributed computing. In consensus, each process p_i proposes a value v_i . Every nonfaulty process has to eventually return a value (the *termination* condition), which has to be the same for all nonfaulty processes (the *agreement* condition). Further, the value returned has to be one of the values proposed (the *validity* condition).

Crash failure: A process is said to *crash* if the process stops executing the algorithm after some point in the execution.

Eventual synchrony: A system is said to exhibit *eventual synchrony* [41] if, in any execution of an algorithm in the system, there exists a point in time after which the relative speeds of processes are bounded. Note that the time bound may be unknown to the processes.

Execution: An *execution* is a sequence of operations performed by a set of processes. To represent an execution, we usually assume discrete time, where at every time unit there is one active process. Thus, an execution can be represented as a string of process identifiers.

Failure: Distributed algorithms may run on hardware that exhibits faulty behavior; such behavior is modeled as process crashes or process Byzantine failures, but also failures of the communication mechanisms, such as message loss or duplication.

Failure detector: A *failure detector* [28] is an abstraction that encapsulates information about process failures in a distributed system.

Lock-free: An object implementation is *lock-free* if it always guarantees global progress; in particular, the failure of a process does not prevent the system from fulfilling client requests.

Process: The *process* is a sequential unit of computation; it can be seen as a Turing machine. Distributed computing considers the computational power of several connected processes (i.e., several connected Turing machines) under various model assumptions.

Renaming: Renaming [10] is a fundamental problem in distributed computing in which a group of processes need to pick unique names from a small namespace.

Scheduler: Synonymous to *adversary*.

Synchronous system: A system is *synchronous* if nonfaulty processes perform communication and computation in perfect lock-step synchrony.

Transactional memory: Transactional memory [62] is a concurrent programming abstraction, which allows the programmer to specify regions of sequential code that are guaranteed to be executed atomically (i.e., the operations appear to occur instantaneously).

Wait-free: An object implementation is *wait-free* [61] if it guarantees per-process progress; in particular, any nonfaulty process returns from any invocation on the object within a finite number of steps.

Further Information

Distributed computing research is presented at several dedicated conferences. The Association for Computing Machinery (ACM) sponsors the annual Symposium on Principles of Distributed Computing (PODC), and publishes its proceedings. The European Association for Theoretical Computer Science (EATCS) sponsors the annual International Symposium on Distributed Computing (DISC), whose proceedings are published by Springer-Verlag. These are the two major conferences of the field. Results of general interest in distributed computing are published in Computer Science theory conferences, such as the ACM Symposium on Theory of Computing (STOC) or the IEEE Symposium on the Foundations of Computer Science (FOCS), and in the ACM Symposium on Parallel Algorithms and Architectures (SPAA). Complete versions of results can be found in journals such as the *Distributed Computing* journal by Springer, the *Journal of the ACM*, the *SIAM Journal on Computing*, or the *Algorithmica* journal.

There are several excellent textbooks presenting several aspects of the field at an introductory level. One of the main references is the *Distributed Algorithms* book by Lynch [80]. Other textbooks focusing on various aspects of distributed systems are *Reliable and Secure Distributed Programming*, by Cachin et al. [21], and *Distributed Computing: Fundamentals, Simulations, and Advanced Topics* by Attiya and Welch [15]. A recent book by Herlihy and Shavit entitled *The Art of Multiprocessor Programming* [64] provides an up-to-date presentation of shared-memory programming. Harris et al. give an overview of transactional memory research in [59]. The theoretical foundations of transactional memory are explored in [56].

17.1 Introduction

This chapter explores combinational and sequential Boolean logic design as well as technologies for implementing efficient, high speed digital circuits. Some of the most common devices used in computers and general logic circuits are described. Sections 17.2 through 17.4 introduce the fundamental concepts of logic circuits and in particular the rules and theorems upon which *combinational logic*, logic with no internal memory, is based. Section 17.5 describes in detail some frequently used combinational logic components and shows how they can be combined to build the arithmetic and logical unit (ALU) for a simple calculator. Section 17.6 introduces the subject of *sequential logic*; logic in which feedback and thus internal memory exist. Two of the most important elements of sequential logic design, the *data flip-flop* (DFF) and the *register*, are introduced. Memory elements are combined with the ALU to complete the design of a simple calculator. The final section of the chapter examines field-programmable gate arrays (FPGAs) which now provide fast, economical solutions for implementing large logic designs for solving diverse problems.

17.2 Overview of Logic

Logic has been a favorite academic subject, certainly since the Middle Ages and arguably since the days of the greatness of Athens. That use of *logic* connoted the pursuit of orderly methods for defining theorems and proving their consistency with certain accepted propositions. In the middle of the nineteenth century, George Boole put the whole subject on a sound mathematical basis and spread “logic” from the Philosophy Department into Engineering and Mathematics. (Boole’s original writings have recently been reissued, Boole, 2009.) Specifically, what Boole did was to create an algebra of two-valued (*binary*) variables. Initially designated as *true* or *false*, these two values can represent any parameter that has two clearly defined states. Boolean algebras of more than two values have been explored, but the original binary variable of Boole dominates the design of circuitry for reasons that we will explore. This chapter presents some of the rules and methods of binary Boolean algebra and shows how it is used to design digital hardware to meet specific engineering applications.

A system that is well adapted to digital (discrete) representation is one that spends little time in a state of ambiguity. All digital systems spend some time in indeterminate states when switching between values. One very common definition of the two states is made for systems operating between 2.5 volts (V) and ground. It is shown in Figure 17.1. One state, usually called *one*, is defined as any voltage greater than 1.7 V. The other state, usually called *zero*, is defined as any voltage less than 0.8 V.

The gray area in the middle is *ambiguous*. When an input signal is between 0.8 and 1.7 V in a 2.5 V complementary metal oxide semiconductor (CMOS) digital circuit, you cannot predict the output value. Most of what you will read in this chapter assumes that input variables are clearly assigned to the state *one* or the state *zero*. In real designs, there are always moments when the inputs are ambiguous. A good design is one in which the system never makes decisions based on ambiguous data. Such requirements limit the speed of response of real systems; they must wait for the ambiguities to settle out.

17.3 Concept and Realization of Digital Gate

A *gate* is the basic building block of digital circuits. A gate is a circuit with one or more inputs and a single output. From a logical perspective in a binary system, any input or output can take on only the values *one* and *zero*. From an analog perspective, the gates make transitions through the ambiguous region with great rapidity and quickly resolve to an unambiguous state.

In Boolean algebra, a good place to begin is with three operations: NOT, AND, and OR. These have similar meaning to their meaning in English. Given two input variables, called *A* and *B*, and an output variable *X*, $X = \text{NOT } A$ is true when *A* is false, and false when *A* is true. When both inputs are true, $X = A \text{ AND } B$ is true, and when either *A* or *B* is true (or both are true), $X = A \text{ OR } B$ is true. This is called an *inclusive or* function because it includes the case where *A* and *B* are both true. There is another Boolean operator, *exclusive or*, that is true when either *A* or *B*, but not both, is true. In fact there are 16 Boolean functions of two variables. The more useful functions are shown in truth table form in Table 17.1. These functions can be generalized to more than one variable, as is shown in Table 17.2.

Functions AND, OR, and NOT are sufficient to describe all Boolean logic functions. Why do we need all these other operators?

Logic gates are themselves an abstraction. The actual physical realization of logic gates is with transistors. Most digital designs are implemented in CMOS technology. In CMOS and most other transistor

TABLE 17.1 Boolean Operators of Two Input Variables

Inputs A B	True	False	A	NOT(A)	AND	OR	XOR	NAND	NOR	XNOR
0 0	1	0	0	1	0	0	0	1	1	1
0 1	1	0	0	1	0	1	1	1	0	0
1 0	1	0	1	0	0	1	1	1	0	0
1 1	1	0	1	0	1	1	0	0	0	1

TABLE 17.2 Boolean Operators Extended to More Than Two Inputs

Operation	Input Variables	Operator Symbol	Output = 1 if
NOT	A	\bar{A}	A = 0
AND	A, B, ...	$A \cdot B \cdots$	All of the set [A, B, ...] are 1.
OR	A, B, ...	$A + B + \cdots$	Any of the set [A, B, ...] are 1.
NAND	A, B, ...	$\overline{(A \cdot B \cdots)}$	Any of the set [A, B, ...] are 0.
NOR	A, B, ...	$\overline{(A + B + \cdots)}$	All of the set [A, B, ...] are 0.
XOR	A, B, ...	$A \oplus B \oplus \cdots$	The set [A, B, ...] contains an odd number of 1's.
XNOR	A, B, ...	$A \odot B \odot \cdots$	The set [A, B, ...] contains an even number of 1's.

FIGURE 17.2 Commonly used graphical symbols for seven of the gates defined in Table 17.1.

technologies, logic gates are naturally inverting. In other words, it is very natural to build NOT, NAND, and NOR gates, even if it is more natural to think about positive logic: AND and OR. Neither XOR nor XNOR are natural building blocks of CMOS technology. They are included for completeness. As we shall see, AND and OR gates are implemented with NAND and NOR gates.

There are widely used graphical symbols for these same operations. These are presented in Figure 17.2. The symbol for NOT includes both a buffer (the triangle) and the actual inversion operation (the open circle). Often, the inversion operation alone is used, as seen in the outputs of NAND, NOR, and XNOR. In writing Boolean operations we use the symbols \bar{A} for NOT A, $A + B$ for A OR B, and $A \cdot B$ for A AND B. $A + B$ is called the *sum* of A and B and $A \cdot B$ is called the *product*. The operator for AND is often omitted, and the operation is implied by adjacency, just like in multiplication. To illustrate the use of these symbols and operators, Figure 17.3 shows two constructs made from the gates of Figure 17.2. These two examples show how to build the expression $AB + CD$ and how to construct an XOR from the basic gates AND, OR, and NOT.

The first construct of Figure 17.3 would fit the logic of the sentence: “I will be content if my federal and state taxes are lowered (A and B, respectively), or if the money that I send is spent on reasonable things

FIGURE 17.3 Two constructs built from the gates in column 1 of Figure 17.2. The first is a common construct in which if either of two paired propositions is TRUE, the output is TRUE. The second is XOR constructed from the more primitive gates, AND, OR, and NOT.

and spent effectively (*C* and *D*, respectively).” You would certainly expect the speaker to be content if either pair is TRUE and most definitely content if both are TRUE. The output on the right side of the construct is TRUE if either or both of the inputs to the OR is TRUE. The outputs of the AND gates are TRUE when both of their inputs are TRUE. In other words, both state and federal taxes must be reduced to make the top AND’s output TRUE.

The right construct in Figure 17.3 gives an example of how one can build one of the basic logic gates, in this case the XOR gate, from several of the others. Let us consider the relationship of this construct to common speech. The sentence: “With the time remaining, we should eat dinner or go to a movie.” The implication is that one cannot do both. The circuit on the right of Figure 17.3 would indicate an acceptable decision (TRUE if acceptable) if either movie or dinner were selected (*asserted* or made TRUE) but an unacceptable decision if both or neither were asserted.

What makes logic gates so very useful is their speed and remarkably low cost. On-chip logic gates today can respond in well under a nanosecond and can cost less than 0.0001 cent each. Furthermore, a rather sophisticated decision-making apparatus can be designed by combining many simple-minded binary decisions. The fact that it takes many gates to build a useful apparatus leads us back directly to one of the reasons why binary logic is so popular. First we will look at the underlying technology of logic gates. Then we will use them to build some useful circuits.

17.3.1 CMOS Binary Logic Is Low Power

A modern microcomputer chip contains on the order of billions of logic gates. If all of those gates were generating heat at all times, the chip would melt. Keeping them cool is one of the most critical issues in computer design. Good thermal designs were significant parts of the success of Cray, IBM, Intel, and Sun. One of the principal advantages of CMOS binary logic is that it can be made to expend much less energy to generate the same amount of calculation as other forms of circuitry.

Gates are classified as *active logic* or *saturated logic* depending on whether they control the current continuously or simply switch it on or off. In active logic, the gate has a considerable voltage across it and conducts current in all of its states. The result is that power is continually being dissipated. In saturated logic, the TRUE–FALSE dichotomy has the gate striving to be perfectly connected to the power bus when the output voltage is high and perfectly connected to the ground bus when the voltage is low. These are zero-dissipation ideals that are not achieved in real gates, but the closer one gets to the ideal, the better the gate. When you start with more than one million gates per chip, small reductions in power dissipation make the difference between usable and unusable chips.

Saturated logic is *saturated* because it is driven hard enough to ensure that it is in a minimum-dissipation state. Because it takes some effort to bring such logic out of saturation, it is a little slower than active logic. Active logic, on the other hand, is always dissipative. It is very fast, but it is always getting hot. Although it has often been the choice for the most active circuits in the fastest computers,

active logic has never been a major player, and it owns a diminishing role in today’s designs. This chapter focuses on today’s dominant family of binary, saturated logic, which is CMOS.

17.3.2 CMOS Switching Model for NOT, NAND, and NOR

The metal–oxide–semiconductor (MOS) transistor is the oldest transistor in concept and still the best in one particular aspect: its control electrode—also called a *gate* but in a different meaning of that word from *logic gate*—is a purely capacitive load. Holding it at constant voltage takes no energy whatsoever. These MOS transistors, like most transistors, come in two types. One turns on with a positive voltage; the other turns off with a positive voltage. This pairing allows one to build *complementary* gates, which have the property that they dissipate no energy except when switching. Given the large number of logic gates and the criticality of power reduction, it is small wonder that the CMOS gate dominates today’s digital technology.

Consider how we can construct a set of primitive gates in the CMOS family. The basic element is a pair of switches in series, the NOT gate. This basic building block is shown in Figure 17.4. The switching operation is shown in the two drawings to the right. If the input is low, the upper switch is closed and the lower one is open—complementary operation. This connects the output to the high side. Apart from voltage drops across the switch itself, the output voltage becomes the voltage of the high bus. If the input now goes high, both switches flip and the output is connected, through the resistance of the switch, to the ground bus, high-in, low-out, and vice versa. We have an inverter. Only while the switches are switching is there significant current flowing from one bus to the other. Thus, in the static state, these devices dissipate almost no power at all. Once one has the CMOS switch concept, it is easy to show how to build NAND and NOR gates with multiple inputs.

Let us look at the switching structure of a 3-input NAND and 3-input NOR, just to show how multiple-input gates are created. The basic inverter or NOT gate of Figure 17.4 is our paradigm; if the lower switch is closed, the upper one is open, and vice versa. To go from NOT to an *N*-input NAND, make the single lower switch in the NOT a series of *N* switches, so only one of these need be open to open the circuit. Then change the upper complementary switch in the NOT into *N* parallel switches. With these, only one switch need be closed to connect the circuit. Such an arrangement with *N* = 3 is shown on the left in Figure 17.5. On the left, if any input is low, the output is high. On the right is the construction for NOR. All three inputs must be low to drive the output high.

An interesting question at this point is: How many inputs can such a circuit support? The answer is called the *fan-in* of the circuit. The fan-in depends mostly on the resistance of each switch in the series string. In most cases, six or seven inputs would be considered a reasonable limit. The number of outputs a gate can support is the *fan-out*. Logic gates can be designed with a considerably higher fan-out than fan-in.

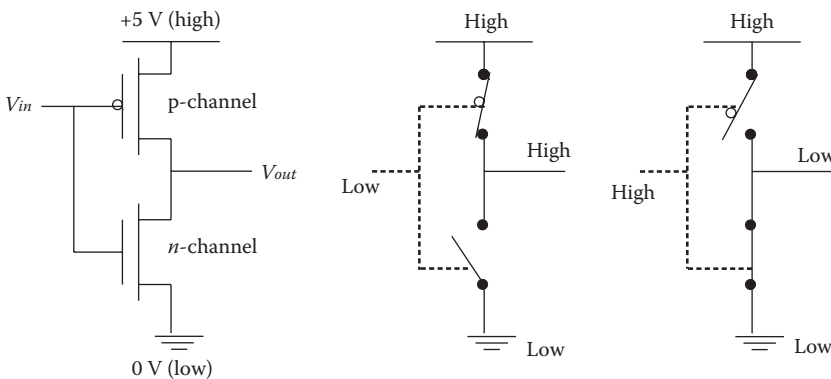

FIGURE 17.4 A CMOS inverter shown as a pair of transistors with voltage and ground and also as pairs of switches with logic levels. The open circle indicates logical negation (NOT).

FIGURE 17.5 Three pairs of CMOS switches arranged on the left to execute the 3-input NAND function and on the right the 3-input NOR. The switches are shown with all the inputs high, putting the output in the low state.

17.3.3 Doing It All with NAND

We think of the basic logic operators as being NOT, AND, and OR, since these seem to be the most natural. When it comes to building logic gates out of CMOS transistor technology, as we have just seen, the “natural” logic gates are NOTs, NANDs, and NORs.

To build an AND or an OR gate, you take a NAND or NOR and add an inverter. The more primitive nature of NAND and NOR comes about because transistor switches are inherently inverting. Thus, a single-stage gate will be NAND or NOR; AND and OR gates require an extra stage. If this is the way one were to implement a design with a million gates, a million extra inverters would be required. Each extra stage requires extra area and introduces longer propagation delays. Simplifying logic to eliminate delay and unnecessary heat are two of the most important objectives of logic design. Instead of using an inverter after each NAND or NOR gate, most designs use the inverting gates directly. We will see how Boolean logic helps as to do this. Consider the declaration: “Fred and Jack will come over this afternoon.” This is equivalent to saying: “Fred will stay away or Jack will stay away, NOT.” This strange construct in English is an exact formulation of one of two relationships in Boolean logic known as *De Morgan’s theorems*. More formally:

$$\overline{A \cdot B} = \overline{A} + \overline{B}$$

$$\overline{A + B} = \overline{A} \cdot \overline{B}$$

In other words, the NAND of A and B is equivalent to the OR of (NOT A) and (NOT B). Similarly, the NOR of A and B is equivalent to the AND of (NOT A) and (NOT B). These two statements can be represented at the gate level as shown in Figure 17.6.

De Morgan’s theorems show that a NAND can be used to implement a NOR if we have inverters. It turns out that a NAND gate is the only gate required. Next we will show that a NOT gate (inverter) can be constructed from a NAND. Once we have shown that NORs and NOTs can be constructed out of

FIGURE 17.6 On the left, the two forms of De Morgan's theorem in logic gates. On the right, the two forms of the circuit on the left of Figure 17.3. In the upper form, we have replaced the lines between the ANDs and OR with two inverters in series. Then, we have used the lower form of De Morgan's theorem to replace the OR and its two inverters with a NAND. The resulting circuit is all-NAND and is simpler to implement than the construction from AND and OR in Figure 17.3.

NANDs, only NAND gates are required. An AND gate is a NAND followed by a NOT and an OR gate is a NOR followed by a NOT. Thus, all other logic gates can be implemented from NANDs. The same is true of NOR gates; all other logic gates can be implemented from NORs.

Take a NAND gate and connect both inputs to the same input A . The output is the function $\overline{(A \cdot A)}$. Since A AND A is TRUE only if A is TRUE ($AA = A$), we have just constructed our inverter. If we actually wanted an inverter, we would not use a 2-input gate where a 1-input gate would do. But we could. This exercise shows that the minimal number of distinct logic gates required to implement all Boolean logic functions is one. In reality we use AND, OR, and NOT when using positive logic and NAND, NOR, and NOT when using negative logic or thinking about how logic gates are implemented with transistors.

17.4 Rules and Objectives in Combinational Design

Once the concept of a logic gate is established, the next natural question is: What useful devices can you build with them? We will look at a few basic building blocks and show how you can put them together to build a simple calculator.

The components of digital circuits can be divided into two classes. The first class of circuits has outputs that are simply some logical combination of their inputs. Such circuits are called *combinational*. Examples include the gates we have just looked at and those that we will examine in this section and in Section 17.5. The other class of circuits, constructed from combinational gates, but with the addition of internal feedback, have the property of *memory*. Thus, their output is a function not only of their inputs but also of their previous state(s). Since such circuits go through a sequence of states, they are called *sequential*. These will be discussed in Section 17.6.

The two principal objectives in digital design are functionality and minimum cost. Functionality requires not only that the circuit generates the correct outputs for any possible inputs but also that those outputs be available quickly enough to serve the application. Minimum cost must include both the design effort and the cost of production and operation. For very small production runs (<10,000), one wants to "program" off-the-shelf devices. For very large runs, costs focus mostly on manufacture and operation. The *operation* costs are dominated by cooling or battery drain, where these necessary peripherals add weight and complexity to the finished product. To fit in off-the-shelf devices, to reduce delays between input and output, and to reduce the gate count and thus the dissipation for a given functionality, designs

must be realized with the smallest number of gates possible. Many design tools have been developed for achieving designs with minimum gate count. In this section and the next, we will develop the basis for such minimization in a way that assures the design achieves logical functionality.

17.4.1 Boolean Realization: Half Adders, Full Adders, and Logic Minimization

One of the basic units central to a calculator or microprocessor is a binary adder. We will consider how an adder is implemented from logic gates. A straightforward way to specify a Boolean logic function is by using a truth table. This table enumerates the output for every possible combination of inputs. Truth tables were used in Table 17.1 to specify different Boolean functions of two variables. Table 17.3 shows the truth table for a Boolean operation that adds two one-bit numbers A and B and produces two outputs: the sum bit S and the carry-out C . Since binary numbers can only have the values 1 or 0, adding two binary numbers each of value 1 will result in there being a carry-out. This operation is called a *half adder*.

To implement the half adder with logic gates, we need to write Boolean logic equations that are equivalent to the truth table. A separate Boolean logic equation is required for each output. The most straightforward way to write an equation from the truth table is to use sum of products (SOP) form to specify the outputs as a function of the inputs. An SOP expression is a set of “products” (ANDs) which are “summed” (ORed) together. Note that any Boolean formula can be expressed in SOP or POS (product of sums) form.

Let us consider output S . Every line in the truth table that has a 1 value for an output corresponds to a term that is ORed with other terms in SOP form. This term is formed by ANDing together all of the input variables. If the input variable is a 1 to make the output 1, the variable appears as is in the AND term. If the input is a zero to make the output 1, the variable appears negated in the AND term. Let us apply these rules to the half adder. The S output has two combinations of inputs that result in its output being 1, therefore its SOP form has two terms ORed together. The C output only has one AND or product term, since only one combination of inputs results in a 1 output. The entire truth table can be summarized as

$$S = \bar{A} \cdot B + A \cdot \bar{B}$$

$$C = A \cdot B$$

Note that we are implicitly using the fact that A and B are Boolean inputs. The equation for C can be read “ C is 1 when A and B are both 1.” We are assuming that C is zero in all other cases. From the Boolean logic equations, it is straightforward to implement S and C with logic gates, as shown in Figure 17.7. The logical function for S is that of an XOR gate, so we show S as an XOR gate in the figure.

The half adder is a building block in an n -bit binary adder. An n -bit binary adder adds n -bit numbers represented in base 2. Table 17.4 shows the representation of three-bit, unsigned binary numbers.

TABLE 17.3 Truth Table for a Half Adder

Inputs		Outputs	
A	B	S	C
0	0	0	0
0	1	1	0
1	0	1	0
1	1	0	1

FIGURE 17.7 The gate level implementation of a half adder.

TABLE 17.4 Binary Representation of Decimal Numbers

Decimal	Binary
0	000
1	001
2	010
3	011
4	100
5	101
6	110
7	111

TABLE 17.5 Adding 3-Bit Binary Numbers

1	0		Carry Bits
0	1	0	2
0	1	1	+3
1	0	1	=5

The left-most bit is the most significant bit. It is in the 4’s place. The middle bit represents the 2’s place and the rightmost bit represents the 1’s place. The largest representable number, 111_2 , represents $4 + 2 + 1$, or 7 in decimal.

Let us examine adding two binary numbers. Table 17.5 shows the operation $2 + 3 = 5$ in binary. The top row is the carry-out from the addition in the previous bit location. Notice that there is a carry-out bit with value 1 from the second position to the third (leftmost) bit position.

The half adder described in the preceding text has two inputs: A and B . This can be used for the rightmost bit where there is no carry-in bit. For other bit positions we use a *full adder* with inputs A , B , and C_{in} and outputs S and C_{out} . The truth table for the full adder is given in Table 17.6. Note that a full adder adds one bit position; it is NOT an n -bit adder.

To realize the full adder as a circuit we need to design it using logic gates. We do this in the same manner as with the half adder, by writing a logic equation for each of the outputs separately. For each 1 in the truth table on the output of the function there is an AND term in the SOP representation. Thus, there are four AND terms for the S equation, and four AND terms for the C_{out} equation. These equations are given as follows:

$$S = \bar{A} \cdot \bar{B} \cdot C_{in} + \bar{A} \cdot B \cdot \bar{C}_{in} + A \cdot \bar{B} \cdot \bar{C}_{in} + ABC_{in}$$

$$C_{out} = \bar{A} \cdot BC_{in} + A \cdot \bar{B} \cdot C_{in} + AB \cdot \bar{C}_{in} + ABC_{in}$$

TABLE 17.6 Truth Table for a Full Adder

	Inputs			Outputs	
	A	B	C_{in}	S	C_{out}
0	0	0	0	0	0
1	0	0	1	1	0
2	0	1	0	1	0
3	0	1	1	0	1
4	1	0	0	1	0
5	1	0	1	0	1
6	1	1	0	0	1
7	1	1	1	1	1

These equations for S and C_{out} are logically correct, but we would also like to use the minimum number of logic gates to implement these functions. The fewer gates used, the fewer gates that need to switch, and hence the smaller amount of power that is dissipated. Next, we will look at applying the rules of Boolean logic to minimize our logic equations.

17.4.2 Axioms and Theorems of Boolean Logic

Our goal is to use the minimum number of logic gates to implement a design. We use logic rules or axioms. These were first described by George Boole, hence the term Boolean algebra. Many of the axioms and theorems of Boolean algebra will seem familiar because they are similar to the rules you learned for algebra in high school. Let us be formal here and state the axioms:

1. Variables are binary: This means that every variable in the algebra can take on one of two values and these two values are not the same. Usually, we will choose to call the two values 1 and 0, but other binary pairs such as TRUE and FALSE, and HIGH and LOW are widely used and often more descriptive. Two binary operators, AND (\cdot) and OR ($+$), and one unary operator, NOT, can transform variables into other variables. These operators were defined in Table 17.2.
2. Closure: The AND or OR of any two variables is also a binary variable.
3. Commutativity: $A \cdot B = B \cdot A$ and $A + B = B + A$.
4. Associativity: $(A \cdot B) \cdot C = A \cdot (B \cdot C)$ and $(A + B) + C = A + (B + C)$.
5. Identity elements: $A \cdot 1 = 1 \cdot A = A$ and $A + 0 = 0 + A = A$.
6. Distributivity: $A \cdot (B + C) = A \cdot B + A \cdot C$ and $A + (B \cdot C) = (A + B) \cdot (A + C)$. (The usual rules of algebraic hierarchy are used here where \cdot is done before $+$.)
7. Complementary pairs: $A \cdot \bar{A} = 0$ and $A + \bar{A} = 1$.

These are the axioms of this algebra. They are used to prove further theorems. Each algebraic relationship in Boolean algebra has a *dual*. To get the dual of an axiom or a theorem, one simply interchanges AND and OR as well as 0 and 1. Because of this principle of *duality*, Boolean algebra axioms and theorems come in pairs. The principle of duality tells us that if a theorem is true, then its dual is also true.

In general, one may prove a Boolean theorem by exhaustion—that is, by listing all of the possible cases—although more abstract algebraic reasoning may be more efficient. Here is an example of a pair of theorems based on the axioms given earlier:

Theorem 17.1 (Idempotency)

$$A \cdot A = A \text{ and } A + A = A.$$

Proof 17.1

The definition of AND in Table 17.1 can be used with exhaustion to complete the proof for the first form.

$$A \text{ is } 1 : 1 \cdot 1 = 1 = A$$

$$A \text{ is } 0 : 0 \cdot 0 = 0 = A$$

The second form follows as the dual of the first.

Now let us consider reducing the expression from the previous section:

$$C_{out} = \bar{A} \cdot BC_{in} + A \cdot \bar{B} \cdot C_{in} + AB \cdot \bar{C}_{in} + ABC_{in}$$

First, we apply idempotency twice to triplicate the last term on the right and put the extra terms after the first and second terms by repeated application of axiom 3:

$$C_{out} = \bar{A} \cdot BC_{in} + ABC_{in} + A \cdot \bar{B} \cdot C_{in} + ABC_{in} + AB \cdot \bar{C}_{in} + ABC_{in}$$

Now we apply axioms 4, 3, and 6 to obtain:

$$C_{out} = (\bar{A} + A)BC_{in} + A(\bar{B} + B)C_{in} + AB(\bar{C} + C)$$

And finally, we apply axioms 7 and 5 to obtain:

$$C_{out} = AB + AC_{in} + BC_{in}$$

The reduced equation certainly looks simpler; let us consider the gate representation of the two equations. This is shown in Figure 17.8. From four 3-input ANDs to three 2-input ANDs and from a 4-input OR to a 3-input OR is a major saving in a basically simple circuit.

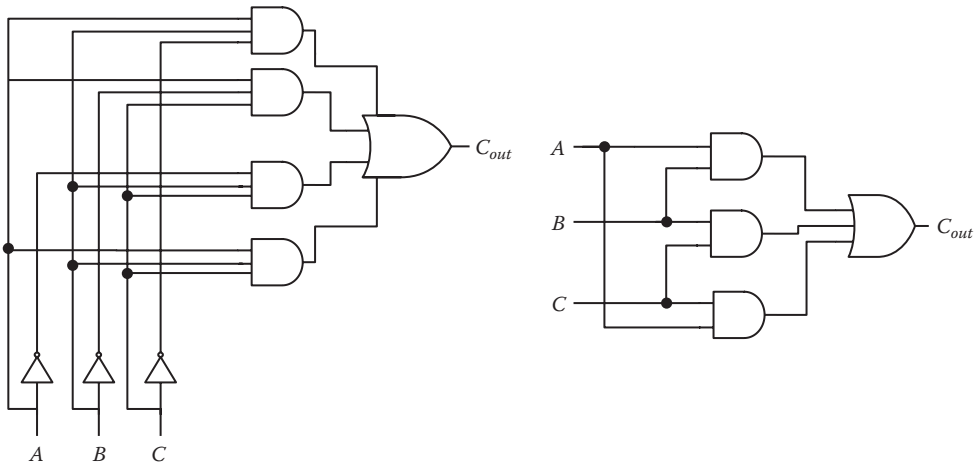

FIGURE 17.8 The direct and reduced circuits for computing the carry-out from the three inputs to the full adder.

The reduction is clear. The savings in a chip containing more than a million gates should build some enthusiasm for gate simplification. What is probably not so clear is how you could know that the key to all of this saving was knowing to make two extra copies of the fourth term in the direct expression. It turns out that there is a fairly direct way to see what you have to do, one that takes advantage of the eye's remarkable ability to see a pattern. This tool, the *Karnaugh map*, is the topic of the next section.

17.4.3 Design, Gate-Count Reduction, and SOP/POS Conversions

The *truth table* for the full adder was given in Table 17.6. All possible combinations of the three input bits appear in the second through fourth columns. Note that the first column is the *numerical value* if the three bits are interpreted as an unsigned binary number. So 000 is the value 0, 101 is the value 5, etc.

Let us rearrange the rows of the truth table, so that rather than being in increasing numerical order, the truth table values are listed in a way that each row differs from its neighbors by only one bit value. (Note that the fourth and fifth row (entries for 2 and 4) differ by more than one bit value.) It should become apparent soon why you would want to do this. The result will be Table 17.7.

Consider the last two lines in Table 17.7, corresponding to 6 and 7. Both have $C_{out} = 1$. On the input side, the pair is represented as $ABC_{in} + ABC_{in} = AB(\bar{C}_{in} + C_{in})$.

The algebraic reduction operation shows up as adjacency in the table. In the same way, the 5,7 pair can be reduced. The two are adjacent and both C_{out} outputs are 1. It is less obvious in the truth table, but notice that 3,7 also forms just such a pair. In other words, all of the steps proposed in algebra are “visible” in this truth table. To make adjacency even clearer, we arrange the groups of four, one above the other, in a table called a *Karnaugh map* after its inventor, M. Karnaugh (1953). In this map, each possible combination of inputs is represented by a box. The contents of the box are the output for that combination of inputs. Adjacent boxes all have numerical values exactly one bit different from their neighbors on any side. It is customary to mark the asserted outputs (the 1's) but to leave the unasserted cells blank (for improved readability). The tables for S and C_{out} are shown in Figure 17.9. The two rows are just the first and second group of four from the truth table with the output values of the appropriate column. First, convince yourself that each and every cell differs from any of its neighbors (no diagonals) by precisely one bit. The neighbors of an outside cell include the opposite outside cell. That is, they wrap around. Thus, 2 and 0 or 4 and 6 are neighbors. The Karnaugh map (or K-map) simply shows the relationships of the outputs of conjugate pairs, which are sets of inputs that differ in exactly one bit location. The item that most people find difficult about K-maps is the meaning and arrangement of the input variables around the map. If you think of these input variables as the bits in a binary number, the arrangement is more logical. The difference between the first four rows of the truth table and the second four is that A has the value 0 in the first four and the value 1 in the second four. In the map, this is shown by having A indicated as asserted in the second row. In other words, where the input parameter is placed, it is asserted.

TABLE 17.7 Truth Table for Full Adder with Rows Rearranged

Input	ABC_{in}	S	C_{out}
0	000	0	0
1	001	1	0
3	011	0	1
2	010	1	0
4	100	1	0
5	101	0	1
7	111	1	1
6	110	0	1

FIGURE 17.9 Karnaugh maps for sum and carry-out. The numbers in the cell corners give the bit patterns of ABC_{in} . The cells whose outputs are 1 are marked; those whose outputs are 0 are left blank.

Where it is not placed, it is unasserted. Accordingly, the middle two columns are those cells which have C_{in} asserted. The right two columns have B asserted. Column 3 has both B and C_{in} asserted.

Let us look at how the carry-out map implies gate reduction while sum's K-map shows that no reduction is possible. Since we are looking for conjugate pairs of asserted cells, we simply look for adjacent pairs of 1's. The carryout map has three such pairs; sum has none. We take pairs, pairs of pairs, or pairs of pairs of pairs—any rectangular grouping of 2^n cells with all 1's. With carryout, this gives us the groupings shown in Figure 17.10.

The three groupings in Figure 17.10 do the three things that we must always achieve:

1. The groups must cover all of the 1's (and none of the 0's).
2. Each group must include at least one cell not included in any other group.
3. Each group must be as large a rectangular box of 2^n cells as can be drawn.

Once we fulfill these three rules, we are assured of a minimal set, which is our goal. Although there is no ambiguity in the application of these rules in this example, there are other examples where more than one set of groups results in a correct, minimal set. K-maps can be used for functions of up to six input variables and are useful aids for humans to minimize logic functions. Computer-aided design programs use different techniques to accomplish the same goal for greater than six input variables.

Writing down the solution once you have done the groupings is done by reading the specification of the groups. The vertical pair in Figure 17.10 is BC_{in} . In other words, that pair of cells is uniquely defined as having B and C_{in} both 1. The other two groups are indicated in the figure. The sum of those three (where "+" is OR) is the very function we derived algebraically in the last section. Notice how you could know to twice replicate cell 7. It occurs in three different groups. It is important to keep in mind that the Karnaugh map simply represents the algebraic steps in a highly visual way. It is not intrinsically different from the algebra.

FIGURE 17.10 The groupings of conjugate pairs in carry-out.

FIGURE 17.11 The K-map for $F(X, Y, Z, T) = \Sigma(0, 1, 2, 3, 4, 8, 9, 12, 15)$ with the minterm groupings shown.

We have used the word “cell” to refer to a single box in the K-map. The formal name for a cell whose value is 1 is the *minterm* of the function. Its counterpart, the *maxterm*, comprises all the cells which represent an output value of 0. Note that all cells are both possible minterms and possible maxterms.

Two more examples will complete our coverage of K-maps. One way to specify a function is to list the minterms in the form of a summation, for example, $C_{out} = \Sigma(2, 5, 6, 7)$. Consider the arbitrary 4-input function $F(X, Y, Z, T) = \Sigma(0, 1, 2, 3, 4, 8, 9, 12, 15)$. With four input variables, there are sixteen possible input states, and every minterm must contact four neighbors. That can be accomplished in a 4×4 array of cells as shown in Figure 17.11. Convince yourself that each cell is properly adjacent to its neighbors. For example, 11_{10} (1011) is adjacent to 15 (1111), 9 (1001), 10_{10} (1010), and 3 (0011) with each neighbor differing by one bit. Now consider the groupings. Minterm 15 has no neighbors whose value is 1. Hence it forms a group on its own, represented by the AND of all four inputs. The top row and first columns can each be grouped as a pair of pairs. It takes only two variables to specify such a group. For example, the top row includes all terms of the form $00xx$, and the first column includes all the terms of the form $xx00$. This leaves us but one uncovered cell, 9. You might be tempted to group it with its neighbor, 8, but rule 3 demands that we make as large a covering as possible. We can make a group of four by including the neighbors 0 and 1 on top. Had we not done that, the bottom pair would be $X \cdot \bar{Y} \cdot \bar{Z}$, but by increasing the coverage, we get that down to $\bar{Y} \cdot \bar{Z}$, a 2-input AND versus a 3-input AND. The final expression is

$$F(X, Y, Z, T) = \bar{X} \cdot \bar{Y} + \bar{Y} \cdot \bar{Z} + \bar{Z} \cdot T + XYZT$$

The aforementioned function is in SOP form because it is a set of products which are summed together. It is just as easy to generate the function with a POS, where several OR gates are joined by a single AND. To get to that expression, we find \bar{F} , the complement of F , and then convert to F using De Morgan’s theorem. One finds \bar{F} by grouping the cells where F is not asserted—the zero cells. This is shown in Figure 17.12, where we get the expression $\bar{F} = \bar{X}\bar{Y}Z + XZ\bar{T} + X\bar{Y}Z + Y\bar{Z}T$.

Let us convert from \bar{F} to F using De Morgan’s theorem to get the POS form:

$$F = \overline{(\bar{X}\bar{Y}Z + XZ\bar{T} + X\bar{Y}Z + Y\bar{Z}T)} = (X + \bar{Y} + \bar{Z})(\bar{X} + \bar{Z} + T)(\bar{X} + Y + \bar{Z})(\bar{Y} + Z + \bar{T})$$

FIGURE 17.12 The K-map for the complement of F from Figure 17.11.

Why would one want to do this? Economy of gates. Sometimes the SOP form has fewer gates, sometimes the POS form does. In this example, the SOP form is somewhat more economical.

17.4.4 Minimizing with Don't Cares

Sometimes, we can guarantee that some combination of inputs will never occur. I don't care what the output value is for that particular combination of inputs because I know that the output can never occur. This is known as an "output" don't care. I can set these outputs to any value I want. The best way to do this is to set these outputs to values that will minimize the gate count of the entire circuit.

An example is the classic seven-segment numerical display that is common in watches, calculators, and other digital displays. The input to a seven-segment display is a number coded in binary-coded-decimal, a 4-bit representation with 16 possible input combinations, but only the 10 numbers 0, ..., 9 ever occur. The states 10, ..., 15 are called *don't cares*. One can assign them to achieve minimum gate count. Consider the entire number set that one can display using seven line segments. We will consider the one line segment indicated by the arrows in Figure 17.13. It is generally referred to as "segment e ," and it is asserted only for the numbers 0, 2, 6, and 8.

Now we will minimize $Se(A, B, C, D)$ with and without the use of the don't cares. We put an "X" wherever the don't cares may lie in the K-map and then treat each one as either 0 or 1 in such a way as to minimize the gate count. This is shown in Figure 17.14.

We are not doing something intrinsically different on the right and left. On the left, all of the don't cares are assigned to 0. In other words, if someone enters a 14 into this 0 : 9 decoder, it will not light up segment e . But since this is a don't care event, we examine the map to see if letting it light up on 14 will help.

FIGURE 17.13 Segment e of the seven-segment display whose decoder we are going to minimize.

FIGURE 17.14 Minimization of S_e without and with deliberate assignment of the don't cares.

The grouping with the choice of don't care values is decidedly better. We choose to assert e only for *don't cares* 10 and 14, but those assignments reduce the gates required from two 3-input ANDs to two 2-input ANDs. For this little circuit, that is a substantial reduction.

17.4.5 Adder/Subtractor

Let us return to the design of the full adder. A full (1-bit) adder can be implemented out of logic gates by implementing the equations for C and S . As we have seen, the simplified version for C is

$$C_{out} = AB + AC_{in} + BC_{in}$$

One cannot simplify S using K-maps. Instead, we will simplify S by inspection of the truth table for the full adder given in Table 17.6. Note that S is high when exactly one of the three inputs is high or when all the inputs are high. This is the same functionality as a 3-input XOR gate, as shown in Table 17.8. Thus, we can implement S with the following equation:

$$S = A \oplus B \oplus C_{in}$$

This completes our design of a full adder. Its implementation in logic gates is shown in Figure 17.15.

TABLE 17.8 Truth Table for 3-Input XOR

Inputs			Outputs	
A	B	C	$A \oplus B$	$A \oplus B \oplus C$
0	0	0	0	0
0	0	1	0	1
0	1	0	1	1
0	1	1	1	0
1	0	0	1	1
1	0	1	0	0
1	1	0	0	0
1	1	1	0	1

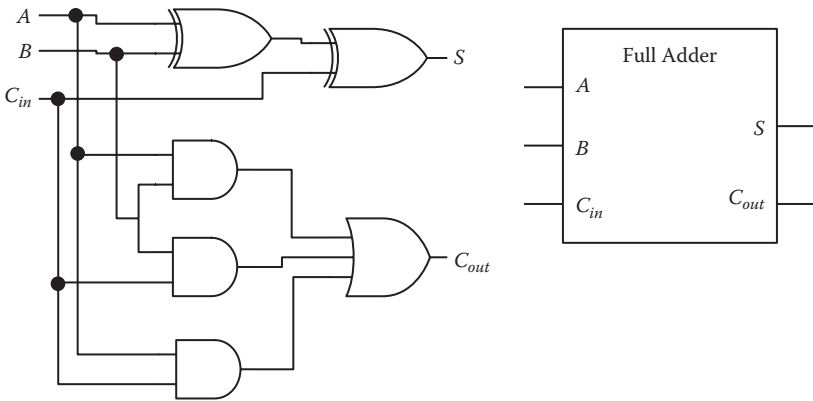

FIGURE 17.15 Implementation of full adder from logic gates on the left. Symbol of full adder on the right.

FIGURE 17.16 Implementation of an n -bit adder from full adders.

We would like to add n -bit binary numbers. To accomplish this we will connect N full adders as shown in Figure 17.16. This configuration connects the carry-out of one bit to the carry-in of the next bit and is called a *ripple-carry adder*. This design is small but slow because the carry must ripple through from the least significant bit to the most significant bit. For designs where speed is of the essence, such as modern high speed microprocessors, various techniques are used to speed up the calculation of the carry chain. Such techniques are beyond the scope of this chapter.

17.4.6 Representing Negative Binary Numbers

We would like to add negative numbers as well as positive numbers, and we would like to subtract numbers as well as add them. To do this we need a way of representing negative numbers in base 2. Two common methods are used: *sign-magnitude* and *2's complement*. A third method, *1's complement*, will also be described to aid in the explanation of 2's complement.

In Table 17.9, four bits are used to represent the values 7–0. The three different methods for representing negative numbers are shown. Note that for *all* three methods the positive numbers have the same representation. Also, the leftmost bit is always the sign bit. It is 0 for a positive number and 1 for a negative number. It is important to note that all these representations are different ways that a *human* interprets the bit patterns. The bit patterns are not what is changing; the interpretations are. Given a bit pattern, you cannot tell which system is being used unless someone tells you. This discussion can be extended to numbers represented with any number of bits.

The sign-magnitude method is the closest to the method we use for representing positive and negative numbers in decimal. The sign bit indicates whether it is positive or negative, and the remaining bits represent the magnitude or value of the number. So for example, to get the binary value of negative 3, you take the positive value 0011 and flip the sign bit to get 1011. While this is the most intuitive for humans to understand, it is not the easiest representation for computers to manipulate. This is true for several reasons.

TABLE 17.9 Binary Representation of Negative Numbers

Decimal	Sign-Magnitude	1's Complement	2's Complement
7	0111	0111	0111
6	0110	0110	0110
5	0101	0101	0101
4	0100	0100	0100
3	0011	0011	0011
2	0010	0010	0010
1	0001	0001	0001
0	0000	0000	0000
-0	1000	1111	
-1	1001	1110	1111
-2	1010	1101	1110
-3	1011	1100	1101
-4	1100	1011	1100
-5	1101	1010	1011
-6	1110	1001	1010
-7	1111	1000	1001
-8			1000

One is that there are two representations for 0, +0 and -0. A very common operation to perform is to compare a number to 0. With two representations of zero, this operation becomes more complex.

Instead, a representation called *2's complement* is more frequently used. The 2's complement representation has the feature that it has only one representation for zero. It has other advantages as well, including the fact that addition and subtraction are straightforward to implement; subtraction is the same as adding a negative number. If you add a number and its complement, the result is zero with no carry-out as one would expect. To form the negative value of a positive number in 2's complement, simply invert all the bits and add 1. Inverting the bits results in the 1's complement, as shown in Table 17.7. The 1's complement representation has many of the advantages of 2's complement, except that it still has two representations of zero. The 2's complement is formed by adding 1 to the 1's complement of a number. Number 3 in binary is 0011. Its one's complement is 1100 and its 2's complement is 1101. Given a negative number, how can I tell its value? Due to properties of 2's complement numbers, if I take the 2's complement of a negative number, I get its positive value. Given 1101, I invert the bits to get 0010 and then add 1 to get 0011, its positive value 3. Note that the 2's complement representation has one representation for zero, and it is the value represented by all zeros. Since I can represent 16 values with 4 bits, this leaves me with a nonsymmetric range. In other words, I can represent one more negative number 1000 than positive number. This number is -8. Its positive value cannot be represented in 4 bits. What happens if I take the 2's complement of -8? The 1's complement is 0111. When I add 1 to form the 2's complement, I get 1000. What is really happening is that the true value, +8, cannot be represented in the number of bits I have available. It overflows the range for the representation I am using.

Representing numbers in 2's complement makes it easy to do subtraction. To subtract two n -bit numbers $A - B$ you simply invert the bits of B and add 1 when you are summing $A + \bar{B}$.

We are now ready to expand our n -bit ripple-carry adder to an n -bit adder/subtractor. Just as we do addition one digit at a time, the adder circuit handles two input bits, A_i and B_i , plus a carry-in C_{in} . We can arrange as many of these circuits in parallel as we have bits. The i th circuit gets the i th bits of two operands plus the carry-out of the previous stage. It is straightforward to modify the full adder to be a one bit adder/subtractor. A one bit adder/subtractor performs the following tasks:

1. Choose B_i or the complement of B_i as the B input.
2. Form the sum of the three input bits, $S_i = A_i + B_i + C_{in}$.
3. Form the carry-out of the three bits, $C_{out_i} = f(A_i, B_i, C_{in})$.

TABLE 17.10 Choosing the B Input for an Adder/Subtractor

SB	B_i	Result
0	0	0
0	1	1
1	0	1
1	1	0

FIGURE 17.17 Connection of n full adders to form an N -bit ripple-carry adder/subtractor. At the rightmost adder, the subtract line (SB) is connected to C_{in_0} .

On a bit by bit basis, the complement of B_i is just $\overline{B_i}$. For an n -bit number, the two's complement is formed by taking the bit by bit complement and adding 1. I can add 1 to an n -bit subtraction by setting the carry-in bit, C_{in_0} to 1. In other words, I want $C_{in_0} = 1$ when subtract is true, and $C_{in_0} = 0$ when subtract is false. This is accomplished by connecting the control signal for subtracting (SB) to C_{in_0} . Similarly when $SB = 0$ I want to use B_i as the input to my full adder. When $SB = 1$, I want to use $\overline{B_i}$ as input. This is summarized in Table 17.10. By inspection, the desired B input bit to the i th full adder is the XOR of SB and B_i . If I put all the components together— n full adders, the carry-in of the LSB set to SB , and the XOR of SB and B_i to form the complement of B , I get an n -bit ripple-carry adder/subtractor as shown in Figure 17.17.

17.5 Frequently Used Digital Components

Many components such as full adders, half adders, 4-bit adders, 8-bit adders, etc. are used over and over again in digital logic design. These are usually stored in a design library to be used by designers. In some libraries these components are parameterized. For example, a generator for creating an n -bit adder may be stored. When the designer wants a 6-bit adder, he or she must instantiate the specific bit width for the component.

Many other, more complex components are stored in these libraries as well. This allows components to be designed efficiently once and reused many times. These include encoders, multiplexers, demultiplexers, and decoders. Such designs are described in more detail in the following text. Later, we will use them in the design of a calculator datapath.

17.5.1 Elementary Digital Devices: ENC, DEC, MUX, DEMUX

17.5.1.1 ENC

An ENCODER circuit has 2^n input lines and n output lines. The output is the number of the input line that is asserted. Such a circuit *encodes* the asserted line. The truth table of a 4-to-2 encoder is shown in Table 17.11. The inputs are $D_0, D_1, D_2,$ and $D_3,$ and the outputs are Q_0 and Q_1 . Note that we assume at

TABLE 17.11 Truth Table for a 4-to-2 Encoder

D_0	D_1	D_2	D_3	Q_1	Q_0	V
0	0	0	0	0	0	0
1	0	0	0	0	0	1
0	1	0	0	0	1	1
0	0	1	0	1	0	1
0	0	0	1	1	1	1

FIGURE 17.18 A four-to-two encoder with outputs Q_0 and Q_1 and valid signal.

most one input can be high at any given time. More complicated encoders, such as priority encoders, that allow more than one input to be high at a time, are described in the following.

An encoder, like all other components, is built out of basic logic gates. The equations for the Q outputs can be determined by inspection. Output Q_0 is 1 if D_1 is 1 or D_3 is 1. Output Q_1 is 1 if D_2 is 1 or D_3 is 1.

Note that there is no difference in the outputs of this circuit if *no* input is asserted or if input D_0 is asserted. To distinguish between these two cases, an output that indicates the Q outputs are valid, V is added. Output V is 1 if any of the inputs are 1 and 0 otherwise. V is considered a control output rather than a data output. A logic diagram of an encoder is shown in Figure 17.18.

17.5.1.2 DEC

A decoder performs the opposite function of an encoder. Exactly one of the outputs is true if the circuit is enabled. That output is the *decoded* value of the input, if I think of the input as a binary number. When the enable input (EN) is 0, the circuit is disabled, and all outputs are 0. The truth table of a 2-to-4 decoder is given in Table 17.12.

Note the use of X values for inputs in the first line of the truth table. Here, X stands for “don’t care.” In other words, I don’t care what the value of the inputs A and B are. If $EN = 0$, the outputs will always have the value 0. I am using the don’t care symbol, X, as a shorthand for the four combinations of input values for A and B . We have already used don’t cares for minimizing circuits with K-maps mentioned earlier. In that case the don’t cares were “output” don’t cares. The don’t cares in the truth table for the encoder are “input” don’t cares. They are shorthand for several combinations of inputs.

TABLE 17.12 Truth Table for a 2-to-4 Decoder with Enable

<i>EN</i>	<i>A</i>	<i>B</i>	<i>Q₀</i>	<i>Q₁</i>	<i>Q₂</i>	<i>Q₃</i>
0	X	X	0	0	0	0
1	0	0	1	0	0	0
1	1	0	0	1	0	0
1	0	1	0	0	1	0
1	1	1	0	0	0	1

17.5.1.3 MUX

Many systems have multiple inputs, which are handled one at a time. *Call waiting* is an example. You are talking on one connection when a clicking noise signals that someone else is calling. You switch to the other, talk briefly, and then switch back. You can toggle between calls as often as you like. Since you are using one phone to talk on two different circuits, you need a *multiplexer* or MUX to choose between the two. There is also an inverse MUX gate called either a DEMUX or a DECODER. Again, a telephone example is the selection of an available line among, say, eight lines between two exchanges. That is, you have one line in and eight possible out, but only one output line is connected at any time. An algorithm based on which lines are currently free determines the choice. Let us design these two devices, beginning with a two-to-one MUX.

What we want in a 2-input MUX is a circuit with one output. The value of that output should be the same as the input that we select. We will call the two inputs *A* and *B* and the output *Q*. The select input *S* chooses which input to steer to the output.

Logically, I can think of *Q* being equal to *A* when *S* = 0 and *Q* being equal to *B* when *S* = 1. I can write this as the Boolean equation: $Q = (A \cdot \bar{S}) + (B \cdot S)$. You can use a truth table to convince yourself that this equation captures the behavior of a 2-input MUX. Note that we now have a new dichotomy of inputs. We call some of them *inputs* and the others *controls*. They are not inherently different, but from the human perspective, we would like to separate them. In logic circuit drawings, *inputs* come in from the left and outputs go out to the right. *Controls* are brought in from top or bottom. The select input for our multiplexer is a control input. Note that, even though I talk about *S* being a control, in the logic equation it is treated the same as an input. An enable is another kind of control input. A *valid* signal can be viewed as a control output. A realization of a 2-to-1 Multiplexer with enable is shown in Figure 17.19.

The 2-to-1 MUX circuit is quite useful and is found in many design libraries. Other similar circuits are the 4-to-1 MUX and the 8-to-1 MUX. In general, you can design *n*-to-1 MUX circuits, where *n* is a power of 2. The number of select bits needed for an *n*-to-1 MUX is $\log_2(n)$.

FIGURE 17.19 A two-to-one MUX with enable. If the enable is asserted, this circuit delivers at its output, *Q*, the value of *A* or the value of *B*, depending on the value of *S*. In this sense, the output is “connected” to one of the input lines. If the enable is not asserted, the output *Q* is low.

FIGURE 17.20 A four-to-one MUX feeding a one-to-four DEMUX. The value on MUX select lines $S_1:S_0$ determines the input connected to Q . EN , in turn, is connected to the output of choice by $S_1:S_0$ on the DEMUX.

Figure 17.20 shows a 4-to-1 multiplexer on the left and a 1-to-4 demultiplexer on the right. The MUX chooses one of four inputs using the two select lines: S_1 and S_0 . If we view the values on the select lines as the binary numbers 0, ..., 3, we understand the selection process as enabling the top AND when the input is 00 and then progressively lower ANDs as the numbers become 01, 10, and 11. Essentially, there is a decoder circuit within the four-to-one multiplexer.

17.5.1.4 DEMUX/DECODER

The inverse circuit to a multiplexer is a demultiplexer or DEMUX. A DEMUX has one line in, which it switches to one of the n possible output lines. A one-to-four DEMUX, used in conjunction with the four-to-one MUX, is shown on the right in Figure 17.20.

Note that the Q output line on the multiplexer is labeled as the EN input line on the DEMUX. If I treat this line as an *enable*, the DEMUX becomes a DECODER, in the sense that, when EN is asserted, one and only one of the four outputs is asserted, that being the output selected by the number on $S_1:S_0$. So a decoder and a DEMUX are the same circuit. You usually do not find a DEMUX in a design library. Rather, what you find is called a DECODER or sometimes a DEMUX/DECODER.

Decoding is an essential function in many places in computer design. For example, random-access memory (RAM) is fed an address—a number—and must return data based on that number. It does this by decoding the address to assert lines which enable the output of the selected data. Similarly, computer instructions are numbers which must be decoded to assert the lines which enable the specific hardware that each instruction requires.

17.5.1.5 Priority Encoder

The encoder we started this section with assumed that exactly one input was asserted at any given time. An encoder which could deal with more than one asserted input would be even more useful, but how would we define the output if more than one line were asserted? One simple choice is to have the encoder deliver the value of the highest-ranking line that is asserted. Thus, it is a *priority encoder*.

The truth table for the priority encoder is given in Table 17.13. This truth table has a lot of similarities to the simple encoder we started this section with. The valid output V tells us if any input is asserted. The output Q_0 is true if the only input asserted is D_1 . The circuit differs in that more than one input may be asserted. In this case, the output encodes the value of the highest input that is asserted.

TABLE 17.13 Truth Table for a 4-to-2 Priority Encoder

D_0	D_1	D_2	D_3	Q_0	Q_1	V
0	0	0	0	0	0	0
1	0	0	0	0	0	1
X	1	0	0	1	0	1
X	X	1	0	0	1	1
X	X	X	1	1	1	1

So, for example, if D_0 and D_1 are both asserted, the output Q_0 is asserted. I don't care if the D_0 input is asserted or not, because the D_1 input has higher priority. Here once again, the don't cares are used as short hand to cover several different inputs. If I listed all possible combinations of inputs in the truth table, my truth table would have $2^4 = 16$ lines. Using don't cares makes the truth table more compact and readable.

17.5.2 Calculator Arithmetic and Logical Unit

Let us look at putting some of these components together to do useful work. The core of a calculator or microprocessor is its ALU. This is the part of the calculator that implements the arithmetic functions, such as addition, subtraction, and multiplication. In addition, logic functions are also implemented such as ANDing inputs and ORing inputs. A microprocessor may have several, sophisticated ALUs. We will examine the design of a very simple ALU for a 4-bit calculator. Our ALU will perform four different operations: AND, OR, addition, and subtraction on two 4-bit inputs, A and B . Two input control signals, I_1 and I_0 , will be used to choose between the operations, as shown in Table 17.14. We will call the 4 bit result R .

A common way to implement such an ALU is to implement the various functions in parallel, then choose the requested result based on the setting of the control inputs. The 4-bit AND requires four AND gates, one for each bit position. Similarly, the 4-bit OR requires four OR gates. We will implement the adder and subtractor using a single adder/subtractor unit, since using two would waste area. The adder/subtractor unit in Figure 17.17 is perfect for our purposes here. Note, in Table 17.14, that I_0 is 0 for adding A and B and 1 for subtracting A and B , so we can use I_0 for the SB input to the adder/subtractor. These units will always operate on the A and B inputs; a multiplexer will select the correct output based on the values of I_1 and I_0 . Four, 4-to-1 multiplexers are used, one for each output bit. 4-to-1 multiplexers are used because there are no 3-to-1 muxes. We will use the fourth input to pass the A input to the output R . The reason for doing this will become apparent when we use the ALU in a calculator datapath. To keep the diagram readable, we use the convention that signals with the same name are wired together. The resulting ALU implementation is shown in Figure 17.21. The symbol for this ALU is shown in Figure 17.22. We will use this symbol when we incorporate the ALU into a calculator datapath.

TABLE 17.14 ALU Instructions for Calculator

I_1	I_0	Result
0	0	$A \text{ AND } B$
0	1	$A \text{ OR } B$
1	0	$A + B$
1	1	$A - B$

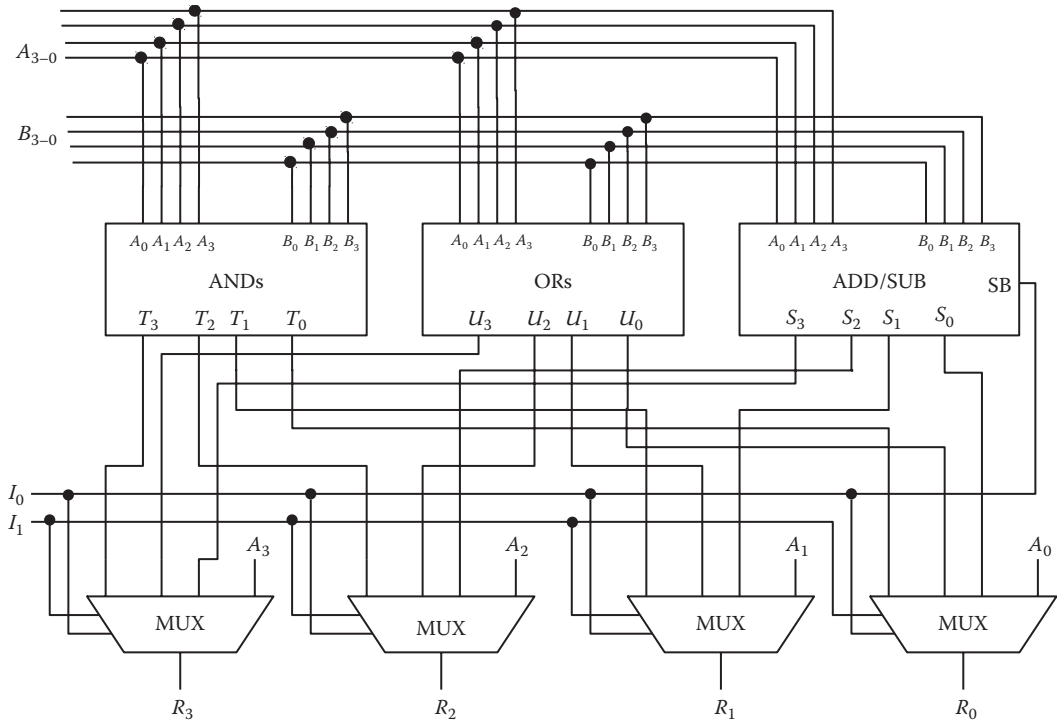

FIGURE 17.21 Implementation of an ALU from other components.

FIGURE 17.22 Symbol of an ALU component.

17.6 Sequential Circuits

17.6.1 Concept of a Sequential Device

So far, all the circuits we have discussed have been combinational. The current output can be determined by knowing the current inputs. Sequential circuits differ from combinational circuits because they have memory. For a circuit with memory, the current outputs depend on the current inputs *and* on the past history of the circuit. Memory elements dramatically change the way a circuit operates.

One of the oldest and most familiar sequential devices is a clock. In its modern implementation, a vibrating crystal of piezoelectric material has a mechanical resonance that is used to create an electrical signal with a very precise frequency. Because clock (CLK) signals oscillate between logic high and logic low states very quickly, and typically appear as a square wave. Figure 17.23 shows an example of a CLK signal. Except during transitions from one state to its successor, the clock is always in a discrete state.

FIGURE 17.23 Example waveform of an oscillating clock signal with a period of 20 ns and frequency 50 MHz.

To be in a discrete state requires some form of memory. I can only know the current output of my clock if I know what its previous output was.

One of the most ubiquitous and essential memory elements in the digital world is the latch or flip-flop (FF). It snaps from one position to the other (storing a 1 or storing a 0) and retains memory of its current position. We shall see how to build such a latch out of logic gates.

Like clocks, computers and calculators are *finite state machines*. All of the states of a computer can be enumerated. Saying this does not in any way restrict what you can compute. The states of a finite state machine capture the history of the behavior of the circuit up to the current state.

By linking memory elements together, we can build predictable sequential machines that do important and interesting tasks. Only the electronic “latch” and the datapath of our simple calculator are included in this short chapter, but from the sequential elements presented here complex machines can be built. There are two kinds of sequential circuits, called *clocked* or *synchronous* circuits and *asynchronous* circuits. The clocked circuits are built from components such as the FF, which are synchronized to a common CLK signal. In asynchronous circuits, the “memory” is the intrinsic delay between input and output. To maintain an orderly sequence of events, they depend on knowing precisely how long it takes for a signal to get from input to output. Although that sounds difficult to manage in a very complex device, it turns out that keeping a common clock synchronized over a large and complex circuit is nontrivial as well. We will limit our discussion to clocked sequential circuits.

17.6.2 Data Flip-Flop and Register

17.6.2.1 SR Latch. Set, Reset, Hold, and Muddle

In all the circuits we have looked at so far, there was a clear distinction between inputs and outputs. Now we will erase this distinction by introducing positive feedback; we will *feed back* the outputs of a circuit to the inputs of the same circuit. In an electronic circuit, positive feedback can be used to force the circuit into a “stable state.” Since saturated logic goes into such states quite normally, it is a very small step to generate an electronic latching circuit from a pair of NAND or NOR gates. The simplest such circuit is shown in Figure 17.24.

FIGURE 17.24 The basic set/reset (SR) latch is shown on the left. If \bar{S} is asserted, Q is asserted (set). If \bar{R} is asserted, Q is deasserted (reset). If neither \bar{S} nor \bar{R} is asserted (both high), the latch retains its current state. If both are asserted, the latch goes into a *muddle* state where Q is asserted and \bar{Q} is deasserted (both high), but upon simultaneous release of the inputs, the next state is unpredictable. The truth table for an NAND gate is shown on the right.

Analyzing Figure 17.24 requires walking through the behavior of the circuit. Let us assume that Q has the value 1 and \bar{Q} has the value 0. Start with both \bar{S} and \bar{R} deasserted. In other words, both have value 1, since they are active low signals. The inputs to B will be high, so \bar{Q} will be low. This is a “steady state” of this circuit; the circuit will stay in this state for some time. This state is called *storing 1*, or sometimes just “1” because Q has the value 1. You could toggle \bar{S} (i.e., change its value to 0 and then back to 1) and no other change would take place in the circuit.

Now, with \bar{S} high, let us assert \bar{R} by setting it to 0. First, \bar{Q} will go high because \bar{R} is one of the inputs to B , and the NAND of 0 with anything is 1. This makes both of the inputs to A high, so Q goes low. Now the upper input to B is low, so deasserting \bar{R} (setting it to 1) will have no effect. Thus, asserting \bar{R} has reset the latch. The latch is in the other steady state, “storing 0” or “0.”

At this point, asserting \bar{S} will set the latch, or put it back into the state “1.” For this reason, the S input is the “set” input to the latch, and the R input is the “reset” input.

What happens if both \bar{S} and \bar{R} are asserted at the same time? The initial result is to have both Q and \bar{Q} go high simultaneously. Now, deassert both inputs simultaneously. What happens? You cannot tell. It may go into either the set or the reset state. Occasionally, the circuit may even oscillate, although this behavior is rare. For this reason, it is usually understood that the designer is *not allowed* to assert both \bar{S} and \bar{R} at the same time. This means that, if the designer asserts both \bar{S} and \bar{R} at the same time, the future behavior of the circuit cannot be guaranteed, until it is set or reset again into a known state.

There is another problem with this circuit. To hold its value, both \bar{S} and \bar{R} must be continuously deasserted. Glitches and other noise in a circuit might cause the state to flip when it should not.

With a little extra logic, we can improve upon this basic latch to build circuits less likely to go into an unknown state, oscillate, or switch inadvertently. These better designs eliminate the muddle state.

17.6.2.2 Transparent D-Latch

A simple way to avoid having someone press two buttons at once is to provide them with a toggle switch. You can push it only one way at one time. We can also provide a single line to enable the latch. This enable control signal is usually called the *clock*. We will modify the S – R latch above. First, we will combine the S and R inputs into one input called the *data* or D input. When the D line is a one we will set the latch. When the D line is a zero we will reset the latch. Second, we will add a CLK signal to control when the latch updates. With the addition of two NANDs and an inverter, we can accomplish both purposes, as shown in Figure 17.25.

Note that we tie the data line, D , to the top NAND gate and the inverse or \bar{D} to the bottom NAND gate. This assures that only one of the two NAND outputs can be low at one time. The CLK signal allows us to open the latch (let data through) or latch the data at will. This device is called a *transparent D-latch* and is found in many digital design libraries. This latch is called *transparent* because the current value of D appears at Q if the CLK signal is high. If CLK is low, then the latch retains the last value D had when CLK was high.

FIGURE 17.25 The transparent D -latch. The circuit is transparent when CLK is high (i.e., the current value D appears at Q) and latched when CLK is low (the value of D when the clock went low is held at Q).

Has this device solved all of the problems we described for the SR-latch? No. Consider what might happen if D changes from low to high just as the clock changes from high to low. For the brief period before the change has propagated through the D -inverter, both NANDs see both inputs high. Thus, at least briefly, both \bar{R} and \bar{S} are asserted. This is the very situation we wanted to avoid. This muddled situation would last only for the propagation time of the inverter, but then the CLK signal arrives and drives both \bar{S} and \bar{R} high. The latch might oscillate or flip either way. In any case, it will be unpredictable.

There is another problem with this circuit. It is indeed transparent during the high CLK signal. This means that Q will mirror D while CLK is high. If D changes rapidly, so will Q . Sometimes you may want transparency. However, frequently you want to be able to guarantee when the output will change and to only allow one transition on the output per clock cycle. In that case you do not want transparency; what you really want is a different circuit: an FF.

17.6.2.3 Master-Slave DFF to Eliminate Transparency

The problem with transparent gates is not a new one. A solution which first appeared in King Solomon's time (ninth century B.C.E.) will work here as well. The Solomonic gate was a series pair of two quite ordinary city gates. They were arranged so that both were never open at the same time. You entered the first and it was shut behind you. While you were stuck between the two gates, a well-armed, suspicious soldier asked your business. Only if you satisfied him was the second gate opened. The solution of putting out-of-phase transparent latches between input and output is certainly one obvious solution to generating a DFF. Such an arrangement of two D -latches is shown in Figure 17.26.

The latch on the left is called the *master*; that on the right is called the *slave*. This master-slave (MS) DFF solves the transparency problem but does nothing to ameliorate the timing problems. While timing problems are not entirely solvable in any FF, accommodating the number of delays in this circuit tends to make the MSFF a slow device and thus a less attractive solution. Why should it be slow? The issue is that to be sure that you do not put either of these devices into a metastable or oscillatory state, you must hold D constant for a relatively long setup time (before the clock edge) and continue it past the clock transition for a sufficient hold time. This accommodation limits the speed with which the whole system can switch.

Can we do better? Yes, not perfect, but better. The device of choice is the edge-triggered DFF. We will not go into the details of the implementation of an edge-triggered FF as it is considerably more complicated than the circuits considered so far. An edge-triggered FF is designed to pass the input datum to the output during a very short amount of time defined by a clock edge. Edge triggered FFs can either be *rising edge*-triggered or *falling edge*-triggered. A rising edge-triggered FF will only change its output on the rising edge of a clock. There is still a setup time and a hold time; a small amount of time right around the clock edge during which the input datum must be stable in order to avoid the FF becoming metastable. The advantage of the edge-triggered design is that there is only one brief moment when any critical changes take place. This improves synchronization and leads to faster circuits.

FIGURE 17.26 The master-slave data flip-flop constructed of two D -latches in series.

There are other types of FFs as well, but the DFF is widely used and useful for building more complex circuits. We will consider these as we build more complex circuits. Most designs of a positive-edge-triggered DFF include two additional **asynchronous** inputs, *preset* and *clear*. Asynchronous inputs cause the output to change independently of the clock input. The *D* input is a **synchronous** input; changes on the *D* input are only reflected at the output during a clock edge. An active signal on the preset input causes the output of the FF to be set to 1; an active signal on the clear input causes the output to be cleared or set to 0. These inputs are useful for putting FFs in a design into a known state.

17.6.3 From DFF to Data Register, Shift Register, and Stack

The simplest and most useful device we can build with DFFs is a data register. A data register stores data. The simplest data register stores new data on every clock edge. Its design is shown in Figure 17.27. It is useful to control when the data register stores new data. We can extend the data register by adding a control signal called *load*. Now our register will load new data only when *load* is high. Otherwise it will store its old data. The new register design is shown in Figure 17.28.

We can also build a *shift* register, which shifts data, one bit at a time, into a parallel register. Shift registers are useful for converting serial data to parallel data. For example, you may receive data one bit at a time from a serial connection to your computer but want to operate on the data in parallel.

FIGURE 17.27 An *n*-bit data register built from *n* DFFs.

FIGURE 17.28 An *n*-bit register with load input. The upper layer is a set of *n* 2-input MUXs. The bottom layer is a set of *n* positive-edge-triggered DFFs.

FIGURE 17.29 An n -bit shift register with serial input, parallel, and serial output. This register shifts one bit to the left at the positive edge of every clock cycle.

Shift registers can sometimes be loaded in parallel also, just like the data register. We will keep things simple; a serial-in parallel-out shift register is shown in Figure 17.29. This shift register also has a serial output.

17.6.3.1 Stack for Holding Data

Our calculator requires memory to store variables that need to be manipulated. We could implement a RAM with addressing, read and write capabilities. Instead, to keep things simple, we will implement a *stack* for storing variables and results. A stack is a group of memory locations with limited access to its contents. At any given time, only the top of the stack can be read. This makes its implementation simple because general addressing does not need to be supported. Our stack supports three operations: push, pop, and hold. When a value is pushed onto the stack, it becomes the value at the top of the stack. All values already in the stack are pushed down by one. If the stack was full *before* the push operation, then the oldest (first in) value on the stack is lost. In a pop operation, the top of the stack is deleted, and all other values move up in the stack by one position. Note that this operation differs from a software *pop* operation. In software, the popped value is stored in a register. In our hardware implementation there is no register storing the removed value, so this value is lost. A stack is sometimes called a Last In First Out because that is the order in which values are accessed. The hold operation ensures that the current contents of the stack are retained. It is important to explicitly support this so that the contents of the stack are not changed during operation. Push, pop, and hold all happen on a clock edge. By default, the stack holds its contents when there is no clock edge.

We will implement a stack to hold 4-bit variables. Our stack will contain four locations. One can implement this stack as four shift registers (one for each bit position) with each shift register containing four FFs. The total memory contents of our stack is held in 16 DFFs. In a real calculator implementation, the stack would be implemented with memory cells which use fewer transistors and consume less power than DFFs, but for our small design, DFFs will suffice.

17.6.4 Datapath for 4-Bit Calculator

Let us put the pieces together and implement the datapath of a 4-bit calculator. We will use the stack described in the preceding text as our memory, and the ALU described in the previous section to implement logical operations. We need to add connections and a way to input data values. We also need an *instruction* to tell the calculator datapath what to do. We will use a 7-bit input that can be connected to toggle switches to provide the data and instructions. The datapath for the calculator is shown in Figure 17.30. The output is the top of stack (TOS). This is represented as the 4 bits $OUT[3:0]$. These could be hooked to a seven-segment display to display the results.

Our calculator will support the instructions: *push*, *pop*, *and*, *or*, *add*, and *subtract*. Note that the last four are the operations that our ALU supports. These are operations that take two 4-bit input values and produce a 4-bit result. The operands will be found on the stack. The input values will be popped off the stack, and the output value will be pushed onto the top of the stack. For a push operation, the

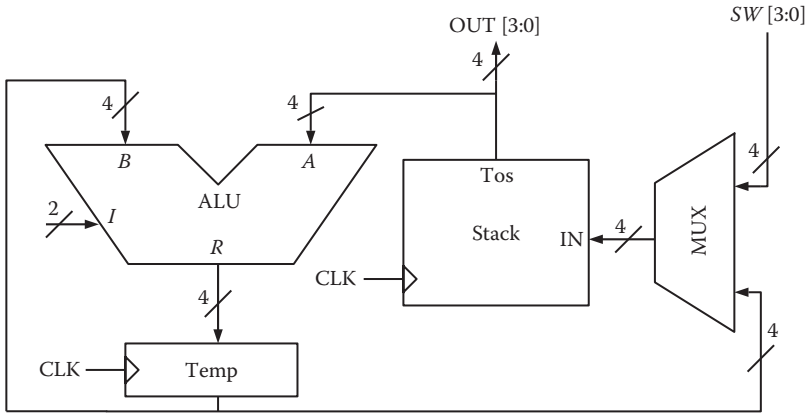

FIGURE 17.30 Calculator datapath. The temp register stores the ALU results every CLK edge.

value to be pushed onto the stack will be entered via the input switches. Suppose we want to calculate: $4 + (5 - 3)$. The operations required are:

- PUSH 4
- PUSH 3
- PUSH 5
- SUB
- ADD

The contents of the stack for this sequence of operations are shown in Figure 17.31.

The format of the instructions and data on the input switches are shown in Table 17.15. Note that only the PUSH instruction uses external data.

What is missing from our calculator design? A controller to make sure that the right operations are performed on the datapath in the correct sequence for each instruction. While the design of such a controller

FIGURE 17.31 Stack contents for calculating $4 + (5 - 3)$.

Instruction	$SW_6 \dots SW_4$	$SW_3 \dots SW_0$
AND	000	Unused
OR	001	Unused
ADD	010	Unused
SUB	011	Unused
PUSH	101	Data
POP	110	Unused

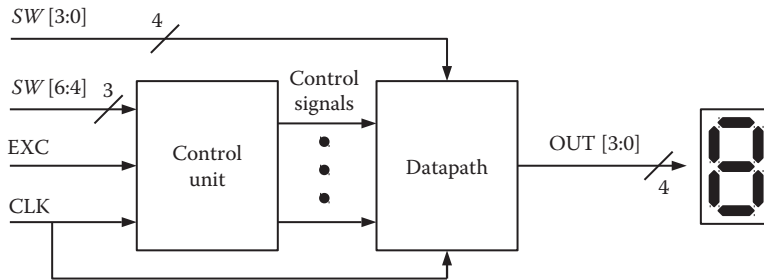

FIGURE 17.32 Connecting the controller, datapath, inputs, and outputs of the calculator.

is beyond the scope of this chapter, we will specify its behavior. For each instruction, the datapath goes through a sequence of operations or states. There are a finite number of such states to describe the behavior of the controller; hence, the controller is a finite state machine. Such a finite state machine can be implemented with FFs to hold the state and combinational logic to generate the next state and the outputs required. The inputs to the state machine are the current state and, for the calculator, the instruction which is entered via the switches. There is also a button the user needs to be able to press that indicates that the next instruction is ready to execute. The outputs are the control signals for the datapath. Our controller needs to output two bits for the ALU to tell it what to do, and two bits for the stack to generate the push, pop, or hold inputs, and 1 bit for the MUX to tell it which input to use. The temporary register requires no control signals—it will be updated every clock cycle. The entire calculator design is shown in Figure 17.32.

Let us look at how the instructions are executed on our calculator. There are three *classes* of instructions: *push*, *pop*, and ALU (*add*, *sub*, *and*, *or*). The *pop* instruction is the simplest. All that is needed is one state to pop the stack. In that state, the control inputs to the stack should be “pop.” We don’t care what the ALU or MUX control inputs are set to. Operation *push* is also a one state instruction. In that state the data on the switches is pushed onto the stack. So the control input for the MUX should be set to select the input switches and the control input for the stack should be set to “push.”

The ALU instructions are more complicated; they require three control states. We assume that our calculator has the two operands on the stack before an ALU instruction is executed. In the first state the data value on the top of the stack is stored in the temp register and the stack is popped. How can we accomplish this in one state? Note that the ALU is a combinational circuit and the TOS is already the A input to the ALU. If we select the ALU operation to pass A through to the output of the ALU, then on the clock edge, we will simultaneously store the current TOS value in the temp register and pop the value off the stack. Now, at the start of the second state, the first operand is at input B of the ALU because the temp register output is connected to input B. The second operand is at input A of the ALU because the TOS is connected to input A. In this state we will execute the correct ALU instruction, store the result in the temp register, and pop the A operand off the stack. Finally, in the third state the contents of the temp register, that is the results of the ALU operation, are pushed onto the stack. At the end of an ALU operation, the two operands have been popped from the stack, and the result pushed on the stack as required. To summarize, the three states of an ALU operation are as follows:

```
state 1: temp <- operand A; pop
state 2: temp <- A op B ; pop
state 3:                push temp
```

We have discussed what happens when an instruction is executing. What happens between instructions? The stack should “hold” its contents. It does not matter what the ALU is doing, or what input the MUX passes through. The memory of this design is in the stack. As long as the stack holds its contents, the memory is maintained. The temporary register is updated every clock cycle, but the results are not saved, so this does not affect the correct operation of the calculator datapath. Note that the output is always active, and it always shows what is currently on the top of the stack.

We have presented basic digital components, both combinational and sequential, and put them together to build a useful design: a simple calculator. Using essentially the same techniques, much more complicated devices can be constructed. Many of the digital devices we take for granted—digital clocks, anti-lock braking systems, microwave oven controllers, etc.—are the implementations of designs using these techniques. In the final section of this chapter, we will consider how such devices are physically realized.

17.7 ASICs and FPGAs—Faster, Cheaper, More Reliable Logic

The circuits we have considered so far—encoders, decoders, muxes, FFs, etc.—can be bought in packages with several to a chip. For example, a 14-pin package containing four 2-input NANDs per package has been available for more than 30 years. These chips are called *small scale integrated circuits*. No one who has watched the astonishing decline in the cost of digital electronics brought about by very large scale integrated circuits (VLSI) would expect to find engineers generating circuits by hooking up vast arrays of such packages. In a world where powerful computer chips roll off the line with more than a billion transistors all properly connected and functioning at clock speeds in excess of 1 GHz, why would we be manually hooking up hundreds of these small packages with 16 transistors in a chip that takes 15–20 ns to get a signal through a single NAND? Today, the equivalent of many pages of random logic circuit diagrams can be implemented in a single chip. There are many different ways to specify such designs and many different ways to physically realize them. The dominant method of design entry is using a hardware description language (HDL). HDLs resemble software programming languages with added features specifically for describing hardware such as bitwidth, I/O ports, and controller state specifications. Design tools translate HDL descriptions of a circuit to the final implementation. One of the goals of an HDL design is to separate the design from the implementation technology. The same HDL description, in theory at least, can be mapped to different target technologies.

There are also many technologies for physically realizing digital logic designs. Application-specific integrated circuits (ASICs) can be implemented as VLSI circuits where millions of transistors are realized on a single chip resulting in very high speeds and very low power dissipation. Such designs are manufactured at a foundry and cannot be changed after they have been implemented. Since high performance VLSI designs are very expensive to manufacture, they are increasingly used only for very large volume designs and designs where low power is critical. For example, VLSI ASIC chips are found in mobile phones, tablets, and other handheld devices that meet these criteria.

Designers are increasingly turning to *programmable* and *reconfigurable* devices for realizing their designs. These devices are manufactured in large quantities using VLSI techniques with the latest technology. They are specialized to a particular design after the fabrication process, hence they are programmable. Devices that can be reprogrammed to fix errors or update functionality are also called *reconfigurable*. One of the most popular of these devices is the FPGA. Modern FPGAs can implement designs with the equivalent of millions of transistors on a single chip and operate with clock speeds of several hundred MegaHertz. For many designs, FPGAs are much more cost effective than ASICs.

For both FPGAs and ASICs, all of the steps that take the initial design to finished chip can be automated. The initial design can be described as a schematic, similar to the diagrams in this chapter, or using an HDL. In the case of FPGAs, design tools translate this specification into programming data that can be downloaded to the chip. As we shall see, FPGA chips are based on memory technology. Rather than downloading a data file to memory, you download a configuration file to an FPGA that changes the way the hardware functions. This *programming* of the chip is very rapid. One can make a change in a complex design and have a working realization in less than an hour. By comparison, ASIC fabrication can take several weeks. By tightening the design cycle, such rapid prototyping has dramatically reduced the cost of designing and producing complex circuits for specific applications.

The underlying technology of an FPGA, and what makes it programmable and reconfigurable, is memory. Writing HDL programs and programming the FPGA makes the design process sound more like software than hardware development. The major difference is that the underlying structures being programmed implement

the hardware structures we have been discussing in this chapter. In this section, we introduce FPGA technology and explain how digital designs are mapped onto the underlying structures. There are several companies that design and manufacture FPGAs. We will use the architecture of the Xilinx FPGA as an example.

17.7.1 FPGA Architecture

Let us consider the architecture of Xilinx FPGAs. Our objective is not to learn how to program them—a task normally accomplished by software—but rather to show the relationship of these sophisticated chips to the logic we have already developed. The Xilinx chip is made up of three basic building blocks:

CLB the configurable logic blocks are where the computation of the user’s circuit takes place.

IOB the input/output blocks connect I/O pins to the circuitry on the chip.

Interconnect interconnect is essential for wiring between CLBs and from IOBs to CLBs.

The Xilinx chip is organized with its configurable logic blocks (CLBs) in the middle, its I/O blocks (IOBs) on the periphery, and lots of different types of interconnect. Wiring is essential to support the versatility of the chips to implement different designs efficiently and to ensure that the resources on the FPGA can be utilized efficiently. The overview of a Xilinx chip is presented in Figure 17.33. Each CLB

FIGURE 17.33 Overview of the Xilinx FPGA. I/O blocks (IOBs) are connected to pads on the chip which are connected to the chip-carrier pins. Several different types of interconnect are shown, including programmable interconnect points (PIPs), programmable switch matrices (PSMs), and long line interconnect.

is programmable and can implement combinational or sequential logic or both. Data enter or exit the chip through the IOBs. The interconnect can be programmed so that the desired connections are made. Distributed configuration memory (not shown in the figure) controls the functionality of the CLBs and IOBs, as well as the wiring connections. Implementation of the CLBs, interconnect, and IOBs is described in more detail in the following text.

17.7.1.1 Configurable Logic Block

How do you use memory to implement different Boolean logic functions? You download the truth table of the function to the memory. Changing the contents of the memory cells changes the functionality of the hardware. One set of memory cells for a one-bit output are referred to as a Look Up Table (LUT) because you “look up” the result. The basic Xilinx logic slice contains a 6-input LUT for realizing combinational logic. The result of this combinational function may or may not be stored in a DFF. The implementation of a logic slice, with 6-input LUT and optional FF on the LUT output, is shown on the left in Figure 17.34. Note that the multiplexer can be configured to output the combinational result of the LUT or the result of the LUT after it has been stored in the FF by setting the memory bit attached to the MUX’s select line. The logic is configured by downloading 17 bits of memory: the 16 bits in the lookup table and the one select bit for the multiplexer. Using this simple structure, all of the designs described so far in this chapter can be implemented.

The real Xilinx CLB is considerably more complicated; however, the way it is programmed is the same. It essentially contains two of the logic slices shown in Figure 17.35. In addition, there is a third LUT whose three inputs can include the outputs of the two 6-input LUTs. The CLB is designed to be able to implement any Boolean function of five input variables, or two Boolean functions each of four input variables. With the third LUT, some functions of up to nine input variables can be realized. Extra logic and routing is also added to speed up the carry chain for an adder, since adders are such common digital components. In addition, additional routing and muxes allow the FFs to be used independently of the LUTs as well as in conjunction with them.

17.7.1.2 Interconnect

Once the CLBs have been configured to implement combinational and sequential logic components, they need to be connected to implement larger circuits, just as we wired together the ALU, register, and muxes to implement the calculator datapath. This requires programmable interconnect, so that an FPGA can be programmed with different connections depending on the circuit being implemented. The key is the programmable interconnect point (PIP) shown on the right in Figure 17.34. This simple

FIGURE 17.34 On the left, a simplified CLB logic slice containing one 6-input lookup table (LUT) and optional DFF. The 16 one-bit memory locations on the left implement the LUT. One additional bit of memory is used to configure the MUX so the output comes either directly from the LUT or from the DFF. On the right is a programmable interconnect point (PIP). LUTs, PIPs, and MUXes are three of the components that make FPGA hardware programmable.

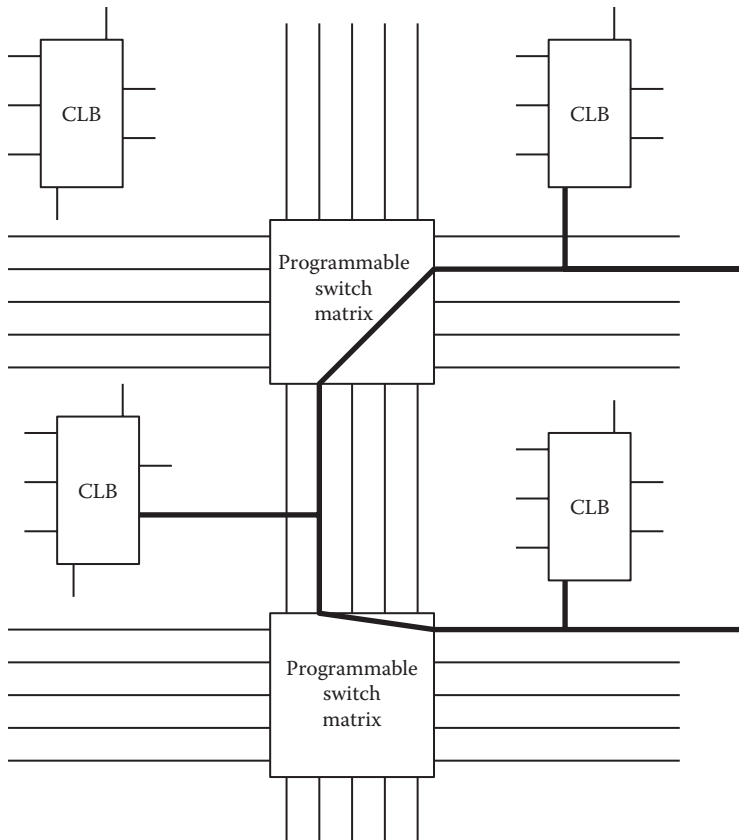

FIGURE 17.35 Programmable interconnect including two programmable switch matrices (PSMs) for connecting the output of one CLB to the input of two other CLBs.

device is a pass transistor with its gate connected to a memory bit. If that memory bit contains a one, the two ends of the transistor are logically connected; if the memory bit contains a zero, no connection is made. By appropriately loading these memory bits, different wiring connections can be realized. Note that there is considerably more delay across the PIP than across a simple metal wire on a chip. This is the tradeoff when using programmable interconnect.

Our FPGA architecture has CLBs arranged in a matrix over the surface of a chip, with routing channels for wiring between the CLBs. Programmable switch matrices (PSMs) are implemented at the intersection between a row and column of routing. These switch matrices support multiple connections, including signals on a row and a column, signals passing through on a row, and signals passing through on a column. Figure 17.35 shows a signal output from one CLB connecting to the inputs of two others. This signal passes through two PSMs and three PIPs, one for each CLB connection.

While programmable interconnect makes the FPGA versatile, each active device in the interconnection fabric slows the signal being routed. For this reason, early FPGA devices, where all the interconnect went through PIPs and PSMs, implemented designs that were considerably slower than their ASIC counterparts. More recent FPGA architectures have recognized the fact that high speed interconnect is essential to high performance designs. In addition to PIPs and PSMs, many other types of interconnect have been added. Many architectures have nearest neighbor connections, where wires connect from one CLB to its neighbors without going through a PIP. Lines that skip PSMs have been added. For example, double lines go through every other PSM in a row or a column. Long lines have been added to support signals that span the chip. Special channels for fast carry chains are available. Finally, global lines that

transmit CLK and reset signals are provided to ensure these signals are propagated with little delay. All of these types of interconnect are provided to support both versatility and performance.

17.7.1.3 Xilinx Input/Output Block

Finally, we need a way to get signals into and out of the chip. This is done with IOBs that can be configured as input blocks, output blocks, or both (but not at the same time). The output enable (OE) signal enables the IOB as an output. If OE is high, the output buffer drives its signal out to the I/O pad. If OE is low, the output function is disabled, and the IOB does not interfere with reading the input from the pad. The OE signal can be produced from a CLB, thus allowing the IOB to sometimes be enabled as an output and sometimes not. In addition, IOBs contain DFFs for latching the input and output signals. The latches can be bypassed by appropriately programming multiplexers. A simplified version of the IOB is shown in Figure 17.36. The actual IOB contains additional circuitry to properly deal with such electrical issues as voltage and current levels, ringing and glitches, and phased-locked loops that are important when interfacing the chip to signals on a circuit board.

Interconnect, CLBs, and IOBs form the basic architecture for implementing many different designs in a single FPGA. The configuration memory locations, distributed across the chip, need to be loaded to implement the appropriate design. For a Xilinx FPGA, these memory bits are SRAM and are loaded on power up. Special I/O pins that are not user configurable are provided to download the configuration bits that define the design to the FPGA. Other devices use different underlying technologies such as SRAM to provide programmability and reconfigurability, and some specialized devices include additional specialized circuitry like digital signal processing (DSP) blocks and an increased number of on-chip SRAM blocks.

17.7.1.4 Mapping Simple Calculator to FPGA

Let us look at how the calculator design (Figure 17.32) is mapped onto a board containing an FPGA. The board used contains a Xilinx 4028E FPGA, switches, push buttons, and seven-segment displays. The calculator was designed to map to this board, with switches used for entering instructions and data, a push button for the EXC command, and a seven-segment display used to show the TOS. The logic of the calculator is mapped to CLBs. The controller is made up of boolean logic and DFFs to hold the state. The datapath is made up of the components developed in this chapter and mapped to LUTs and DFFs.

FIGURE 17.36 Simplified version of the IOB. The IOBs can be configured to input or output signals to the FPGA. When OE is high, the output buffer is enabled so the output signal is driven on the I/O pad. When OE is low, the IOB functions as an input block. Buffers handle electrical issues with signals from the I/O pad.

This calculator was developed as an undergraduate laboratory experiment. Students enter the design using a schematic capture tool, which involves drawing diagrams like the ones in this chapter. Synthesis tools translate the design to LUTs and FFs, breaking the logic up into 4-input chunks of logic, each of which is implemented with one truth table. Alternatively, the design can be described using a HDL to specify behavior. A different synthesis tool is involved, but the end result is a set of LUTs and DFFs that implement the design. Placement tools map these components to CLBs on the chip, and routing tools route the connections making use of the various kinds of interconnect available. The tools translate the logic design to a bitstream that is downloaded to the board from a PC through a download cable. The result is a functioning calculator on an FPGA board.

An advantage of this design flow is that designers can migrate their designs to the newest chip architecture without changing the specification. Only the tools need to change to target a faster or cheaper device.

17.7.2 Higher Levels of Complexity

Integrating functionality on a single chip allows for higher performance and smaller packages. As more and more transistors can be realized on a single chip, and functionality increases, it also has become increasingly clear that one particular structure for implementing a design does not suit all needs. While many digital designs can be implemented using FPGA structures, others are less well suited to this technology. For example, hardware multipliers are particularly inefficient when mapped to CLBs. Certain functions perform better on a microprocessor or a programmable DSP than in digital hardware. For this reason, FPGA manufacturers have begun integrating large functionality blocks on FPGAs. For example, both Xilinx and Altera, two of the major FPGA manufacturers, have introduced FPGAs with embedded multipliers, embedded RAM blocks, and embedded processors. Altera calls this approach “System on a Programmable Chip”. Similarly, to support reconfigurability after manufacturing, ASIC designers are increasingly adding blocks of FPGA logic to their designs. It is clear that the future will bring more complex chips with more functionality, higher clock speeds, and more types of logic integrated on a single chip. Digital logic and reconfigurable hardware will be part of these designs for the foreseeable future.

Key Terms

Active logic: Digital logic which operates all of the time in the active, dissipative region of the electronic amplifiers from which it is constructed. Such logic is generally faster than saturated logic, but it dissipates much more energy. See *saturated logic*.

ASIC: Application-specific integrated circuit. Integrated circuits that are designed for a specific application. The term is used to describe VLSI circuits which can be configured before manufacturing to meet the specific needs of the application. High performance ASICs are low power and high speed but also expensive.

CLB: Configurable logic block in a Xilinx FPGA. This is where the computation occurs in an FPGA. CLBs implement truth tables and DFFs.

Clock: The input which provides the timing signal for a circuit. In general, the oscillator circuit which generates a synchronization signal.

CMOS: Complementary metal–oxide–semiconductor. The dominant family of binary, saturated logic. CMOS circuits are built from MOS transistors in complementary pairs. When one transistor is open, its complement is closed, ensuring that no current flows through the switch itself. Such a configuration has minimum power dissipation in any static state.

Combinational circuit: A logic circuit whose output is a function only of its inputs. Apart from propagation delays, the output always represents a logical combination of its present inputs. See sequential circuit.

- Critical race:** In a sequential circuit, a situation in which the “next state” is determined by which of two (or more) internal gates is first to reach saturated state. Such a race is dependent on minor variations in circuit parameters and on temperature, making the circuit unpredictable and possibly even unstable.
- Decoder:** A logic circuit with N inputs and 2^N outputs, one and only one of which is asserted to indicate the numerical value of the N input lines read as a binary number. A decoder and demultiplexer use the same internal circuitry.
- Demultiplexer (DEMUX):** A logic circuit with K control inputs which steers the data input to the one of the 2^K outputs selected by the control inputs.
- D flip-flop (DFF):** A fundamental sequential circuit whose output changes only upon a CLK signal and whose output represents the data on its input at the time of the last clock.
- Don't care:** In a truth table or Karnaugh map, a state which is irrelevant to the correct functioning of the circuit (e.g., because it never occurs in the intended application). Thus, the designer “doesn't care” whether that state is asserted, and he or she may choose the output that best minimizes the number of gates.
- Edge-triggered FF:** An FF which changes state on a clock transition from low to high or high to low rather than responding to the level of the CLK signal. Contrast to MS FF.
- Encoder:** A logic circuit with 2^N inputs and N outputs, the outputs indicating the binary number of the one input line that is asserted. See also *priority encoder*.
- Flip-flop:** Any of several related bistable circuits which form the memory elements in clocked, sequential circuits.
- FPGA:** Field-programmable gate array. VLSI chips with a large number of reconfigurable gates that can be “programmed” to function as complex logic circuits. The programming can be done on site and in some cases may be dynamically (in circuit) reprogrammable.
- Glitch:** A transient transition between logic states caused by different delays through parallel paths in a logic circuit. They are unintentional transitions, so they do not correctly represent the logic of the intended design.
- HDL:** Hardware Description Language. A language that resembles a programming language with added features for specifying hardware designs.
- IOB:** I/O block in a Xilinx FPGA. Block on the periphery of an FPGA that supports the input and/or output of a signal from the FPGA to its external environment.
- Karnaugh map:** A mapping of a truth table into a rectangular array of cells in which the nearest neighbors of any cell differ from that cell by exactly one binary input variable. K-maps are useful for minimizing Boolean logic functions.
- Master–slave FF:** An FF which changes state when the clock voltage reaches a threshold level. Contrast to edge-triggered FF.
- Multiplexer (MUX):** A circuit with N control inputs to select among one of 2^N data inputs and connect the appropriate data input to the single output line.
- PIP:** Programmable interconnect point on a Xilinx FPGA. A pass transistor with a memory bit connected to its gate terminal. If the memory is loaded with a “1” the two ends are connected; if loaded with a “0” the two ends are not connected. This is the basis of programmable interconnect.
- Priority encoder:** An encoder with the additional property that if several inputs are asserted simultaneously, the output number indicates the numerically highest input that is asserted. For example, if lines 1 and 3 were both asserted, the output value would be 3.
- Saturated logic:** Logic gates whose output is fully on or fully off. Saturated logic dissipates no power except while switching. The opposite of *saturated logic* is *active logic*.
- Sequential circuit:** A circuit which goes through a sequence of stable states, transitioning between such states at times determined by a CLK signal. The output of a sequential circuit depends both on its current inputs and its history, which is captured in the states. Contrast with *combinational* circuit.

Transparent latch: Essentially, an FF which continuously passes the input to the output (thus *transparent*) when the clock is high (low) but holds the last output during any interval when the clock is low (high). The circuit is said to have *latched* when it is holding its output constant regardless of the value of the input.

VLSI: Very large scale integrated circuit. A semiconductor device that integrates millions of transistors on a single chip. VLSI chips are typically very high speed and have very high power dissipation.

Further Information

This is a very quick pass through digital circuit design. What has been covered in this chapter provides a good overview of the principles as well as information to help the reader understand the chapter on computer architecture in this volume.

There are many textbooks devoted to the subject of digital logic design. Wakerly (2005) emphasizes basic principles and the underlying technologies. Other digital logic texts emphasize logic design tools (Katz, 2004) and computer design fundamentals (Mano and Kime, 2007).

There have also been many volumes published on design entry, tools for automating the digital design process, and mapping designs onto Field Programmable Logic (FPL). The Hardware Description Languages (HDLs) most widely used today are VHDL (Ashenden, 2008) and Verilog (Moorby and Thomas, 2008). The interested reader may also wish to pursue the topic of design with field programmable logic (Zeidman, 2002). The subjects of logic design, FPL and HDLs, are brought together in one volume (Salcic and Smailagic, 2000).

Ongoing research in this area is concerned with design entry, automation of the design process and new architectures, and technologies for implementing digital designs. The research in design entry is focused on raising the level of specification of digital logic designs. New HDLs based on high level languages such as Java and C are being developed. Another approach is design environments which incorporate sophisticated libraries of very complex, parameterized components such as digital filters, ALUs, and Ethernet controllers. The user can customize these blocks for their specific design. One such widely used environment is Simulink, a product of Mathworks.

Along with higher levels of design specification, researchers are investigating more sophisticated design automation tools. The goal is to have designers specify the functionality of their designs and to use synthesis tools to automatically translate that functionality to efficient hardware implementations.

18.1 Introduction

As shown in Figure 18.1, a computing system consists of three fundamental units: (i) units of computation to perform operations on data (e.g., processors), (ii) units of storage (or memory) that store data to be operated on or archived, (iii) units of communication that communicate data between computation units and storage units. The storage/memory units are usually categorized into two: (1) *memory system*, which acts as a *working storage area*, storing the data that is currently being operated on by the running programs, and (2) the backup *storage system*, for example, the hard disk, which acts as a *backing store*, storing data for a longer term in a persistent manner. This chapter will focus on the “working storage area” of the processor, that is, the memory system.

The memory system is the repository of data from where data can be retrieved and updated by the processor (or processors). Throughout the operation of a computing system, the processor reads data from the memory system, performs computation on the data, and writes the modified data back into the memory system—continuously repeating this procedure until all the necessary computation has been performed on all the necessary data.

18.1.1 Basic Concepts and Metrics

The *capacity* of a memory system is the total amount of data that it can store. Every piece of data stored in the memory system is associated with a unique *address*. For example, the first piece of data has an

FIGURE 18.1 Computing system.

address of 0, whereas the last piece of data has an address of $capacity - 1$. The full range of possible addresses, spanning from 0 to $capacity - 1$, is referred to as the *address space* of the memory system. Therefore, in order to access a particular piece of data from the memory system, the processor must supply its address to the memory system.

The *performance* of a memory system is characterized by several important metrics: (i) latency, (ii) bandwidth, and (iii) parallelism. A high-performance memory system would have low latency, high bandwidth, and high parallelism. *Latency* is the amount of time it takes for the processor to access one piece of data from the memory system. *Bandwidth*, also known as *throughput*, is the rate at which the processor can access pieces of data from the memory system. At first blush, latency and bandwidth appear to be inverses of each other. For example, if it takes time T seconds to access one piece of data, then it would be tempting to assume that $1/T$ pieces of data can be accessed over the duration of 1 s. However, this is not always true. To fully understand the relationship between latency and bandwidth, we must also examine the third metric of a memory system's performance. *Parallelism* is the number of accesses to the memory system that can be served concurrently. If a memory system has a parallelism of 1, then all accesses are served one-at-a-time, and this is the only case in which bandwidth is the inverse of latency. But if a memory system has a parallelism of more than 1, then multiple accesses to different addresses can be served concurrently, thereby overlapping their latencies. For example, when the parallelism is equal to two, during the amount of time required to serve one access (T), another access is served in parallel. Therefore, while the latency of an individual access remains unchanged at T , the bandwidth of the memory system doubles to $2/T$. More generally, the relationship among latency, bandwidth, and parallelism of a memory system can be expressed as follows:

$$\text{Bandwidth [accesses/time]} = \frac{\text{Parallelism [unitless]}}{\text{Latency [time/access]}}$$

While the bandwidth can be measured in the unit of accesses-per-time (preceding equation), another way of expressing bandwidth is in the unit of bytes-per-time—that is, the-amount-of-data-accessed-per-time (the following equation):

$$\text{Bandwidth [bytes/time]} = \frac{\text{Parallelism [unitless]}}{\text{Latency [time/access]}} \times \text{DataSize [bytes/access]}$$

An additional characteristic of a memory system is cost. The *cost* of a memory system is the capital expenditure required to implement it. Cost is closely related to the capacity and performance of the memory system: increasing the capacity and performance of a memory system *usually* also makes it more expensive.

FIGURE 18.2 Memory system.

18.1.2 Two Components of the Memory System

When designing a memory system, computer architects strive to optimize for all of the three characteristics explained in the preceding text: large capacity, high performance, and low cost. However, a memory system that has both large capacity and high performance is also very expensive. For example, when one wants to increase the capacity of memory, it is almost always the case that the latency of memory also increases. Therefore, when designing a memory system within a reasonable cost budget, there exists a fundamental trade-off relationship between capacity and performance: it is possible to achieve either large capacity or high performance but not both at the same time in a cost-effective manner.

As a result of the trade-off between capacity and performance, a modern memory system typically consists of two components, as shown in Figure 18.2: (i) a *cache* [44] (pronounced “cash”), a component that is small but relatively fast-to-access and (ii) *main memory*, a component that is large but relatively slow-to-access. Between the two, main memory is the all-encompassing (i.e., “main”) repository whose capacity is usually determined to minimize accesses to the storage system. If the memory system were to consist only of main memory, then all accesses to the memory system would be served by main memory, which is slow. That is why a memory system also contains a cache: Although a cache is much smaller than main memory, it is fast (exactly because it is smaller). The memory system utilizes the cache by taking a subset of the data from main memory and placing it into the cache—thereby enabling some of the accesses to the memory system to be served quickly by the cache. The data stored in the cache are replicas of the data that are already stored in main memory. Hence, the capacity of the memory system as a whole is defined by the capacity of only the main memory while ignoring the capacity of the cache. In other words, while the processor can always access the data it wants from main memory, the cache exists to *expedite* some of those accesses as long as they are to data that are replicated in the cache. In fact, most memory systems employ not just one but *multiple* caches, each of which provides a different trade-off between capacity and performance. For example, there can be two caches, one of which is 3 smaller and faster than the other. In this case, the data in the smaller cache is a subset of the data in the larger cache, similar to how the larger cache is a subset of the main memory.

Note that the structure and operation of the hardware components that make up the cache and main memory can be similar (in fact, they can be exactly the same). However, the structure and operation of cache and memory components are affected by (i) the function of the respective components and (ii) the technology in which they are implemented. The main function of caches is to store a small amount of data such that it can be accessed quickly. Traditionally, caches have been designed using the SRAM technology (so that they are fast), and main memory has been designed using the DRAM technology (so that it has large capacity). As a result, caches and main memory have evolved to be different in structure and operation, as we describe in Sections 18.4 and 18.5.

18.2 Memory Hierarchy

An ideal memory system would have the following three properties: high performance (i.e., low latency and high bandwidth), large capacity, and low cost. Realistically, however, technological and physical constraints limit the design of a memory system that achieves all three properties at the same time. Rather, one property can be improved only at the expense of another—that is, there exists a fundamental

trade-off relationship that tightly binds together performance, capacity, and cost of a memory system. (To simplify the discussion, we will assume that we always want low cost, restricting ourselves to the “zero-sum” trade-off relationship between performance and capacity.) For example, main memory is a component of the memory system that provides large capacity but at relatively low performance, while a cache is another component of the memory system that provides high performance but at relatively small capacity. Therefore, caches and main memory lie at opposite ends of the trade-off spectrum between performance and capacity.

We have mentioned earlier that modern memory systems consist of both caches and main memory. The reasoning behind this is to achieve the best of both worlds (performance and capacity)—that is, a memory system that has the high performance of a cache and the large capacity of main memory. If the memory system consists only of main memory, then *every* access to the memory system would experience the high latency (i.e., low performance) of main memory. However, if caches are used in addition to main memory, then *some* of the accesses to the memory system would be served by the caches at low latency, while the remainder of the accesses are assured to find their data in main memory due to its large capacity—albeit at high latency. Therefore, as a net result of using both caches and main memory, the memory system’s *effective latency* (i.e., average latency) becomes lower than that of main memory, while still retaining the large capacity of main memory.

Within a memory system, caches and main memory are said to be part of a *memory hierarchy*. More formally, a memory hierarchy refers to how multiple components (e.g., cache and main memory) with different performance/capacity properties are combined together to form the memory system. As shown in Figure 18.3, at the “top level” of the memory hierarchy lies the fastest (but the smallest) component, whereas at the “bottom level” of the memory hierarchy lies the slowest (but the largest) component. Going from top to bottom, the memory hierarchy typically consists of multiple levels of caches (e.g., L1, L2, L3 caches in Figure 18.3, standing for, respectively, level-1, level-2, level-3)—each of whose capacity is larger than the one above it—and a single level of main memory at the bottom whose capacity is the largest. The bottom-most cache (e.g., the L3 cache in Figure 18.3, which lies immediately above main memory) is also referred to as the *last-level cache*.

When the processor accesses the memory system, it typically does so in a sequential fashion by first searching the top component to see whether it contains the necessary data. If the data is found, then the access is said to have “hit” in the top component and the access is served there on-the-spot without having to search the lower components of the memory hierarchy. Otherwise, the access is said to have “missed” in the top component and it is passed down to the immediately lower component in the memory hierarchy, where the access may again experience either a hit or a miss. As an access goes lower into the hierarchy, the probability of a hit becomes greater due to the increasing capacity of the lower components, until it reaches the bottom level of the hierarchy where it is guaranteed to always hit (assuming the data is in main memory).

FIGURE 18.3 Example of a memory hierarchy with three levels of caches.

Assuming a two-level memory hierarchy with a single cache and main memory, the effective latency of the memory system can be expressed by the following equation. In the equation, $P_{\text{cache}}^{\text{hit}}$ denotes the probability that an access would hit in the cache, also known as the cache *hit-rate*:

$$\text{Latency}_{\text{effective}} = P_{\text{cache}}^{\text{hit}} \times \text{Latency}_{\text{cache}} + (1 - P_{\text{cache}}^{\text{hit}}) \times \text{Latency}_{\text{main_memory}}$$

- $0 \leq P_{\text{cache}}^{\text{hit}} \leq 1$
- $\text{Latency}_{\text{cache}} \ll \text{Latency}_{\text{main_memory}}$

Similarly, for a three-level memory hierarchy with two caches and main memory, the effective latency of the memory system can be expressed by the following equation:

$$\begin{aligned} \text{Latency}_{\text{effective}} = & P_{\text{cache1}}^{\text{hit}} \times \text{Latency}_{\text{cache1}} + (1 - P_{\text{cache1}}^{\text{hit}}) \\ & \times \left\{ P_{\text{cache2}}^{\text{hit}} \times \text{Latency}_{\text{cache2}} + (1 - P_{\text{cache2}}^{\text{hit}}) \times \text{Latency}_{\text{main_memory}} \right\} \end{aligned}$$

- $0 \leq P_{\text{cache1}}^{\text{hit}}, P_{\text{cache2}}^{\text{hit}} \leq 1$
- $\text{Latency}_{\text{cache1}} < \text{Latency}_{\text{cache2}} \ll \text{Latency}_{\text{main_memory}}$

As both equations show, a high hit-rate in the cache implies a lower effective latency. In the best case, when all accesses hit in the cache ($P_{\text{cache}}^{\text{hit}} = 1$), then the memory hierarchy has the lowest effective latency, equal to that of the cache. While having a high hit-rate is always desirable, the actual value of the hit-rate is determined primarily by (i) the cache's size and (ii) the processor's memory access behavior. First, compared to a small cache, a large cache is able to store more data and has a better chance that a given access will hit in the cache. Second, if the processor tends to access a small set of data over and over again, the cache can store those data so that subsequent accesses will hit in the cache. In this case, a small cache would be sufficient to achieve a high hit-rate.

Fortunately, many computer programs—that the processor executes—access the memory system in this manner. In other words, many computer programs exhibit *locality* in their memory access behavior. Locality exists in two forms: *temporal locality* and *spatial locality*. First, given a piece of data that has been accessed, temporal locality refers to the phenomenon (or memory access behavior) in which the same piece of data is likely to be accessed again in the near future. Second, given a piece of data that has been accessed, spatial locality refers to the phenomenon (or memory access behavior) in which neighboring pieces of data (i.e., data at nearby addresses) are likely to be accessed in the near future. Thanks to both temporal and spatial locality, the cache—and, more generally, the memory hierarchy—is able to reduce the effective latency of the memory system.

18.3 Managing the Memory Hierarchy

As mentioned earlier, every piece of data within a memory system is associated with a unique address. The set of all possible addresses for a memory system is called the address space and it ranges from 0 to *capacity* - 1, where *capacity* is the size of the memory system. Naturally, when software programmers compose computer programs, they rely on the memory system and assume that specific pieces of the program's data can be stored at specific addresses without any restriction, as long as the addresses are valid—that is, the addresses do not overflow the address space provided by the memory system. In practice, however, the memory system does *not* expose its address space directly to computer programs. This is due to two reasons.

First, when a computer program is being composed, the modern software programmer has no way of knowing the capacity of the memory system on which the program will run. For example, the program

may run on a computer that has a very large memory system (e.g., 1 TB capacity) or a very small memory system (e.g., 1 MB capacity). While an address of 1 GB is perfectly valid for the first memory system, the same address is invalid for the second memory system, since it exceeds the maximum bound (1 MB) of the address space. As a result, if the address space of the memory system is directly exposed to the program, the software programmer can never be sure which addresses are valid and can be used to store data for the program she is composing.

Second, when a computer program is being composed, the software programmer has no way of knowing which other programs will run simultaneously with the program. For example, when the user runs the program, it may run on the same computer as many other different programs, all of which may happen to utilize the same address (e.g., address 0) to store a particular piece of their data. In this case, when one program modifies the data at that address, it overwrites another program's data that was stored at the same address, even though it should not be allowed to do so. As a result, if the address space of the memory system is directly exposed to the program, then multiple programs may overwrite and corrupt each other's data, leading to incorrect execution for all of the programs.

18.3.1 Virtual vs. Physical Address Spaces

As a solution to these two problems, a memory system does not directly expose its address space but instead provides the illusion of an extremely large address space that is separate for each individual program. While the illusion of a *large* address space solves the first problem of different capacities across different memory systems, the illusion of a *separate* large address space for each individual program solves the second problem of multiple programs modifying data at the same address. Since such large and separate address spaces are only an illusion provided to the programmer to make her life easier in composing programs, they are referred to as *virtual address spaces*. In contrast, the actual underlying address space of the memory system is called the *physical address space*. To use concrete numbers from today's systems (circa 2013), the physical address space of a typical 8 GB memory system ranges from 0 to 8 GB - 1, whereas the virtual address space for a program typically ranges from 0 to 256 TB - 1.*

A virtual address, just by itself, does not represent any real storage location unless it is actually backed up by a physical address. It is the job of the operating system—a program that manages all other programs as well as resources in the computing system—to substantiate a virtual address by mapping it to a physical address. For example, at the very beginning of when a program is executed, none of its virtual addresses are mapped to physical addresses. At this point, if the program attempts to store a piece of data to a particular virtual address, the operating system must first intervene on behalf of the program: the operating system maps the virtual address to a physical address that is *free*—that is, a physical address that is not yet mapped to another virtual address. Once this mapping has been established, it is memorized by the operating system and used later for “translating” any subsequent access to that virtual address to its corresponding physical address (where the data is stored).

18.3.2 Virtual Memory System

The entire mechanism, described so far, in which the operating system maps and translates between virtual and physical addresses is called *virtual memory*. There are three considerations when designing a virtual memory system as part of an operating system: (i) when to map a virtual address to a physical address, (ii) the mapping granularity, and (iii) what to do when physical addresses are exhausted.

First, most virtual memory systems map a virtual address when it is accessed for the very first time—that is, *on-demand*. In other words, if a virtual address is never accessed, it is never mapped

* For example, the current generation of mainstream x86-64 processors manufactured by Intel uses 48-bit virtual addresses—that is, a 256 TB virtual address space ($2^{48} = 256 T$) [13].

to a physical address. Although the virtual address space is extremely large (e.g., 256 TB), in practice, only a small fraction of it is actually utilized by most programs. Therefore, mapping the entirety of virtual address space to the physical address space is wasteful, because the overwhelming majority of the virtual addresses will never be accessed. Not to mention the fact that the virtual address space is much larger than the physical address space such that it is not possible to map all virtual addresses to begin with.

Second, a virtual memory system must adopt a granularity at which it maps addresses from the virtual address space to the physical address space. For example, if the granularity is set equal to 1 byte, then the virtual memory system evenly divides the virtual/physical address into 1-byte virtual/physical “chunks,” respectively. Then, the virtual memory system can arbitrarily map a 1-byte virtual chunk to any 1-byte physical chunk, as long as the physical chunk is free. However, such a fine division of the address spaces into large numbers of small chunks has a major disadvantage: it increases the complexity of the virtual memory system. As we recall, once a mapping between a pair of virtual/physical chunks is established, it must be memorized by the virtual memory system. Hence, large numbers of virtual/physical chunks imply a large number of possible mappings between the two, which increases the bookkeeping overhead of memorizing the mappings. To reduce such an overhead, most virtual memory systems coarsely divide the address spaces into fewer of chunks, where a chunk is called a *page* and whose typical size is 4 kB. As shown in Figure 18.4, a 4 kB chunk of the virtual address space is referred to as a *virtual page*, whereas a 4 kB chunk of the physical address space is referred to as a *physical page* (alternatively, a *frame*). Every time a virtual page is mapped to a physical page, the operating system keeps track of the mapping by storing it in a data structure called the *page table*.

Third, as a program accesses a new virtual page for the very first time, the virtual memory system maps the virtual page to a free physical page. However, if this happens over and over, the physical address space may become exhausted—that is, none of the physical pages are free since all of them have been mapped to virtual pages. At this point, the virtual memory system must “create” a free physical page by reclaiming one of the mapped physical pages. The virtual memory system does so by *evicting* a physical page’s data from main memory and “unmapping” the physical page from its virtual page. Once a free physical page is created in such a manner, the virtual memory system can map it to a new virtual page. More specifically, the virtual memory system takes the following three steps in order to reclaim a physical page and map it to a new virtual page. First, the virtual memory system selects the physical page that will be reclaimed, that is, the *victim*. The selection process of determining the victim is referred to as the *page replacement policy* [5]. While the simplest policy is randomly selecting any physical page, such a policy may significantly degrade the performance of the computing system. For example, if a

FIGURE 18.4 Virtual memory system.

very frequently accessed physical page is selected as the victim, then a future access to that physical page would be served by the hard disk. However, since a hard disk is extremely slow compared to main memory, the access would incur a very large latency. Instead, virtual memory systems employ more sophisticated page-replacement policies that try to select a physical page that is unlikely to be accessed in the near future, in order to minimize the performance degradation. Second, after a physical page has been selected as the victim, the virtual memory system decides whether the page's data should be migrated out of main memory and into the hard disk. If the page's data had been modified by the program while it was in main memory, then the page must be written back into the hard disk—otherwise, the modifications that were made to the page's data would be lost. On the other hand, if the page's data had *not* been modified, then the page can simply be evicted from main memory (without being written into the hard disk) since the program can always retrieve the page's original data from the hard disk. Third, the operating system updates the page table so that the virtual page (that had previously mapped to the victim) is now mapped to the hard disk instead of a physical page in main memory. Finally, now that a physical page had been reclaimed, the virtual memory system maps the free physical page to a new virtual page and updates the page table accordingly.

After the victim has been evicted from main memory, it would be best if the program does not access the victim's data ever again. This is because accessing the victim's data incurs the large latency of the hard disk where it is stored. However, if the victim is eventually accessed, then the virtual memory system brings the victim's data back from the hard disk and places it into a free physical page in main memory. Unfortunately, if main memory has no free physical pages remaining at this point, then another physical page must be chosen as a victim and be evicted from main memory. If this happens repeatedly, different physical pages are forced to *ping-pong* back and forth between main memory and hard disk. This phenomenon, referred to as *thrashing*, typically occurs when the capacity of the main memory is not large enough to accommodate all of the data that a program is actively accessing (i.e., its working set). When a computing system experiences thrashing, its performance degrades since it must constantly access the extremely slow hard disk instead of the faster main memory.

18.4 Caches

Generally, a cache is any structure that stores data that is likely to be accessed again (e.g., frequently accessed data or recently accessed data) in order to avoid the long latency operation required to access the data from a much slower structure. For example, web servers on the internet typically employ caches that store the most popular photographs or news articles so that they can be retrieved quickly and sent to the end user. In the context of the memory system, a cache refers to a small but fast component of the memory hierarchy that stores the most recently (or most frequently) accessed data among all data in the memory system [26,44]. Since a cache is designed to be faster than main memory, data stored in the cache can be accessed quickly by the processor. The effectiveness of a cache depends on whether a large fraction of the memory accesses “hit” in the cache and, as a result, are able to avoid being served by the much slower main memory. Despite its small capacity, a cache can still achieve a high hit-rate thanks to the fact that many computer programs exhibit locality (Section 18.2) in their memory access behavior: data that have been accessed in the past are likely to be accessed again in the future. That is why a small cache, whose capacity is much less than that of main memory, is able to serve most of the memory accesses as long as the cache stores the most recently (or most frequently) accessed data.

18.4.1 Basic Design Considerations

There are three basic design considerations when implementing a cache: (i) physical substrate, (ii) capacity, and (iii) granularity of managing data. In the following text, we discuss each of them in that order.

First, the physical substrate used to implement the cache must be able to deliver much lower latencies than that used to implement main memory. That is why *SRAM* (static random-access memory, pronounced “es-ram”) has been—and continues to be—by far the most dominant physical substrate for caches. The primary advantage of SRAM is that it can operate at very high speeds that are on par with the processor itself. In addition, SRAM consists of the same type of semiconductor-based transistors that make up the processor. (This is not the case with DRAM, which is used to implement main memory, as we will see in Section 18.5.) So an SRAM-based cache can be placed—at low cost—side-by-side with the processor on the same semiconductor chip, allowing it to achieve even lower latencies. The smallest unit of SRAM is an *SRAM cell*, which typically consists of six transistors. The six transistors collectively store a single bit of data (0 or 1) in the form of electrical voltage (“low” or “high”). When the processor reads from an SRAM cell, the transistors feed the processor with the data value that corresponds to their voltage levels. On the other hand, when the processor writes into an SRAM cell, the voltage of the transistors is appropriately adjusted to reflect the updated data value that is being written.

Second, when determining the capacity of a cache, one must be careful to balance the need for high hit-rate, low cost, and low latency. While a large cache is more likely to provide a high hit-rate, it also has two shortcomings. First, a large cache has high cost due to the increased number of transistors that are required to implement it. Second, a large cache is likely to have a higher latency. This is because orchestrating the operation of many transistors is a complex task that introduces extra overhead delays (e.g., it may take a longer time to determine the location of an address). In practice, a cache is made large enough to achieve a sufficiently high hit-rate but not large enough to incur significantly high cost and latency.

Third, a cache is divided into many small pieces, called *cache blocks*, as shown in Figure 18.5. A cache block is the granularity in which the cache manages data. The typical size of a cache block is 64-bytes in modern memory systems. For example, a 64 kB cache consists of 1024 separate cache blocks. Each of these cache blocks can store data that corresponds to an arbitrary 64-byte “chunk” of the address space—that is, any given 64-byte cache block can contain data from address 0, or address 64, or address 128, address 192, and so on. Therefore, a cache block requires some sort of a “label” that conveys the address of the data stored in the cache block. For exactly this purpose, every cache block has its own *tag* where the address of the data (not the data itself) is stored. When the processor accesses the cache for a piece of data at a particular address, it searches the cache for the cache block whose tag matches the address. If such a cache block exists, then the processor accesses the data contained in the cache block—as explained earlier, this is called a cache hit. In addition to its address, a cache block’s tag may also store other types of information about the cache block. For example, whether the cache block is empty, whether the cache block has been written to, or how recently the cache block has been accessed. These topics and more will soon be discussed in this section.

FIGURE 18.5 Cache.

18.4.2 Logical Organization

In addition to the basic considerations discussed in the preceding text, the computer architect must decide how a cache is logically organized—that is, how it maps 64-byte chunks of the address space onto its 64-byte cache blocks. Since the memory system’s address space is much larger than the cache’s capacity, there are many more chunks than there are cache blocks. As a result, the mapping between chunks and cache blocks is necessarily “many-to-few.” However, for each individual chunk of the address space, the computer architect can design a cache that has the ability to map the chunk to (i) any of its cache blocks or (ii) only a specific cache block. These two different logical organizations represent two opposite extremes in the degree of freedom when mapping a chunk to a cache block. This freedom, in fact, presents a crucial trade-off between the complexity and utilization of the cache, as described in the following text.

On the one hand, a cache that provides the greatest freedom in mapping a chunk to a cache block is said to have a *fully associative* organization (Figure 18.6, lower-left). When a new chunk is brought in from main memory, a fully associative cache does not impose any restriction on where the chunk can be placed—that is, the chunk can be stored in *any* of the cache blocks. Therefore, as long as the cache has at least one empty cache block, the chunk is guaranteed to be stored in the cache without having to make room for it by evicting an already occupied (i.e., nonempty) cache block. In this regard, a fully associative cache is the best at efficiently utilizing all the cache blocks in the cache. However, the downside of a fully associative cache is that the processor must exhaustively search *all* cache blocks whenever it accesses the cache, since any one of the cache blocks may contain the data that the processor wants. Unfortunately, searching through all cache blocks not only takes a long time (leading to high access latency), but also wastes energy.

On the other hand, a cache that provides the least freedom in mapping a chunk to a cache block is said to have a *direct-mapped* organization (Figure 18.6, lower-middle). When a new chunk is brought in from main memory, a direct-mapped cache allows the chunk to be placed in only *a specific* cache block. For example, let us assume a 64 kB cache consisting of 1024 cache blocks (64 bytes). A simple implementation of a direct-mapped cache would map every 1024th chunk (64 bytes) of the address space to the same

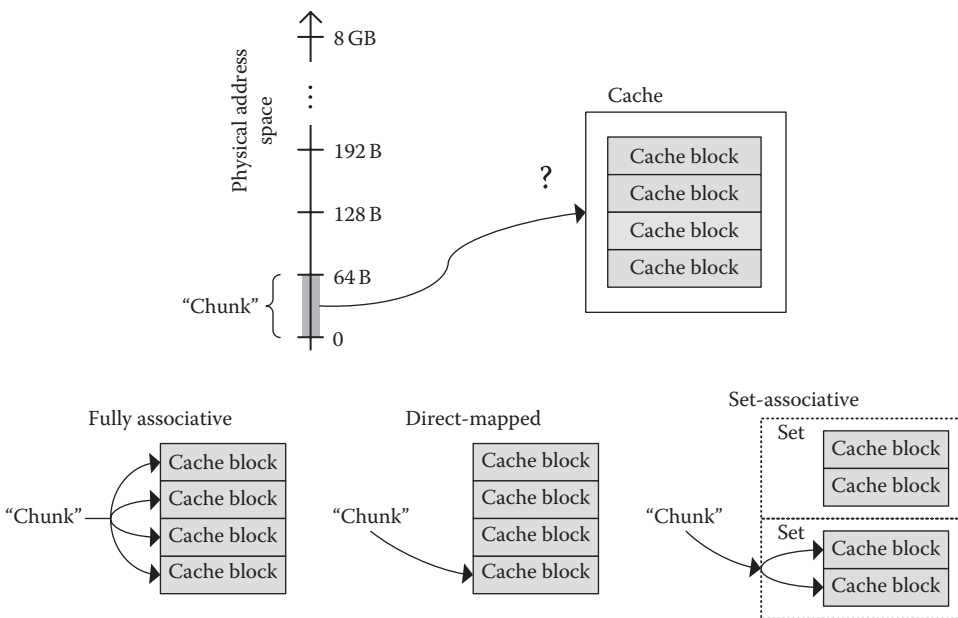

FIGURE 18.6 Logical organization.

cache block—for example, chunks at address 0, address 64K, address 128K, etc. would all map to the 0th cache block in the cache. But if the cache block is already occupied with a different chunk, then the old chunk must first be evicted before a new chunk can be stored in the cache block. This is referred to as a *conflict*—that is, when two different chunks (corresponding to two different addresses) contend with each other for the same cache block. In a direct-mapped cache, conflicts can occur at one cache block even when all other cache blocks are empty. In this regard, a direct-mapped cache is the worst at efficiently utilizing all the cache blocks in the cache. However, the upside of a direct-mapped cache is that the processor can simply search only *one* cache block to quickly determine whether the cache contains the data it wants. Hence, the access latency of a direct-mapped cache is low.

As a middle ground between the two organizations (fully associative vs. direct-mapped), there is a third alternative called the *set-associative* organization [12] (Figure 18.6, lower-right), which allows a chunk to map to one of multiple (but not all) cache blocks within a cache. If a cache has a total of N cache blocks, then a fully associative organization would map a chunk to any of the N cache blocks, while a direct-mapped organization would map a chunk to only one specific cache block. A set-associative organization, in contrast, is based on the concept of *sets*, which are small nonoverlapping groups of cache blocks. A set-associative cache is similar to a direct-mapped cache in that a chunk is mapped to only one specific set. However, a set-associative cache is also similar to a fully associative cache in that the chunk can map to any cache block that belongs to the specific set. For example, let us assume a set-associative cache in which each set consists of two cache blocks, which is called a *two-way* set-associative cache. Initially, such a cache maps a chunk to one specific set out of all $N/2$ sets. Then, within the set, the chunk can map to either of the two cache blocks that belong to the set. More generally, a W -way set-associative cache ($1 < W < N$) directly maps a chunk to one specific set, while fully associatively mapping a chunk to any of the W cache block within the set. For a set-associative cache, the value of W is fixed when the cache is designed and cannot be changed afterward. However, depending on the value of W , a set-associative cache can behave similarly to a fully associative cache (for large values of W) or a direct-mapped cache (for small values of W). In fact, an N -way set-associative cache degenerates into a fully associative cache, whereas a one-way set-associative cache degenerates into a direct-mapped cache.

18.4.3 Management Policies

If a cache has unlimited capacity, it would have the highest hit-rate since it can store all of the processor's data that is in memory. Realistically, however, a cache has only a limited capacity. Therefore, it needs to be selective about which data it should store—that is, the cache should store only the data that is the most likely to be accessed by the processor in the near future. In order to achieve that goal, a cache employs various management policies that enable it to make the best use of its small capacity: (i) allocation policy and (ii) replacement policy. In the following text, we discuss each of them, respectively.

First, the cache's *allocation policy* determines how its cache blocks become populated with data. Initially, before the execution of any program, all of the cache blocks are empty. As a program starts to execute, it accesses new chunks from the memory system that are not yet stored in the cache. Whenever this happens (i.e., a cache miss), the cache's allocation policy decides whether the new chunk should be stored in one of the empty cache blocks. Since many programs exhibit locality in their memory accesses, a chunk that is accessed (even for the first time) is likely to be accessed again in the future. That is why *always-allocate* is one of the most popular allocation policies: for every cache miss, the always-allocate policy populates an empty cache block with the new chunk. (On the other hand, a different allocation policy may be more discriminative and prevent certain chunks from being allocated in the cache.) However, when the cache has no empty cache blocks left, a new chunk cannot be stored in the cache unless the cache "creates" an empty cache block by reclaiming one of the occupied cache blocks. The cache does so by *evicting* the data stored in an occupied cache block and *replacing* it with the new chunk, as described next.

Second, when the cache does not have an empty cache block where it can store a new chunk, the cache's *replacement policy* selects one of the occupied cache blocks to evict, that is, the *victim* cache block. The replacement policy is invoked when a new chunk is brought into the cache. Depending on the cache's logical organization, the chunk may map to one or more cache blocks. However, if all such cache blocks are already occupied, the replacement policy must select one of the occupied cache blocks to evict from the cache. For a direct-mapped cache, the replacement policy is trivial: since a chunk can be mapped to only one specific cache block, then there is no choice but to evict that specific cache block if it is occupied. Therefore, a replacement policy applies only to set-associative or fully associative caches, where a chunk can potentially be mapped to multiple cache blocks—any one of which may become the victim if all of those cache blocks are occupied. Ideally, the replacement policy should select the cache block that is expected to be accessed the farthest away in the future, such that evicting the cache block has the least impact on the cache's hit-rate [3]. That is why one of the most common replacement policies is the *LRU* (*least-recently used*) policy, in which the cache block that has been the least recently accessed is selected as the victim. Due to the principle of locality, such a cache block is less likely to be accessed in the future. Under the LRU policy, the victim is the least recently accessed cache block among (i) all cache blocks within a set (for a set-associative cache) or (ii) among all cache blocks within the cache (for a fully associative cache). To implement the LRU policy, the cache must keep track of each block in terms of the last time when it was accessed. A similar replacement policy is the *LFU* (*least-frequently used*) policy, in which the cache block that has been the least frequently accessed is selected as the victim. We refer the reader to the following works for more details on cache replacement policies: Liptay [26] and Qureshi et al. [36,39].

18.4.4 Managing Multiple Caches

Until now, we have discussed the design issues and management policies for a single cache. However, as described previously, a memory hierarchy typically consists of more than just one cache. In the following, we discuss the policies that govern how multiple caches within the memory hierarchy interact with each other: (i) inclusion policy, (ii) write handling policy, and (iii) partitioning policy.

First, the memory hierarchy may consist of multiple levels of caches in addition to main memory. As the lowest level, main memory always contains the superset of all data stored in any of the caches. In other words, main memory is *inclusive* of the caches. However, the same relationship may not hold between one cache and another cache depending on the *inclusion policy* employed by the memory system [2]. There are three different inclusion policies: (i) inclusive, (ii) exclusive, and (iii) noninclusive. First, in the *inclusive* policy, a piece of data in one cache is guaranteed to be also found in all lower levels of caches. Second, in the *exclusive* policy, a piece of data in one cache is guaranteed *not* to be found in all lower levels of caches. Third, in the *noninclusive* policy, a piece of data in one cache may or may not be found in lower levels of caches. Among the three policies, the inclusive and exclusive policies are opposites of each other, while all other policies between the two are categorized as noninclusive. On the one hand, the advantage of the exclusive policy is that it does not waste cache capacity since it does not store multiple copies of the same data in all of the caches. On the other hand, the advantage of the inclusive policy is that it simplifies searching for data when there are multiple processors in the computing system. For example, if one processor wants to know whether another processor has the data it needs, it does not need to search all levels of caches of that other processor but instead search only the lowest-level cache. (This is related to the concept of *cache coherence*, which is not covered in this chapter.) Lastly, the advantage of the noninclusive policy is that it does not require the effort to maintain a strict inclusive/exclusive relationship between caches. For example, when a piece of data is inserted into one cache, inclusive or exclusive policies require that the same piece of data be inserted into or evicted from other levels of caches. In contrast, the noninclusive policy does not have this requirement.

Second, when the processor writes new data into a cache block, the data stored in the cache block is modified and becomes different from the data that was originally brought into the cache. While the

cache contains the newest copy of the data, all lower levels of the memory hierarchy (i.e., caches and main memory) still contain an old copy of the data. In other words, when a write access hits in a cache, a discrepancy arises between the modified cache block and the lower levels of the memory hierarchy. The memory system resolves this discrepancy by employing a *write handling policy*. There are two types of write handling policies: (i) write-through and (ii) write-back. First, in a *write-through policy*, every write access that hits in the cache is propagated down to the lower levels of the memory hierarchy. In other words, when a cache at a particular level is modified, the same modification is made for all lower levels of caches and for main memory. The advantage of the write-through policy is that it prevents any data discrepancy from arising in the first place. But, its disadvantage is that every write access is propagated through the entire memory hierarchy (wasting energy and bandwidth), even when the write access hits in the cache. Second, in a *write-back policy*, a write access that hits in the cache modifies the cache block at only that cache, without being propagated down to the rest of the memory hierarchy. In this case, however, the cache block contains the only modified copy of the data, which is different from the copies contained in lower levels of caches and main memory. To signify that the cache block contains modified data, a write-back cache must have a *dirty flag* in the tag of each cache block: when set to “1,” the dirty flag denotes that the cache block contains modified data. Later on, when the cache block is evicted from the cache, it must be written into the immediately lower level in the memory hierarchy, where the dirty flag is again set to “1.” Eventually, through a cascading series of evictions at multiple levels of caches, the modified data is propagated all the way down to main memory. The advantage of the write-back policy is that it can prevent write accesses from always being written into all levels of the memory hierarchy—thereby conserving energy and bandwidth. Its disadvantage is that it slightly complicates the cache design since it requires additional dirty flags and special handling when modified cache blocks are evicted.

Third, a cache at one particular level may be partitioned into two smaller caches, each of which is dedicated to two different types of data: (i) instruction and (ii) data. Instructions are a special type of data that tells the computer how to manipulate (e.g., add, subtract, move) other data. Having two separate caches (i.e., an instruction cache and a data cache) has two advantages. First, it prevents one type of data from monopolizing the cache. While the processor needs both types of data to execute a program, if the cache is filled with only one type of data, the processor may need to access the other type of data from lower levels of the memory hierarchy, thereby incurring a large latency. Second, it allows each of the caches to be placed closer to the appropriate parts of the processor—lowering the latency to supply instructions and data to the processor. Typically, one part of the processor (i.e., the instruction fetch engine) accesses instructions, while another part of the processor (i.e., the data fetch engine) accesses noninstruction data. In this case, the two caches can each be colocated with the part of the processor that accesses its data—resulting in lower latencies and potentially higher operating frequency for the processor. For this reason, usually only the highest level of the cache in the memory hierarchy, which is *directly* accessed by the processor, is partitioned into an instruction cache and a data cache.

18.4.5 Specialized Caches for Virtual Memory

Specialized caches have been used to accelerate address translation in virtual memory systems (discussed in Section 18.3). The most commonly used such cache is referred to as a *TLB* (translation lookaside buffer). The role of a TLB is to cache the recently used virtual to physical address translations by the processor such that the translation is quick for the virtual addresses that hit in the TLB. Essentially, a TLB is a cache that caches the parts of the page table that have been used by the processor.

18.5 Main Memory

While caches are predominantly optimized for high speed, in contrast, the foremost purpose of main memory is to provide as large capacity as possible at low cost and at reasonably low latency. That is why the preferred physical substrate for implementing main memory is *DRAM* (dynamic

random-access-memory, pronounced “dee-ram”) [6]. The smallest unit of DRAM is a *DRAM cell*, consisting of one transistor (1T) and one capacitor (1C). A DRAM cell stores a single bit of data (0 or 1) in the form of electrical charge in its capacitor (“discharged” or “charged”). DRAM’s primary advantage over SRAM lies in its small cell size: a DRAM cell requires fewer electrical components (1T and 1C) than an SRAM cell (6T). Therefore, many more DRAM cells can be placed in the same amount of area on a semiconductor chip, enabling DRAM-based main memory to achieve a much larger capacity for approximately the same amount of cost.

Typically, SRAM-based caches are integrated on the same semiconductor chip as the processor. In contrast, DRAM-based main memory is implemented using one or more dedicated DRAM chips that are separate from the processor chip. This is due to two reasons. First, a large capacity main memory requires such a large number of DRAM cells that they cannot all fit on the same chip as the processor. Second, the process technology needed to manufacture DRAM cells (with their capacitors) is not compatible at low cost with the process technology needed to manufacture processor chips. Therefore, placing DRAM and logic together would significantly increase cost in today’s systems. Instead, main memory is implemented as one or more DRAM chips that are dedicated for the large number of DRAM cells. From the perspective of the processor, since DRAM-based main memory is not on the same chip as the processor, it is sometimes referred to as “off-chip” main memory.

A set of electrical wires, called the *memory bus*, connects the processor to the DRAM chips. Within a processor, there is a *memory controller* that communicates with the DRAM chips using the memory bus. In order to access a piece of data from the DRAM chips, the memory controller sends/receives the appropriate electrical signals to/from the DRAM chips through the memory bus. There are three types of signals: (i) address, (ii) command, and (iii) data. The address conveys the location of the data being accessed, the command conveys how the data is being accessed (e.g., read or write), and the data is the actual value of the data itself. Correspondingly, a memory bus is divided into three smaller sets of wires, each of which is dedicated to a specific type of signal: (i) address bus, (ii) command bus, and (i) data bus. Among these three, only the data bus is bidirectional since the memory controller can either send/receive data from the DRAM chips, whereas the address and command buses are unidirectional since only the memory controller sends the address and command to the DRAM chips.

18.5.1 DRAM Organization

As shown in Figure 18.7, a DRAM-based main memory system is logically organized as a hierarchy of (i) channels, (ii) ranks, and (iii) banks. *Banks* are the smallest memory structures that can be accessed in parallel with respect to each other. This is referred to as *bank-level parallelism* [34]. Next, a *rank* is a collection of DRAM chips (and their banks) that operate in lockstep. A DRAM rank typically consists of eight DRAM chips, each of which has eight banks. Since the chips operate in lockstep, the rank has only eight independent banks, each of which is the set of all *i*th bank across all chips. Banks in different ranks are fully decoupled with respect to their chip-level electrical operation and, consequently, offer better bank-level parallelism than banks in the same rank. Lastly, a *channel* is the collection of all banks that share the same memory bus (address, command, data buses). While banks from the same channel experience contention at the memory bus, banks from different channels can be accessed completely independently

FIGURE 18.7 DRAM organization.

FIGURE 18.8 Bank organization. (a) High-level view, (b) low-level view, and (c) cell.

of each other. Although the DRAM system offers varying degrees of parallelism at different levels in its organization, two memory requests that access the same bank must be served one after another. To understand why, let us examine the logical organization of a DRAM bank as seen by the memory controller.

Figure 18.8 presents the logical organization of a DRAM bank. A DRAM bank is a two-dimensional array of capacitor-based DRAM cells. It is viewed as a collection of *rows*, each of which consists of multiple *columns*. Therefore, every cell is identified by a pair of addresses: a row address and a column address. Each bank contains a *row-buffer* which is an array of sense-amplifiers. The purpose of a *sense-amplifier* is to read from a cell by reliably detecting the very small amount of electrical charge stored in the cell. When writing to a cell, on the other hand, the sense-amplifier acts as an electrical driver and programs the cell by filling or depleting its stored charge. Spanning a bank in the columnwise direction are wires called the *bitlines*, each of which can connect a sense-amplifier to any of the cells in the same column. A wire called the *wordline* (one for each row) determines whether or not the corresponding row of cells is connected to the bitlines.

18.5.2 Bank Operation

To serve a memory request that accesses data at a particular row and column address, the memory controller issues three commands to a bank in the order as shown in the following list. Each command triggers a specific sequence of events within the bank to access the cell(s) associated with the address:

1. **ACTIVATE** (issued with a row address): Load the entire row into the row-buffer.
2. **READ/WRITE** (issued with a column address): From the row-buffer, access the data stored in a column. For a **READ**, transfer the data out of the row-buffer to the processor. For a **WRITE**, modify the data in the row-buffer according to the data received from the processor.
3. **PRECHARGE**: Clear the row-buffer.

Each DRAM command incurs a latency while it is processed by the DRAM chip. Undefined behavior may arise if a command is issued before the previous command is fully processed. To prevent such occurrences, the memory controller must obey a set of *timing constraints* while issuing commands to a DRAM chip [16]. These constraints define when a command becomes ready to be scheduled depending on all other commands issued before it to the same channel, rank, or bank. The exact values of the timing constraints are specified by the DRAM chip's datasheet and are different on a chip-by-chip basis. However, a rule of thumb is that the three DRAM commands (**ACTIVATE**, **READ/WRITE**, and **PRECHARGE**) each take about 15 ns [16]. For more information on the organization and operation of a DRAM bank, we refer the reader to Kim et al. [20].

18.5.3 Memory Request Scheduling

When there are multiple memory requests waiting to access DRAM, the memory controller must choose one of the memory requests to schedule next. The memory controller does so by employing a *memory*

scheduling algorithm [40] whose goal, in many current high-performance systems, is to select the most favorable memory request for reducing the overall latency of the memory requests. For example, let us assume there is a memory request waiting to access a row that happens to be loaded in the row-buffer. In this case, since the row is already in the row-buffer, the memory controller can skip the ACTIVATE and PRECHARGE commands and directly proceed to issue the READ/WRITE command. As a result, the memory controller can quickly serve that particular memory request. Such a memory request—that accesses the row in the row-buffer—is called a *row-buffer hit*. Many memory-scheduling algorithms exploit the low latency nature of row-buffer hits and prioritize such requests over others [18,19,33,34]. For more information on memory request scheduling, we refer the reader to recent works that explored the topic [18,19,33,34].

18.5.4 Refresh

A DRAM cell stores data as charge on a capacitor. Over time, this charge steadily leaks, causing the data to be lost. That is why DRAM is named “dynamic” RAM; its charge changes over time. In order to preserve data integrity, the charge in each DRAM cell must be periodically restored or *refreshed*. DRAM cells are refreshed at the granularity of a row by reading it out and writing it back in—which is equivalent to issuing an ACTIVATE and a PRECHARGE to the row in succession.

In modern DRAM chips, all DRAM rows must be refreshed once every 64 ms [16], which is called the *refresh interval*. The memory controller internally keeps track of time to ensure that it refreshes all DRAM rows before their refresh interval expires. When the memory controller decides to refresh the DRAM chips, it issues a REFRESH command. Upon receiving a REFRESH command, a DRAM chip internally refreshes a few of its rows by activating and precharging them. A DRAM chip refreshes only a few rows at a time since it has a very large number of rows and refreshing all of them would incur a very large latency. Since a DRAM chip cannot serve any memory requests while it is being refreshed, it is important that the refresh latency is kept short such that no memory request is delayed for too long. So instead of refreshing *all* rows at the end of each 64 ms interval, throughout a given 64 ms time interval, the memory controller issues many REFRESH commands, each of which triggers the DRAM chip to refresh only a subset of rows. However, the memory controller ensures that REFRESH commands are issued frequently enough such that all rows eventually do become refreshed before 64 ms has passed. For more information on DRAM refresh (and methods to reduce its effect on performance and energy), we refer the reader to Liu et al. [27].

18.6 Current and Future Research Issues

The memory system continues to be a major bottleneck in almost all computing systems (especially in terms of performance and energy/power consumption). It is becoming even more of a computing system bottleneck today and looking into the future: more and increasingly diverse processing cores and agents are sharing parts of the memory system; applications that run on the cores are becoming increasingly data and memory intensive; memory is consuming significant energy and power in modern systems; and, there is increasing difficulty scaling the well-established memory technologies, such as DRAM, to smaller technology nodes. As such, managing memory in significantly better ways at all levels of the transformation hierarchy, including both the software and hardware levels, is becoming even more important. Techniques or combinations of techniques that integrate the best ideas cooperatively at multiple levels together appear promising to solve the difficult performance, energy efficiency, correctness, security, and reliability problems we face in designing and managing memory systems today. In this section, we briefly discuss some of the major research problems (as we see them) related to caches and main memory and describe recent potential solution directions. Note that a comprehensive treatment of all research issues is out of the scope of this chapter, and neither is it our intent. For an illustrative treatment of some of the

major research issues in memory systems, we refer the reader to Mutlu [32] (<http://users.ece.cmu.edu/~omutlu/pub/onur-ismm-mspc-keynote-june-5-2011-short.pptx>).

18.6.1 Caches

Efficient Utilization. To better utilize the limited capacity of a cache, many replacement policies have been proposed to improve upon the simple LRU policy. The LRU policy is not always the most beneficial across all memory-access patterns that have different amounts of locality. For example, in the LRU policy, the most-recently accessed data is always allocated in the cache even if the data has low-locality (i.e., unlikely to be ever accessed again). To make matters even worse, the low-locality data is unnecessarily retained in the cache for a long time. This is because the LRU policy always *inserts* data into the cache as the most-recently accessed and evicts the data only after it becomes the least-recently accessed. As a solution, researchers have been working to develop sophisticated replacement policies using a combination of three approaches. First, when a cache block is allocated in the cache, it should not always be inserted as the most-recently accessed. Instead, cache blocks with low-locality should be inserted as the least-recently accessed, so that they are quickly evicted from the cache to make room for other cache blocks that may have more locality (e.g., [15,35,41]). Second, when a cache block is evicted from the cache, it should not always be the least-recently accessed cache block. Ideally, “dead” cache blocks (which will never be accessed in the future) should be evicted—regardless of whether they are least-recently-accessed or not. Third, when choosing the cache block to evict, there should also be consideration for how costly it is to refetch the cache block from main memory. Between two cache blocks, all else being equal, the cache block that is likely to incur the shorter latency to refetch from main memory should be evicted [36].

Quality-of-service. In a multicore system, the processor consists of many cores, each of which can independently execute a separate program. In such a system, parts of the memory hierarchy may be shared by some or all of the cores. For example, the last-level cache in a processor is typically shared by all the cores. This is because the last-level cache has a large capacity and, hence, it is expensive to have multiple last-level caches separately for each core. In this case, however, it is important to ensure that the shared last-level cache is utilized by all the cores in a fair manner. Otherwise, a program running on one of the cores may fill up the last-level cache with only its data and evict the data needed by programs running on the other cores. To prevent such occurrences, researchers have proposed mechanisms to provide quality-of-service when a cache is shared by multiple cores. One mechanism is to partition the shared cache among the cores in such a way that each core has a dedicated partition where only the core’s data is stored (e.g., [14,17,25,37]). Ideally, the size of a core’s partition should be just large enough to hold the data that the core is actively accessing (the core’s working set) and not any larger. Furthermore, as the size of a core’s working set changes over time, the size of the core’s partition should also dynamically expand or shrink in an appropriate manner.

Low power. Increasing the energy efficiency of computing systems is one of the key challenges faced by computer architects. Caches are one of the prime targets for energy optimization since they require large numbers of transistors, all of which dissipate power. For example, researchers have proposed to reduce a cache’s power consumption by lowering the operating voltage of the cache’s transistors [43]. However, this introduces new trade-offs in designing a cache that must be balanced: while a low voltage cache consumes less power, it may also be slower and more prone to errors. Researchers have been examining solutions to enable low-voltage caches that provide acceptable reliability at acceptable cost [43].

18.6.2 Main Memory

Challenges in DRAM scaling. Primarily due to its low cost-per-bit, DRAM has long been the most popular physical substrate for implementing main memory. In addition, DRAM’s cost-per-bit has continuously decreased as DRAM process technology scaled to integrate more DRAM cells into the same area

on a semiconductor chip. However, improving DRAM cell density by reducing the cell size, as has been done traditionally, is becoming more difficult due to increased manufacturing complexity/cost and reduced cell reliability. As a result, researchers are examining alternative ways of enhancing the performance and energy-efficiency of DRAM while still maintaining low cost. For example, there have been recent proposals to reduce DRAM access latency [24], to increase DRAM parallelism [20], and to reduce the number of DRAM refreshes [27].

3D-Stacked memory. A DRAM chip is connected to the processor chip by a memory bus. In today's systems, the memory bus is implemented using electrical wires on a motherboard. But, this has three disadvantages: high power, low bandwidth, and high cost. First, since a motherboard wire is long and thick, it takes a lot of power to transfer an electrical signal through it. Second, since it takes even more power to transfer many electrical signals in quick succession, there is a limit on the bandwidth that a motherboard wire can provide. Third, the processor chip and the DRAM chip each have a stub (called a *pin*) to which either end of a motherboard wire is connected. Unfortunately, pins are expensive. Therefore, a memory bus that consists of many motherboard wires (which requires just as many pins on the chips) increases the cost of the memory system. As a solution, researchers have proposed to stack one more DRAM chips directly on top of a processor chip [4,28] instead of placing them side by side on the motherboard. In such a 3D-stacked configuration, the processor chip can communicate directly with the DRAM chip(s), thereby eliminating the need for motherboard wires and pins.

Emerging technology. DRAM is by far the most dominant technology for implementing main memory. However, there has been research to develop alternative main memory technologies that may replace DRAM or be used in conjunction with DRAM. For example, *PCM* (phase-change memory, pronounced “pee-cee-em”) is a technology in which data is stored as a resistance value. A PCM cell consists of a small crystal whose resistance value can be changed by applying heat to it at different rates. If heat is abruptly applied by a short burst of high current, then the crystal is transformed into the amorphous state, which has high resistance. On the other hand, if heat is steadily applied by a long burst of low current, then the crystal is transformed into the crystalline state, which has low resistance. PCM has important advantages that make it an attractive candidate for main memory [21,38]: nonvolatility (i.e., data is not lost when the power is turned off and there is no need to refresh PCM cells) and scalability (i.e., compared to DRAM, it may be easier to make smaller PCM cells in the future). However, PCM also has the disadvantages of large latency (especially for writes) and limited write-endurance (i.e., the PCM cell becomes unreliable beyond a certain number of writes), the solution to which is the topic of on-going research. To overcome the shortcomings of different technologies, several recent works have examined the use of multiple different technologies (e.g., PCM and DRAM together) as part of main memory, an approach called *hybrid memory* or *heterogeneous memory* [7,29,38,45]. The key challenge in hybrid memory systems is to devise effective algorithms that place data in the appropriate technology such that the system can exploit the advantages of each technology while hiding the disadvantages of each [29,45].

Quality-of-service. Similar to the last-level cache, main memory is also shared by all the cores in a processor. When the cores contend to access main memory, their accesses may interfere with each other and cause significant delays. In the worst case, a memory-intensive core may continuously access main memory in such a way that all the other cores are denied service from main memory [30]. This would detrimentally degrade the performance of not only those particular cores, but also of the entire computing system. To address this problem, researchers have proposed mechanisms that provide quality-of-service to each core when accessing shared main memory. For example, memory request scheduling algorithms can ensure that memory requests from all the cores are served in a fair manner [18,19,33,34]. Another approach is for the user to explicitly specify memory service requirements of a program to the memory controller so that the memory scheduling algorithm can subsequently guarantee that those requirements are met [42]. Other approaches to quality-of-service include mechanisms proposed to map the data of those applications that significantly interfere with each other to different memory channels [31] and mechanisms proposed to *throttle down* the request rate of the processors that cause significant interference to other processors [8]. Request scheduling mechanisms that prioritize bottleneck

threads in parallel applications have also been proposed [10]. The QoS problem gets exacerbated when the processors that share the main memory are different, for example, when main memory is shared by a CPU consisting of multiple processors and a GPU, and recent research has started to examine solutions to this [1]. Finally, providing QoS and high performance in the presence of different types of memory requests from multiple processing cores, such as speculative *prefetch* requests that aim to fetch the data from memory before it is needed, is a challenging problem that recent research has started providing solutions for [9,11,22,23].

18.7 Summary

The memory system is a critical component of a computing system. It serves as the repository of data from where the processor (or processors) can access data. An ideal memory system would have both high performance and large capacity. However, there exists a fundamental trade-off relationship between the two: it is possible to achieve either high performance or large capacity but not both at the same time in a cost-effective manner. As a result of the trade-off, a memory system typically consists of two components: caches (which are small but relatively fast-to-access) and main memory (which is large but relatively slow-to-access). Multiple caches and a single main memory, all of which strike a different balance between performance and capacity, are combined to form a memory hierarchy. The goal of the memory hierarchy is to provide the high performance of a cache at the large capacity of main memory. The memory system is cooperatively managed by both the operating system and the hardware.

This chapter provided an introductory level description of memory systems employed in modern computing systems, focusing especially on how the memory hierarchy, consisting of caches and main memory, is organized and managed. The memory system continues to be an even more critical bottleneck going into the future, as described in Section 18.6. Many problems abound, yet the authors of this chapter remain confident that promising solutions, some of which are also described in Section 18.6, will also abound and hopefully prevail.

19.1 Introduction

Desirable properties for a storage system (in no particular order) are: (1) Low cost per GigaByte (GB), (2) nonvolatility, (3) reliability, (4) low access latency, (5) high access bandwidth, (6) low power consumption, (7) high recording density, small footprint, (8) data compression and deduplication, (9) data security via encryption, (10) data retention or longevity, (11) endurance or high maximum number of cycles, and (12) *Compound Annual Growth Rate (CAGR)*.

* The writing of this chapter was started when the author was affiliated with Shenzhen Institutes of Advanced Technology—SIAT, which is part of Chinese Academy of Sciences, in Shenzhen, China.

No single storage technology has all these properties, but a combination of storage technologies can be used to meet data storage requirements. Low access time is achieved at the processor level via a memory hierarchy with fast, small, high cost per GB static RAM (SRAM) cache memories at the highest levels, followed by larger, slower, and lower cost dynamic RAM (DRAM) memories at the lower levels. Memory hierarchies are beneficial because of the locality of reference principle.* Temporal locality implies that code and associated variables accessed once will be referenced repeatedly, such as those inside a loop. Spatial locality implies that data in close proximity to data being accessed has a higher probability of being accessed, such as successive elements of a one-dimensional array. The hierarchical reuse model implied by the fractal structure of data reference is a powerful tool for understanding cache and database behaviors on many scales of size and time [63]. Prefetching is applicable to many levels of the memory hierarchy, for example, at the CPU cache level in [38] and disk level in [49].

The DRAM technology for main memories is volatile so that permanent data is held on magnetic hard disk drives (HDDs). CPU caches, DRAM (main memories), and disks are reviewed in [49]. Magnetic tape drives which were used for backup and archival storage are being challenged by less expensive, low-performance, and high capacity *Serial Advanced Technology Attachment (SATA)* HDDs,[†] as opposed to more expensive, high-performance, and smaller capacity *Small Computer Systems Interface (SCSI)* HDDs [49].[‡] SCSI and SATA drives are compared in [2]. SCSI drives are used in enterprise storage and SATA drives are used in personal computers, and archival storage systems.

DRAM caches in disk array controllers (DACs) and main memories are the best way to improve I/O performance by eliminating disk accesses altogether as much as possible. Part of DAC's cache can be turned into *non volatile storage (NVS)* by backing it up by uninterruptible power supply (UPS). NVS holds dirty data blocks, which have not been written to disk, to avert data loss in case of a power outage. Even without UPS, lost updates in *transaction (txn)* processing systems are averted by write ahead logging (WAL), which writes updated data to NVS, before a txn is committed [81].

Flash memories are gaining popularity as replacements for disks in handheld devices, but also as disk caches.[§] This configuration is not suited for a write intensive workload with small writes (see Section 19.11). Flash memories outperform *Serial Attached SCSI (SAS)* drives and allow a significant reduction in power consumption (see Section 19.7).

Storage systems mainly in the form of HDDs constitute a significant fraction of information technology (IT) expenditure. The early IBM *Random Access Method for Accounting and Control (RAMAC)* computer was equipped with a 5 megabyte (MB) capacity disk drive, which cost \$10,000 [62].[¶] There has been a dramatic drop in HDD cost per GB due to the exponential growth in disk recording densities. HDDs are highly reliable with a *Mean Time to Failure (MTTF)* exceeding a million hours (114 years) [91]. The technological impact of HDDs on storage systems is discussed in [32].

HDDs have two weaknesses due to their electromechanical nature: (i) high power consumption to rotate disks and (ii) poor performance as a result of high access time. The projection in [27] that DRAM will surpass disks in cost has not come true, but with the advent of *Storage Class Memories (SCM)* the quest for replacing HDDs with solid-state disks (SSDs) is becoming a reality. Ten SCM technologies are currently under consideration and are expected to be fast, inexpensive, and power efficient [11]. Phase change memory is one of the more promising SCM technologies [80]. Using SCM as a disk drive replacement yields a performance for random requests that is orders of magnitude faster than comparable disk-based systems and requires much less space and power in the data center.

‡ <http://en.wikipedia.org/wiki/SCSI>.

§ http://en.wikipedia.org/wiki/Flash_memory.

¶ http://en.wikipedia.org/wiki/IBM_305_RAMAC.

An extrapolation of disk and SCM technology trends up to 2020 in [25] concludes that there will be a 100- to 1000-fold advantage for SCM in terms of the data-center space and power.

This is a major rewriting of the chapter titled “Secondary Storage Systems” in the previous edition of the handbook. It consists of the following sections. Trends in tape storage based on [23] are reported in Section 19.2. Section 19.3 discusses various aspects of HDDs. HDD characteristics are discussed in Section 19.3.1. Disk arm scheduling and data placement are discussed in Section 19.3.2. The log-structured file systems (LFS) paradigm is discussed in Section 19.3.3, followed by active disks in Section 19.3.4. RAID with erasure coding is discussed in Section 19.4. The starting point is RAID5, RAID6, and their variations in Section 19.4.1. RAID operation in normal/degraded/rebuild modes is discussed in Sections 19.4.2 through 19.4.4. In Sections 19.4.4.2 and 19.4.4.3, we discuss rebuild performance analysis and methods to improve RAID5 reliability for rebuild processing. RAID1 or mirrored disks are discussed in Section 19.5. RAID1 organizations are discussed in Section 19.5.1. Scheduling of requests in RAID1 is discussed in Section 19.3.2. RAID reliability is discussed in Section 19.6. Section 19.6.1 is a general introduction to reliability analysis. Section 19.6.2 lists expressions for mirrored disks reliabilities. Section 19.6.3 provides the approximate reliability analysis of disk arrays with emphasis on RAID1. Section 19.6.4 provides an analysis of RAID1 arrays with repair. Power conservation in RAID is discussed in Section 19.7. Three interesting RAID arrays are discussed in Section 19.8. Grid codes are discussed in Section 19.8.1. Hierarchical RAID (HRAID) is discussed in Section 19.8.2. Heterogeneous disk arrays (HDAs) are discussed in Section 19.8.3. Storage area networks (SANs) and network attached storage (NAS) are discussed in Section 19.9. Data deduplication is discussed in Section 19.10. SSDs with emphasis on flash memories are discussed in Section 19.11. Section 19.11.1 describes a new sparing method to increase the lifetime of flash memories, while Section 19.11.2 describes the partial MDS (PMDS) for dealing with sector as well as component failures. Conclusions are presented in Section Conclusions.

19.2 Magnetic Tapes for Low-Cost Archival Storage

Magnetic tapes preceding HDDs in 1950s as a data storage medium were considerably less costly than the removable disk drives at the time [62]. Magnetic tapes record data on Mylar (a polyester film) coated with magnetic material. Data is recorded and read from tapes using *Read/Write (R/W)* heads against which tapes are moved at a fixed speed. Early tapes which came in open reels were susceptible to being torn and there was a later conversion to cartridges. The problem of the wrong tape being loaded by the operator was solved by automated tape libraries with robotic arms. IBM’s 3850 *Mass Storage System (MSS)* introduced in 1974 is an early system. Tape storage is discussed in [62], but there have been numerous publications on this topic since then.*

Early data processing applications held customer records on a tape “masterfile,” which was sorted according to customer number. Access to find a customer’s record based on customer number was not attempted, because scanning half of the file on the average to find a record (the whole file if the customer number was not there) would take time linearly proportional on the number of records in the file. Updates to the masterfile were in batches sorted by customer number. For example, in a monthly billing application, typical of an electric utility, the sorted file of customer numbers and meter readings is applied to the masterfile to compute the monthly bill.

Clever algorithms for sorting on tape discussed in Knuth’s 3rd volume on *Sorting and Searching* are now mainly of historical interest. Hashing and indexing methods for direct disk access and algorithms for relational database operations such as joins and sorting, which utilize large main memory buffers for sequentially accessed disk data, are described in texts on data base management systems (*DBMSs*) [81].

* http://en.wikipedia.org/wiki/Magnetic_tape_data_storage.

Digital magnetic tape recording is quite complex [62].* Data compression, deduplication, and encryption were introduced in magnetic tapes before disks. IBM system storage tape encryption solutions are described in [36]. Encryption is also provided at disk-resident databases, which is beyond the scope of this discussion.

Linear Tape Open Generation LTX-4 has a lifetime of 30+ years and an error rate an order-of-magnitude lower than SAS drives. When a tape drive fails, the tape may be read on another drive [23], which was also the case with early disk drives with removable disks [62]. The inconvenience of accessing tape files is addressed in LTX-5, which provides indexing with a convenient interface for downloading files.

Tapes do not consume power unless they are being read or written, so that it is estimated in [23] that tape-based archival systems consume 290 times less power than disk-based archives. It is also noted that although 3 terabytes (TB) disks (four times 750 GB or five times 600 GB) are available at a reasonable price (\$250) at this time, there is the issue of *total cost of ownership (TCO)*. Power consumption is 5 w/h for 3.5" and 2 w for 2.5" disks, while disk reads/writes are in progress.

Long-term data storage is rapidly gaining in importance. According to [10], the 2700 petabytes (PB) of long-term storage in 2008 is expected to increase 10-fold by 2010. The requirements for such storage systems are quoted as follows:

- (1) Standard interfaces for ingestion and retrieval of documents
- (2) Flexible and secure access to documents
- (3) Efficient search mechanisms
- (4) Policies for multitier storage management to meet service-level agreements
- (5) Scalability
- (6) Ability to archive original file and metadata with assistance for its specification, generation, and discovery
- (7) Dynamically varying system scale based on business needs
- (8) Security controls, nonrepudiation, and auditing to meet compliance and data governance requirements
- (9) Business continuity and protections, media migration provisions as technology changes

Redundant array of independent libraries (RAIL) is a tertiary storage system architecture that couples multiple small and inexpensive "building block" tape libraries [24]. It is shown that RAIL has performance and availability characteristics superior to conventional tertiary storage systems, for almost the same dollar/megabyte cost. The log-structured library array (LSLA) allows data compression and alleviates certain inefficiencies associated with RAID5 described in Section 19.4.

There have been recent proposals for long-term archival storage systems based on low-cost SATA disks, such as Pergamum [96], which is discussed in more detail in Section 19.7. Encrypting the data offers a higher level of security in case data is lost, stolen, or accessed by an unauthorized person. Solutions to problems associated with long-term archival storage system are addressed in [97].

19.3 Hard Disk Drives (HDDs)

The section first describes HDD characteristics in Section 19.3.1. We then proceed to disk arm scheduling in Section 19.3.2. The LFS is described in Section 19.3.3, followed by active disks in Section 19.3.4.

19.3.1 HDD Characteristics

Disks consist of one or more circular platters, which are attached to a spindle rotated by a motor at a constant angular velocity (CAV). The spindles are made of a light-weight aluminum alloy, which is

* <http://www.quadibloc.com/comp/tapeint.htm>.

coated with magnetic material. One or both sides of a platter may be accessed, based on the availability of R/W heads on the surfaces. Data are written on HDD tracks as 512 byte (B) sectors. Advanced format 4096 B sector disks provide a higher recording efficiency.*

Disks associated with IBM mainframes had the *count key data* (CKD) format [62].† The key is a unique field per record in ISAM and VSAM files, where the latter is a variation on ubiquitous B-trees [81]. The key search in early IBM disk drives was carried out by the disk controller [62]. IBM 3390 disks with extended CKD (ECKD) are not manufactured anymore, but are simulated by DAC's software on fixed block architecture (FBA) disks.§ The advantage of the latter format is that the data is addressable as an array of sectors by the logical block number (LBN).

When the radius of the outermost track is twice that of the innermost track, disk zoning increases the disk capacity by as much as 50% by maintaining approximately the same bits per inch (BPI) at all tracks. The bookkeeping for the varying numbers of sectors per track is simplified by zoned bit recording (ZBR), which at the cost of reduced storage efficiency assigns the same number of sectors to multiple contiguous tracks. Adaptive zoning is a relatively new trend described in [56], so that the disk transfer rate from the same relative disk (track) position may vary from 6% faster to 14% slower.

In addition to BPI, disk recording density is determined by tracks per inch (TPIs), which may exceed 100,000. The BPI versus TPI trade-off is discussed in Section 19.3 in [49]. Increases in BPI are preferable to TPI, since higher TPIs result in an increased head settling time. With *Perpendicular Magnetic Recording* (PMR) technology, 630 gigabits per square inch and even 1 terabit are possible from leading HDD manufacturers, such as Seagate.§

Smaller form factor HDDs with 3.5 and 2.5 in. diameters have been adopted, since with increasing recording densities sufficient capacity is attained even with one surface of a platter. Higher capacity is attainable by recording on both surfaces of a platter or stacking multiple disk platters, which however require more power for disk rotation. Tracks on one or both surfaces of a platter, which are placed on top of each other form a cylinder. These are accessible simultaneously (without moving the arm) by multiple R/W heads attached to a single disk arm. Files are therefore usually written on successive disk tracks and cylinders. The head switching time is accounted for by skewing the starting points across tracks and cylinders, so that no latency is incurred in accessing large blocks of data [49]. Track-aligned extents utilize disk-specific knowledge to match access patterns to disks, for example, placing disk blocks to avoid track boundaries and using zero latency reads (ZLR) to minimize latency [89]. ZLR allows data transfers to start at any sector of a requested block, so that the latency to read a full track is just one half the sector time.

The movement of R/W heads across disk tracks is called seeking. Seek time is a significant component of disk access time, which depends on the placement of blocks being accessed. Seek times have improved significantly over the years, but the year to year improvement is quite small. The seek time depends on the number of disk tracks traversed by the arm. The seek time characteristic (STC) $t_{\text{seek}}(d)$, $1 \leq c - 1$, where c is the number of disk cylinders obtained by subjecting the disk to seeks with various distances and averaging the seek time over multiple trials. The STC has several regions for the HDD considered in [90]. For $d \leq 100$, the seek time is a small constant, followed by a discontinuity, after which it is approximately the square root of the seek distance. $t_{\text{seek}}(d)$ is linear for $d \geq (c - 1)/3$. Because short seeks incur less delay than head-switching time, the “serpentine” organizations shown in Figure 4 in [90] places successive blocks of a file on the same surface, before proceeding to the next one.

* http://en.wikipedia.org/wiki/Advanced_Format.

† http://en.wikipedia.org/wiki/Count_Key_Data.

‡ http://en.wikipedia.org/wiki/Fixed_Block_Architecture.

§ http://en.wikipedia.org/wiki/Magnetic_storage.

The seek distance distribution for nonzoned disks with uniform accesses to c disk cylinders is as follows:

$$P[d] = (1-p) \frac{2(c-d)}{c(c-1)}, 1 \leq d \leq c-1, P[0] = p,$$

where p is the probability that no seek is required with $p = 1/c$ for uniform accesses. $p[d]$ linearly drops from its maximum value at $d = 1$ to its minimum at $d = c - 1$. $t_{\text{seek}}(d)$, $1 \leq d \leq c - 1$ is obtained by exercising the disk drive. The mean disk seek time is then $\bar{t}_{\text{seek}} = \sum_{d=1}^{c-1} t_{\text{seek}}(d)P[d]$.

In zoned disks with uniform accesses to disk blocks, $p[d]$ is computed by noting that the probability of accessing a cylinder is proportional to the number of blocks that it holds [119]. The $p[d]$ in this case exceeds the straight line for nonzoned disks for smaller seek distances, but there is a crossover point at higher seek distances.

The HDD rotational speed, expressed in rotations per minute (RPM), has increased over the years: 2400, 3600, 7200, 10,000, 15,000, and beyond. The disk rotation time is $T_{\text{rot}} = 60000/\text{RPM}$ in ms (milliseconds), determines the rotational delay, the time for a requested block to become accessible by the R/W heads after a seek is completed. For accesses to small data blocks $\bar{x}_{\text{lat}} \approx T_{\text{rot}}/2$. The mean transfer time of small blocks equals the number of sectors per block (16 for 8 KB blocks) divided by the number of sectors on the track times T_{rot} . To summarize the mean disk access time is $\bar{x}_{\text{disk}} = \bar{x}_{\text{seek}} + \bar{x}_{\text{lat}} + \bar{x}_{\text{xfer}}$. Data read from disk is initially transferred to an onboard disk cache, which is also used for prefetching when a sequential access pattern is detected.

The mean response time for disk accesses is the sum of mean waiting time (W) and mean disk service time: $R = \bar{x}_{\text{disk}} + W$. When the arrival process of disk requests is Poisson with rate λ and assuming that x_{disk} is exponentially distributed then: $W = \rho \bar{x}_{\text{disk}} / (1 - \rho)$, where $\rho = \lambda \bar{x}_{\text{disk}}$ is the disk utilization [55]. R_{disk} increases rapidly with increasing λ as $\rho \rightarrow 1$. With the implicit assumption of FCFS scheduling and for a general distribution of x_{disk} , only its mean and second moment: \bar{x}_{disk}^i , $i = 1, 2$ are required to determine W , which is given as

$$W = \frac{\lambda \bar{x}_{\text{disk}}^2}{2(1-\rho)} = \frac{\rho \bar{x}_{\text{disk}} (1 + c_{\text{disk}}^2)}{2(1-\rho)}. \quad (19.1)$$

The squared coefficient of variation of service time: $c_{\text{disk}}^2 = \bar{x}_{\text{disk}}^2 / (\bar{x}_{\text{disk}})^2 - 1$ was found to be less than one for random accesses to small disk blocks in [112]. Since $c_{\text{disk}} = 1$ for the exponential distribution, W is overestimate with this assumption.

Disk reads which affect application response time can be processed at a higher priority than writes. Assuming that the fraction of reads in the arrival stream is f_{R} , the mean waiting time for reads is given as [55]: $W = \rho \bar{x}_{\text{disk}} / (1 - \rho_{\text{R}})$, where $\rho_{\text{R}} = \lambda f_{\text{R}} \bar{x}_{\text{disk}}$ is the disk utilization due to read requests only. That is, read requests are not affected by the disk utilization due to write requests.

19.3.2 Disk Arm Scheduling

The FCFS disk scheduling policy in early HDDs was later superseded by more sophisticated disk scheduling methods. An easy method to reduce the mean disk service time \bar{x}_{disk} is to keep track of the disk arm by the operating system (OS) as in the case of the *Shortest Seek Time First (SSTF)* and *SCAN* scheduling [20]. The scheduling was to be carried out by the OS, which kept track of the position of the disk arm. SCAN reduces the seek time of outstanding disk requests by processing them as the arm is moved from the outermost to innermost tracks. A combination of SSTF and SCAN is described in [26], which alleviates SSTF's susceptibility to starvation. It allows accesses in the opposite direction of SCAN, provided that their seek distance plus the product $r \times c$ is smaller than the seek distance in the forward direction.

The number of cylinders is c and r , $0 \leq r \leq 1$ is a coefficient, whose optimal value was determined to be $r = 0.2$ for the workload under consideration with the target HDD.

The *Shortest Access Time First (SATF)* method processes requests, which minimize the positioning time (sum of projected seek time and latency) first [50]. SATF is implemented at the HDD controller, which can better estimate the positioning time than the OS. Improvements to SATF utilizing lookahead to minimize disk access time and incorporation of priorities in SATF are described in [105]. Lookahead takes into account the time to process additional requests beyond the first request, but at a discounted cost. Priority scheduling with SATF discounts the access time for higher priority requests. In fact, Equation 19.1 is applicable to scheduling methods that do not take into account service time.

In addition to disk arm scheduling, the placement of disk files affects the seek time. The organ-pipe arrangement reduces the seek distance by placing most frequently accessed disk files at middle disk cylinders, that is, at an equal distance from innermost and outermost tracks, surrounded by less frequently accessed files [49]. The *Automatically Locality Improving Storage (ALIS)* method described in [44], in addition to optimizing placement, coalesces disk requests to exploit the efficiency of sequential accesses.

Multimedia systems with fixed rate requests and deadlines for guaranteed completion of requests require specialized disk scheduling methods. SCAN-EDF scheduling combines the efficiency of SCAN with the *Earliest Deadline First (EDF)* real-time scheduling policy [69]. The performance metric is the number of streams that can be supported, which increases with larger buffer space and for deadlines exceeding interrequest periods.

Two notable studies of disk-scheduling performance are [131] and [43], while [105] is a recent survey of this subject, with emphasis on author's research in this area.

19.3.3 Log-Structured File System (LFS)

LFS optimizes writing to disk in an environment where read accesses to disk are uncommon due to the high hit rate of a large cache [84]. LFS accumulates modified files in a buffer and writes them to disk in large chunks called segments to reduce disk arm positioning overhead. Similarly to database logging [81], segments are written onto consecutive disk locations.

The fact that files are not written in place allows file compression, since otherwise there is the possibility that a file will not compress below its previous size. Disk space held by modified files is designated as free space. A background garbage collection process merges half-empty segments into full segments and creates empty segments for future destaging. For example, two half empty segments will result in one full and one empty segment. Files are located by inodes written to the log.

The write cost in LFS is a steeply increasing function of the utilization of disk capacity (u), which is the fraction of live data in segments (see Figure 3 in [84]). The crossover point with respect to UNIX's *Fast File System (FFS)* is at $u = 0.5$. The following issues related to segment cleaning policies are investigated in [84]: (1) When should the segment cleaner be executed? (2) How many segments should be cleaned? (3) Which segments should be cleaned? (4) How should be live blocks grouped into segments?

19.3.4 Active Disks

There have been numerous proposals to offload database operations to specialized processors associated with disks. Early work on database machines is reviewed in [41]. The Teradata *Data Base Computer - DBC/1012* with 10^{12} bytes or a TB storage capacity. DBC/1012 was designed for the efficient processing of relational algebra operators, see, for example, [81].*

HDDs are equipped with relatively powerful microprocessors, which have low utilizations, so that this processing power can be utilized in carrying out background tasks. Freeblock scheduling (FS) is based on opportunistic disk accesses, as the arm moves in processing regular requests [61]. This is

* http://en.wikipedia.org/wiki/DBC_1012.

advantageous since due to their mechanical nature, disk arms constrain the access bandwidth to disks with ever-increasing capacities. FS can be used in conjunction with LFS to prepare free segments, process nearest-neighbor queries, carry out data mining [81] and disk scrubbing [53], etc. [83].

Off-loading database activities work well for simpler operations, such as SQL SELECTs, but this is not the case for more complex SQL operations, such as relational joins and star-joins in data warehousing, which may involve multiple disks [81]. The SmartStor project at Almaden provided multiprocessor access to multiple disks, so that more complex database operations can be undertaken [42]. While a performance advantage is demonstrable, there is the additional cost of developing software with parallel processing capabilities at the storage level.

There has been recent activity at IBM to offload database applications from mainframes, such that most of their processing capacity remains available for *OnLine Txn Processing (OLTP)* applications with high-performance requirements [12]. There is the cost saving due to having a single copy of the database with a single set of disks. A 70%–97% reduction in CPU times and 9%–78% reduction in bytes transferred were observed in [79]. A key issue is that the “backend” software has the capability to process legacy file systems, such as VSAM (IBM’s version of B+ trees). Little interference is expected at the disks, since OLTP applications will access most of the required data in main memory, but require logging on dedicated disks. The need by queries to read consistent data from relational tables requires innovative concurrency control solutions, see for example, [99].

19.4 Redundant Arrays of Independent Disks (RAID)

The five-level Berkeley RAID classification introduced in late 1980s was extended to seven levels with the addition of RAID0 and RAID6 in [15]. RAID0 has no redundancy, but utilizes striping for load balancing. Striping partitions the data associated with the file system into fixed size stripe-units or strips, which are placed round-robin across the disks. The data strips in a row constitute a stripe. Mirroring or replication, which is classified as RAID1, is described in Section 19.5. RAID5 and RAID6 arrays with erasure coding are described in Section 19.4.1. In Sections 19.4.2 through 19.4.4, we describe RAID5 operation in normal, degraded, and rebuild modes. The four RAID levels are shown in Figure 19.1.

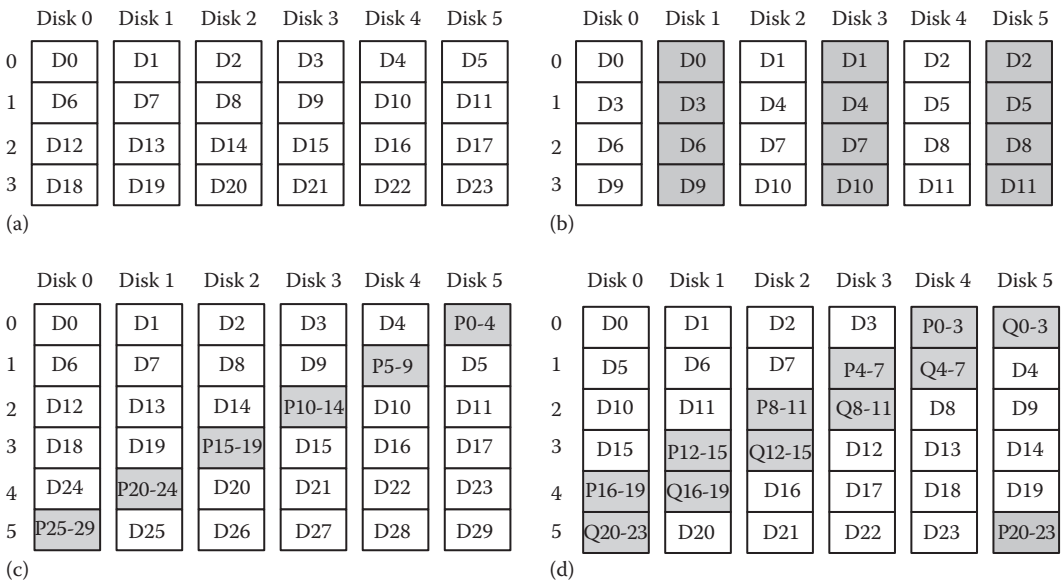

FIGURE 19.1 RAID0, RAID1, RAID5, and RAID6 layouts. (a) RAID0, (b) RAID1, (c) RAID5, and (d) RAID6 data layouts.

19.4.1 RAID5, RAID6, and Their Variations

RAID4 extends RAID0 with $N - 1$ disks, with an additional N th disk dedicated to parity. Parity strips hold the *eXclusive-OR* (XOR) of the corresponding $N - 1$ data strips in the same stripe, for example, $P_N = \oplus_{i=1}^{N-1} D_i$. The strips of a failed disk (or their blocks) can be reconstructed by XORing the corresponding strips (or blocks) on surviving disks. For example, $D_1 = (\oplus_{i=2}^{N-1} D_i) \oplus P_N$. Two disadvantages of RAID4 are that the dedicated parity disk is not utilized at all by read requests and that it may constitute a bottleneck for write intensive workloads.

RAID5 disk array balances disk loads for processing updates by placing check strips in right to left diagonals, known as the left-symmetric organization [15], as shown in Figure 19.1. Diff-RAID, described in Section 19.11, utilizes an unbalanced allocation of parities to attain a higher reliability [6].

Parity striping is a variation on RAID5, which does not stripe the data at all, but dedicates $1/N$ th of the capacity of all disks to parity. This placement sacrifices higher data transfer rates to the ability to access the strips of a file in parallel, thus increasing the throughput of the RAID5 array (see Section 19.4.2). The performance of RAID5 and parity striping is compared in [14].

In general, RAID($4 + k$), $k \geq 1$ arrays are extensions of RAID0 with k check strips, where k is also the number of failed disks that can be tolerated, hence the classification *k disk failure tolerant (kDFT)* [109]. Although, under the best circumstances, RAID1 arrays can tolerate up to one half of disk failures without data loss, as discussed in Section 19.5, a second disk failure may lead to data loss, hence RAID1 is a 1DFT.

Reed-Solomon (RS) codes are *maximum distance separable (MDS)* in that they incur the capacity equivalent of $k \geq 1$ redundant disks to tolerate as many disk failures [109]. RS is costly to implement, since it is based on Galois field finite arithmetic [75,76]. *EVENODD (EO)* is a 2DFT which uses parity coding with a significantly lower cost than RS for check code calculations [8], but is outperformed by the *Rotated Diagonal Parity (RDP)* invented 10 years later [18]. Figure 19.2 is an RDP array with n^2 data blocks and $n = 4$. The updating of almost all data blocks requires the updating of two blocks with the exception of one block in each row, that is, we need $2n^2 - 2n$ XORs to protect n^2 data blocks, or $2 - 2/n$ XORs per data block. This is smaller than $2 - 2/(n - 1)$ for EO [109]. A performance evaluation of storage erasure coding libraries is reported in [77].

X-code is another 2DFT MDS code [133], which dedicates two (horizontal) stripes to P and Q parities per segment, which is an $N \times N$ array of strips, so that N data stripes in $N - 2$ rows are protected. A shortcoming of X-code is that the number of disks (N) should be prime. The two parities cover strips placed in diagonals with positive and negative slopes, as shown in Figures 19.3 and 19.4.

RM2 is non-MDS but similarly to the X-code uses horizontally placed check codes. Each data strip is covered by two check strips, so that RM2 is 2DFT. Depending on the redundancy level $p = 1/M$, there are $M - 1$ data strips per parity stripe [74]. Based on constraints given in the paper, the smallest number of possible disks for $p = 1/3$ is $N = 7$, so that the redundancy level is higher than a RAID6 with seven disks, which is $2/7$. In Figure 19.5 P_0, \dots, P_6 are the parity strips for the seven parity groups. Data strip $D_{i,j}$ is protected by two parity strips P_i and P_j .

RAID operation in normal/degraded/rebuild modes are discussed in Sections 19.4.2 through 19.4.4.

19.4.2 RAID5 Operation in Normal Mode

The updating of each data block in RAID($k + 4$), $k \geq 1$ requires the reading and writing of k check blocks protecting a data block. For RAID5 with $k = 1$ given the updated data block d_{new} , the difference block is computed as the XOR of the new and old data block: $d_{diff} = d_{old} \oplus d_{new}$. The parity block is updated as $p_{new} = p_{old} \oplus d_{diff}$. If d_{old} and p_{old} are not cached, the updating of a single block in RAID5 requires the reading of the data and parity blocks and writing them. The four disk accesses are referred to as the small write penalty (SWP) in [15]. In the case of RS codes, d_{diff} is multiplied by an appropriate coefficient, before being XORed with the Q check blocks [75,76]. Disks are assumed to have an XOR capability and the XOR can be carried out as part of a read modify write (RMW) operation at the check disks consists of a read followed by an XOR and a disk rotation before the check blocks is overwritten. *Disk Architecture for Composite Operations (DACO)* is a proposal to place a write head followed by a read head to eliminate the disk rotation time [60]. The shortcomings of this approach are discussed in [106].

Optimum strip sizes, their layout, and efficient methods to update parities were areas of early RAID research, which are reviewed in [15]. Larger strip sizes facilitating single disk accesses to larger files are beneficial in a multiuser environment, but preclude parallel access in single user environments. Strip sizes should be large enough to accommodate most block sizes in order to preclude multiple disk

accesses and unnecessary seeks, which would result in an unnecessary increase in disk utilization. The optimum strip size for database applications may be recommended by database companies to optimize the performance of their products.

A simple and pragmatic method for dealing with SWP is caching dirty blocks in NVS portion of DAC's cache [64]. Trace analysis shows that dirty blocks tend to be overwritten several times before they are destaged. Such blocks exhibit locality, for example, multiple blocks are destaged on the same track. This effect was taken into account in the performance analysis in [112]. Disk scheduling can be applied to reduce destage time. A detailed study of RAID5 cache behavior is reported in [122], which does not recommend the caching of parity blocks, since they do not contribute to the hit rate for read accesses.

The log structured array (LSA) is an extension of LFS to RAID5 according to [65]. In fact, LSA was first implemented in conjunction with StorageTek's Iceberg RAID6 disk array [15]. It has been implemented as the RAID5 portion of HP's AutoRAID disk array [127] (see Section 19.8.3). LSA eliminates SWP by utilizing full stripe writes, by first accumulating a sufficient volume of data in the form of modified files in DAC's cache. The check strips can be computed on the fly as data strips are written to consecutive disks. Similarly to LFS, the previous version of files is designated for garbage collection. This task is carried out periodically to coalesce n not fully utilized stripes onto $m < n$ almost full stripes and $n-m$ empty stripes. Since files are not written in place, they may be compressed to attain a higher storage efficiency.

19.4.3 RAID5 Operation in Degraded Mode

RAID5 takes advantage of its redundancy to reconstruct disk blocks on demand. A data block on a failed disk or an unreadable block due to media failure requires the $N - 1$ corresponding blocks from surviving disks to be read and XORed. A read access to the failed disk is thus converted to an $(N - 1)$ -way fork-join request, which is considered completed when the corresponding blocks from surviving disks are accessed and XORed. There is a doubling in disk loads due to for-join requests to reconstruct blocks on the failed disk, since in addition each disk processes its own read accesses. Read redirection accesses reconstructed blocks directly by simply keeping track of the progress made by the rebuild process, which systematically reconstructs the contents of a failed disk on a spare disk [68].

Clustered RAID (CRAID) or parity declustering is a data layout, which reduces the load increase in degraded mode [68]. This is accomplished by settling the number of disks in a parity group to G , which is smaller than the number of disks N . The load increase due to read requests is specified as the declustering ratio: $\alpha = (G - 1)/(N - 1)$. For $N = 10$ and $G = 4$, we have $\alpha = 1/3$ and 2.5 parity groups per stripe. Since as many strips are reconstructed per stripe, this will result in overloading of the spare disk. Adjusting the fraction of redirected reads to the spare disk is proposed as a solution to this problem in [68], since the increased load on surviving disks will result in reduced rate in rebuild reading (see Section 19.4.4). This may not be an adequate solution in all cases, since it may result in a backlog of rebuild units (RUs), which are the smallest block sizes for rebuild processing, in the rebuild buffer. Throttling of rebuild reads is then a more robust solution to this problem.

CRAID has a twofold effect on reducing the mean response time: (i) The mean response time at each disk lowers because of the smaller disk utilizations. (ii) We have a $(G - 1)$ -way rather than an $(N - 1)$ -way fork-join request, whose mean response time is proportional to H_{G-1} , rather than H_{N-1} , where $H_n = \sum_{i=1}^n 1/i$ is the Harmonic sum (strictly speaking this is true for exponential distributed disk response times). When the bandwidth of the rebuild buffer constitutes a bottleneck, CRAID, which requires $G - 1$ -way, rather than an $N - 1$ -way XOR processing with associated DRAM accesses, improves rebuild time, as shown in Figure 6 in [125].

Balanced incomplete block designs (BIBD) [72,39] and nearly random permutations (NRP) [67] are two efficient implementations of CRAID to balance disk update loads [109]. BIBD has the shortcoming that data layouts are not available for all values of N and α [109].

19.4.4 RAID5 Rebuild Processing

The discussion is organized in four parts. Section 19.4.4.1 is a general discussion of rebuild processing. Section 19.4.4.2 discusses rebuild performance. Section 19.4.4.3 discusses methods to improve RAID5 reliability by improving the chances that rebuild is completed successfully. Section 19.4.4.4 discusses methods to reduce rebuild cost.

19.4.4.1 General Discussion of Rebuild Processing

RAID5 rebuild is the systematic reconstruction of the contents of a failed disk on a spare disk. In the case of RAID5 with N disks successive RUs, for example, tracks, are read from the $N - 1$ surviving disks, XORed to reconstruct the next missing RU, which is then written to disk.

In stripe-oriented rebuild (SOR), the strips in a stripe constitute RUs [39]. Since rebuild reading proceeds one stripe at a time, the synchronization at this level results in an unnecessary slowdown compared to disk-oriented rebuild (DOR), where contents of surviving disks are read in parallel into a rebuild buffer. They are then XORed to reconstruct the next RU to be written to disk. It follows from simulation results in [39] that DOR outperforms SOR.

In *distributed sparing* spare areas are distributed among the disks in the RAID array, so that the contents of a failed disk can be reconstructed on surviving disks [66,112]. It has the advantage over dedicated sparing in that the bandwidth of the hot spare is not wasted and conversely a higher access bandwidth is provided. Once a spare disk becomes available, the spare areas are copied onto this disk to free up space for further rebuilds, so that rebuild is a two-step process.

Parity sparing is another method, where two RAID5 arrays are merged into one, by utilizing one of two parities [66]. In the case of a single RAID5, *restriping* overwrites the parity strips, so that the disk array reverts to RAID0 [82]. In the case of RAID7, we have the following transitions:

$$\text{RAID7} \rightarrow \text{RAID6} \rightarrow \text{RAID5} \rightarrow \text{RAID0}.$$

Interestingly as check blocks are overwritten by restriping, there is an increase in the maximum disk I/Os per second (IOPS) with the progression of disk failures, since the effect of SWP is reduced as the redundancy level is lowered [120].

With the advent of multiterabyte disks, a substantial increase rebuild time is to be expected. Rebuild time can be reduced by carrying out rebuild processing at the level of identifiable objects, as discussed in Section 19.8.3.

19.4.4.2 Rebuild Performance Analysis

The vacationing server model (VSM) reduces the effect of rebuild reads on the response time of external requests, which are already higher in degraded operating mode. This is accomplished by starting rebuild reading when the disk becomes idle [111,112,118] and stopping it with the arrival of an external request. Provided disk requests arrive according to a Poisson process, each disk in a RAID5 array correspond to an $M/G/1$ queueing system, which has alternating busy and idle periods [55]. Disk accesses are processed in a busy period and an idle period starts when there are no requests pending. There is no forced idleness, although the latter has been shown to improve performance if a succeeding request in the same stream of requests is anticipated. The duration of an idle period is simply the interarrival time of external requests with rate λ , so that $\bar{t}_{\text{idle}} = 1/\lambda$. As shown in Figure 19.6, the first rebuild read requires a seek, while successive reads do not. It is assumed that the RU is a disk track.

To simplify the discussion, we assume all disk requests are reads with mean service time \bar{x}_{disk} , so that the disk utilization is $\rho = \lambda \bar{x}_{\text{disk}}$. The duration of the busy period \bar{t}_{busy} can be obtained by noting that it is the fraction of time the system is busy: $\bar{t}_{\text{busy}}/(\bar{t}_{\text{busy}} + \bar{t}_{\text{idle}}) = \rho$, so that $\bar{t}_{\text{busy}} = \bar{x}_{\text{disk}}/(1 - \rho)$ [55].

With rebuild processing, the duration of the busy period is modified since the service time of the first request starting the modified busy period is elongated by the residual lifetime of the rebuild read in progress: $\bar{z} = \bar{x}_{\text{disk}} + \bar{y}_r$, by the first request arriving during the final vacation during which a

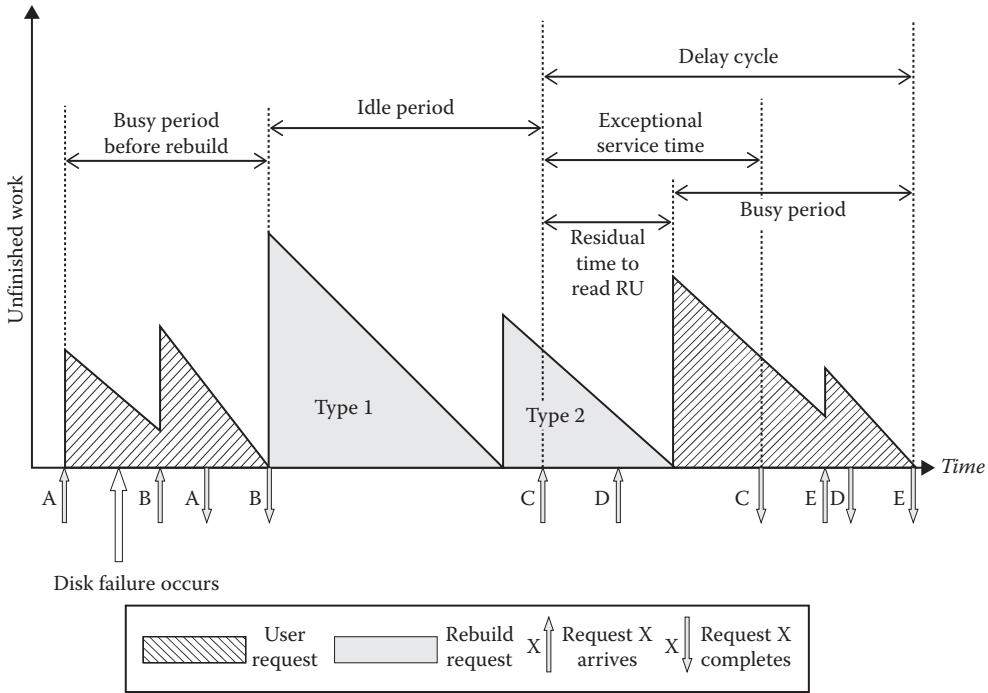

FIGURE 19.6 Key parameters associated with rebuild processing. (From Thomasian, A. et al., *Comput. J.*, 50(2), 217, March 2007.)

request arrives. To simplify the discussion, we assume that vacation times have a fixed duration $y = v$, so that mean remaining vacation time after an arrival in a vacation period is given as

$$v_r = T - \frac{\int_0^T \lambda e^{-\lambda t} dt}{\int_0^T e^{-\lambda t} dt} = \frac{v}{1 - e^{-\lambda T}} - \frac{1}{\lambda}. \tag{19.2}$$

The mean effective service time of the first request starting the next modified busy period, referred to as the delay cycle (with mean \bar{d}) is: $\bar{z} = v_r + \bar{x}$, so that [55]: $\bar{t}_{\text{busy}} = \bar{z}/(1 - \rho)$.

Similarly, ignoring the initial seek time the probability that a disk request arrives during a disk rotation is $p = 1 - e^{-\lambda T_{\text{rot}}} \approx \lambda T_{\text{rot}}$. One can estimate \bar{z} more accurately by noting that it is the residual lifetime of the first arrival during rebuild reading that really matters [118]. The probability of n tracks being read in an idle period is: $p_n = p(1 - p)^{n-1}$, so that $\bar{n} = 1/p$. The rebuild reading time of a disk with N_{track} tracks is

$$T_{\text{rebuild}}(\rho) = [\bar{T}_{\text{busy}} + \bar{T}_{\text{idle}}] \frac{N_{\text{track}}}{\bar{n}},$$

where ρ denotes the initial disk utilization, before the failure of the disk, after which the load on surviving disks is doubled. The arrival rate of read requests at the start of rebuild processing is twice the rate in normal mode for read requests, but the arrival rate returns to normal mode as a result of read redirection. The variation in disk utilization in computing $T_{\text{rebuild}}(\rho)$ can be taken into account by computing rebuild processing time over k intervals [111]:

$$T_{\text{rebuild}}(\rho) = \sum_{i=1}^k T_{\text{rebuild}}(\rho_i), \quad \rho_i = \left[2 - \frac{2i-1}{2k} \right] \rho.$$

The mean response time of external disk requests is increased by the mean residual time for rebuild reads. The larger the RU, the shorter the rebuild time, since fewer seeks are required to complete the rebuild time. This trade-off is explored in [40] by setting the RU to be a block, a track, or a cylinder, but not the whole disk in which case rebuild time would be minimized.

The mean response time for external requests can be improved by the split-seek option, that is, the reading of a track is abandoned if there is a pending request following the completion of a seek [111]. The simulation study in [100] investigates the effect of preempting rebuild reads during the latency and even the transfer phases. In all three cases, the wasted positioning time for rebuild reading results in the elongation of rebuild time, so that more external requests are processed in degraded mode. The efficiency of rebuild policies from the viewpoint of external requests can be compared as the excess response time of user requests processed during rebuild processing compared with mean disk response time in normal mode operation.

The analysis of VSM with dedicated sparing in [111] is extended to distributed sparing in [112], which takes the extra load due to rebuild writes on a disk. An iterative solution is required since the rate of rebuild writes depends on the rate of rebuild reads, which are not known a priori.

The reading of surviving disks for rebuild takes approximately the same time at all disks, provided the disk loads are balanced due to striping [112]. If the writing of the RUs is pipelined with disk reading, rebuild time can be approximated by the time to complete the reading of disks. This is provided the spare disk is not a bottleneck in dedicated sparing, but this is not the case with CRAID as was noted earlier.

Rebuild time increases rapidly with higher disk utilization (ρ) due to external disk requests before the disk failure occurred. This is because rebuild progresses at a rate $1 - 2\rho$ at the start of rebuild processing. Curve-fitting against simulation results yields $T_{\text{rebuild}}(\rho) = T_{\text{rebuild}}(0)/(1 - \beta\rho)$ with $\beta = 1.75$ [109], where $T_{\text{rebuild}}(0)$ is the time for reading an idle disk or when the processing of external requests is deferred, which is not a practical solution.

The permanent customer model (PCM) for rebuild processing inserts a new rebuild read into the queue of pending disk requests as soon as another rebuild read is completed [67]. Given that disk requests are processed in FCFS order, the arrival of disk requests while a rebuild read is enqueued and being processed will result in more interruptions in rebuild reads than with VSM, which is only affected by arrivals while a rebuild read is being processed [109]. It is easy to see that VSM has less effect on external requests than PCM in that: (1) Rebuild reads are not processed ahead of external requests. (2) Rebuild reading with VSM takes less time than PCM, so that it interferes with fewer external requests.

The analysis in [112] is extended in [118] to zoned disks, with whole tracks constituting RUs. If a fixed size RU is selected, then partial tracks reads will result in multiple accesses to a track and additional latencies. Caching into disk's track buffer can be used to reduce the number of accesses to the same track. Lookahead reading into the track buffer while user requests are pending may, however, affect the response time of user requests.

19.4.4.3 Improved Reliability for Rebuild Processing

Rebuild may be unsuccessful due to: (1) A second disk failure before rebuild is completed. (2) Latent sector errors (LSEs) encountered, while rebuild is in progress. It was observed in [8] that 4% of unsuccessful rebuilds are due to LSEs and this was used as the motivation to develop EO. Using the data in [48], it can be shown that the probability of unsuccessful rebuilds due to LSEs is two orders of magnitude more likely than a second disk failure.

Intra-disk redundancy (IDR) is a novel method which applies redundancy at the level of disk sectors, so that LSEs are masked [22]. IDR utilized in several RAID products has been termed vertical coding, as opposed to horizontal coding at interdisk level in RAID5. The effectiveness of the single parity (SP), the RS, and interleaved parity (IP) codes are analyzed in [22]. It is shown that IP, which is less expensive to implement than RS, provides the same reliability level as RS. The reliability analysis in [22] shows that IDR+RAID5 yields the same reliability as RAID6. The small increase in disk block lengths due to IDR has a negligible effect on disk access time in RAID5, which provides a significant performance advantage with respect to RAID6 in that it updates a single check block instead of two [119].

Disk scrubbing is the periodic reading of disks to detect and correct LSEs using the redundancy provided by the RAID5 paradigm [53]. The advantage of disk scrubbing is that sector errors are detected and corrected early, before they hinder the completion of the rebuild process. Four disk scrubbing methods are proposed in [53]. The original *Disk Scanning Algorithm (DSA)* starts a scrubbing request when the disk is idle after a certain waiting time wt has expired. Adaptive DSA adjusts wt based on system activity, that is, wt is increased for heavier loads and decreased for lighter loads. Simplified DSA maintains two queues, one for user and one for scanning requests. After the user queue has been empty for a sufficiently long interval, a scanning request is issued. Rather than starting DSA right away, it can be issued periodically, for example, once a day. DSA with the *VERIFY* command transfers read data into internal disk buffers where the consistency of data is checked.

A straightforward analysis of disk scrubbing is reported in [48]. The probability of an error due to a write is P_w and writes constitute a fraction r_w of disk accesses with rate h . The probability of error in reading a sector without scrubbing is $P_e = r_w P_w$. The probability of sector failure for deterministic scrubbing and random (exponentially distributed) scrubbing period are $P_s = [1 - (1 - e^{-hT_s}) / (hT_s)] P_e$ and $P_s = [hT_s / (1 + hT_s)] P_e$, respectively, where T_s denotes the mean scrub period. It follows that deterministic scrubbing is preferable, since random scrubbing has double the value for P_s . Furthermore $P_s \leq P_e \leq P_w$. The effectiveness of disk scrubbing and IDR for dealing with LSEs is investigated in [92] and [48], with the latter concluding that IDR is preferable to disk scrubbing.

When the memory bandwidth constitutes a bottleneck, rebuild time can be reduced via CRAID. This is because fewer RUs are XORed for rebuild and less memory bandwidth is required [125]. Taking into account hardware resource contention, rebuild time is the maximum of the delay due to disk and DRAM buffer transfer times [22].

19.4.4.4 Reducing the Cost of Rebuild Processing

The supplementary parity augmentation (SPA) method, in addition to the P parity which covers all disks, introduces the S parity which covers half of the disks [121]. This implies that two parities need to be updated for one half of the disks, but only one half of the disks are protected against two disk failures. There is a similarity to Pyramid codes proposed in [46]. Briefly, a disk array with three RS codes P , Q , and R , the P parity strips are replaced by two strips P_0 and P_1 , so that given an even number of disks N , P_0 covers disks $1:N/2$ and P_1 covers $N/2 + 1:N$. While SPA and Pyramid codes have the same level of redundancy, only one of two parities should be modified per update in the case of Pyramid codes. Both methods have the advantage of halving the volume of the data to be read for rebuild, which reduces the possibility of LSE being encountered during rebuild reading. Given that RAID5+IDR introduces the same level of reliability as RAID6, the overhead associated with SPA is hard to justify. A more detailed discussion of SPA appears in [107].

The *Local Reconstruction Codes (LRC)*, which was developed for *Windows Azure Storage (WAS)* similarly to Pyramid codes [46], partitions data fragments into groups to reduce rebuild processing cost [47]. As an example, we consider the (k, l, r) code with $k = 6$ data fragments, $l = 2$ local parities, and $r = 2$ global parities. LRC can tolerate arbitrary three failures by choosing the sets of coding coefficients:

$$q_{x,0} = \alpha_0 x_0 + \alpha_1 x_1 + \alpha_2 x_2, \quad q_{x,1} = \alpha_0^2 x_0 + \alpha_1^2 x_1 + \alpha_2^2 x_2, \quad q_{x,0} = x_0 + x_1 + x_2.$$

$$q_{y,0} = \beta_0 y_0 + \beta_1 y_1 + \beta_2 y_2, \quad q_{y,1} = \beta_0^2 y_0 + \beta_1^2 y_1 + \beta_2^2 y_2, \quad q_{y,0} = y_0 + y_1 + y_2.$$

The two local parities are $p_x = q_{x,2}$ and $p_y = q_{y,2}$. The two global parities are: $p_0 = q_{x,0} + q_{y,0}$ and $p_1 = q_{x,1} + q_{y,1}$. The choice of α 's and β 's from the Galois Field $GF(2^4)$ is specified in the paper. The key properties of the LRC codes are: (i) single data fragments failure can be decoded from k/ℓ fragments; (ii) arbitrary failures

up to $r + 1$ can be decoded. It is shown in the paper that for a set of typical parameters (6,2,2) outperforms the MTTF of (6,3) RS code by an order of magnitude.

Note that construction does not take into account the partial parities when computing the global parity, so that special cases need to be considered when decoding.

An important detail about WAS is that the data is initially written into three replicas, but periodically the replicas are sealed at the extent level (large chunks of data), which are not expected to be modified anymore, and converted to the LRC format for higher data efficiency. Unlike AutoRAID, this conversion is not reversible and the replicates are then deleted.

An improvement in the number of disk strips accessed for rebuilding a single disk block is possible by taking advantage of the fact that disk strips are protected by two parities. It is shown in [124] that in a distributed RDP storage system with two redundancy nodes, only 3/4 of the information needs to be transmitted to rebuild one node. In the case of X-code with p nodes, the “repair bandwidth” is at most $(3p^2 - 2p + 5)/4$ while the repair bandwidth for RDP and X-code is given as $3(p - 1)^2$. This is given as a lower bound for RDP disk arrays in [132], which adopts a symbol size equal to the strip size in a disk array context. RDP disk arrays similar to EO adopts small symbol sizes in the context of disk arrays, which makes their access pattern the same as RAID6.

Large symbol sizes equaling strip sizes are utilized by X-code [133], so that the method to reduce the cost of rebuilding a single disk is applicable to it [115]. Referring back to Figures 19.3 and 19.4 we assume that disk 0 has failed. Rather than reconstructing all blocks using P or Q parities, we reconstruct four blocks using P and the other three blocks using Q parities. In what follows we have specified block accesses to reconstruct strips (0,0), (1,0), (2,0), and (5,0) or $p(0)$ using P parities, followed by (3,0), (4,0), (6,0), or $q(0)$ using Q parities. With two disk failures, RDP with large symbol sizes requires a multistep recovery method [58], similarly to the X-code [115].

(0,0) using $p(2)$: (5,1), (4,2), (3,3), (2,4), (1,5)₁
 (1,0) using $p(3)$: (5,3), (4,4), (3,5)₂, (2,6)₃, (0,1)
 (2,0) using $p(4)$: (5,4), (4,5), (3,6)₄, (1,1), (0,2)₅
 (5,0) using $p(0)$: (4,1)₆, (3,2), (2,3), (1,4)₇, (0,5)
 (3,0) using $q(2)$: (4,1)₆, (6,2), (0,4), (1,5)₁, (2,6)₃
 (4,0) using $q(1)$: (6,1), (0,3), (1,4)₇, (2,5), (3,6)₄
 (6,0) using $q(0)$: (0,2)₅, (1,3), (2,4), (3,5)₂, (4,6)

Repeated accesses to the same strip are specified by unprimed subscripts in a first occurrence and a primed subscript in a second occurrence. Rather than $N \times (N - 2) = 35$ accesses, 28 block accesses are required, provided seven strips are cached, after they are accessed, which amounts to a 20% decrease in the number of accessed strips.

This concept is extended to cloud storage in [54], where a rotated RS code is proposed such that strips are reused in the construction process, reducing its cost. We illustrate the savings in cost using Figure 7 in the paper, with $k = 6$ columns, $m = 3$ check strips, and $r = 4$ rows. All four rows are referred to as a stripe in this work. The coding for row 0 is then

$$c_{j,0} = \sum_{i=0}^{k-1} (2^i)^j d_{i,0}, \quad 0 \leq j \leq m-1.$$

Data strips from different rows are used in computing the check strips, according to the following equations, where $n = (kj/m)$ and $\%r$ stands for modulo r :

$$c_{j,b} = \sum_{i=0}^{n-1} (2^i)^j d_{(i,b+1)\%r} + \sum_{i=n}^k (2^i)^j d_{i,k}, \quad 0 \leq k \leq r-1, \quad 0 \leq j \leq m-1.$$

Four of the check strips required for reconstructing the four strips on disk 0 which has failed are as follows:

$$p_0 = \sum_{i=0}^5 d_{i,0}, \quad q_0 = d_{1,0} + 2d_{1,1} + \sum_{i=2}^5 2^i d_{i,0} \quad p_2 = \sum_{i=0}^5 2^i d_{i,2}, \quad q_2 = d_{0,3} + 2d_{1,3} + \sum_{i=2}^5 2^i d_{i,2}.$$

It can be observed that only 16 symbols (strips) are required for recovery, versus 24 strips which would be otherwise required. For even r the cost of reconstructing a disk is $\frac{r}{2} \left(k + \left\lceil \frac{k}{m} \right\rceil \right)$ versus $k \times r$.

A disadvantage of this method is that $m \times r$ check strips need to be buffered when data is being written. It is assumed that rows constituting data strips are read one row at a time and applied to the check strips.

19.5 Mirrored Disks or RAID1

We start with a discussion of mirrored disk organizations in Section 19.5.1. This is followed by a discussion of efficient processing of disk requests without and with an NVS cache.

19.5.1 Mirrored Disk Organizations

Basic Mirroring (BM) with two disks is the simplest form of data replication, which was utilized in Tandem's (now HP) fault-tolerant computers, such as NonStop SQL, before its classification as RAID level 1 (RAID1) in [15]. For higher volumes of data, we have RAID1/0 with $N = 2M$ disks or M disk pairs, that is, two mirrored RAID0 arrays. Alternatively we have RAID0/1, a RAID0 array where each virtual disk is a mirrored pair, that is, striping is applied across mirrored pairs to balance disk loads. For RAID1/0 with $N = 8$, the four primary disks hold strips $(B_{1,1}, B_{1,2}, B_{1,3}, B_{1,4})$ and the secondary disks hold strips $(B'_{1,1}, B'_{1,2}, B'_{1,3}, B'_{1,4})$, where the indices denote the stripe (or row) and disk number, respectively. The failure of up to $M = N/2$ disks will not result in data loss in either case, as long as they do not constitute a pair, but the failure of only two disks constituting a pair will result in data loss, GRD, ID, and CD RAID1 arrays, described below, are 1DFTs, while LSI RAID1 is a 2DFT.

Group Rotate Declustering (GRD) is similar to RAID1/0, but rotates data on the secondary disks from row to row, so that the second row on the mirrors is: $(B'_{2,2}, B'_{2,3}, B'_{2,4}, B'_{2,1})$, and so on. The advantage of GRD over BM is that upon the failure of a single disk, its read load is evenly distributed over M disks at "the other side." Up to M disk failures will not lead to data loss as long as they are all on one side. The probability that a second disk failure leads to data loss is then $M/(2M - 1) > 0.5$, while it is only $1/(2M - 1)$ for BM.

Interleaved Declustering (ID) was introduced in Teradata's DBC/1012 computer. Disks are partitioned into equal-sized clusters, for example, for $N = 8$ and $c = 2$ clusters there are $K = N/c = 4$ disks per cluster. Disks are divided into primary and secondary areas, which replicate each other. We use capital letters for primary and small letters for secondary data blocks. Primary blocks B_i , $1 \leq i \leq 4$ have each $K - 1 = 3$ secondary blocks: $(b_{i,1}, b_{i,2}, b_{i,3})$ with $B_i = b_{i,1} || b_{i,2} || b_{i,3}$. The latter are placed in rotated manner at the other disks in the cluster, so that the read load of a failed disk is distributed evenly across the disks in the other cluster. The advantage of ID over BM is that the read load increase due to a single disk failure is $1/(K - 1) < 1/2$. Up to c disk failures can be tolerated by ID, as long as they are in different clusters.

Chained Declustering (CD) is an improvement over ID in terms of reliability, but unlike ID it requires careful routing of read request to balance disk loads. The space on D_i , $1 \leq i \leq N$ disks is partitioned into primary and secondary areas with equal sizes. Unprimed data blocks in the primary area of each disk are replicated on primed data blocks in the secondary area of the following disk, for example, disk D_i holds data blocks $B_i, B'_{(i-1) \bmod N}$, $1 \leq i \leq N$. Read requests can be accessed from the primary or secondary area, using static load balancing methods, which adjust the fraction of requests to balance disk loads as disk failures occur. Up to M disk failures can be tolerated by CD, as long as the two failed disks are not contiguous.

LSI RAID1. This is a hybrid disk array, which is described in a patent by LSI Logic Corp. [128] (LSI stands for Large Scale Integration). LSI RAID1 combined mirroring and parity, as shown in the following for $N = 8$ disks, four of which are data and four parity disks:

$$(D_1, P_{1,2}, D_2, P_{2,3}, D_3, P_{3,4}, D_4, P_{4,1})$$

Each *Parity disk (Pdisk)* is the XOR of the two neighboring *Data disks (Ddisks)*, for example, $P_{1,2} = D_1 \oplus D_2$. Ddisks can be reconstructed as follows, for example, $D_1 = P_{1,2} \oplus D_2 = D_4 \oplus P_{4,1}$. Three disks failures can be tolerated by LSI RAID1, unless they are three consecutive disk failures with a parity disk in the middle [113]. The failure of four Ddisks and also two Ddisk and two Pdisks can lead to data loss. Enumeration is used to extend the reliability analysis of mirrored disks to LSI RAID1 [113].

Survivable Storage using Parity in Redundant Array Layout (SSPiRAL) extends the LSI RAID paradigm to the case where Pdisks are computed over $m = 3$ Ddisks and each Ddisk is protected by $m = 3$ Pdisks, so that $D_{out} = P_{in} = 3$ [93]. For $N = 8$ the four Ddisks $A, B, C,$ and D are protected by the four Pdisks holding $A \oplus B \oplus C, B \oplus C \oplus D, C \oplus D \oplus A,$ and $D \oplus A \oplus B$. If Ddisks and Pdisks are placed in two rows, then each Pdisk is the XOR of the Ddisk above it and the two Ddisks that follow it, modulo $M = N/2$. It is easy to verify that up to three disk failures can be tolerated in all cases. If all Ddisks fail they can be reconstructed using Pdisks, which is not the case for LSI RAID. There is data loss if a Ddisk and the three Pdisks in which it participates fail. There are $\binom{8}{4} = 70$ configurations with four disk failures. Enumeration shows that for $N = 8$, data loss occurs in $1/5$ th of four disk failure cases.

19.5.2 Routing of Disk Requests in RAID1

In addition to higher reliability, mirrored disks provide twice the access bandwidth of single disks for processing read requests, which tended to dominate write requests in many applications. This is less so with the availability of very large caches, which results in fewer read misses.

A reduction in seek distance for read requests can be achieved in BM by judicious routing. Routing policies can be classified as static and dynamic, where the latter take into account the states of the disks. Assuming that the R/W heads and disk blocks are positioned at random disk tracks, then selecting the R/W head closest to a requested block results in a mean seek distance $c/5$ for reads and $7c/25$ to complete both writes [7], versus $c/3$ for a single disk. There are many complications, such as the effect of two R/W heads being positioned on the same track after a write. Refinements to this performance analysis are discussed in [101]. The following static routing policies are considered in [101]:

Private Queue (PQ): Read requests are immediately routed to one of the disks according to some routing policy, while write requests are sent to both disks.

Shared Queue (SQ): Read requests are held in this queue and are routed to the first disk that becomes available. Dynamic routing can be pursued in this case.

Hybrid Queue (HQ): The routing of read requests from SQ to PQs can be deferred.

Routing of requests to PQ can be classified as static or dynamic [101]. Uniform and round-robin routing are two examples of static routing policies. Round-robin routing is simpler to implement than uniform routing. It improves the mean disk response time by making the arrival process more regular than exponential interarrival times with coefficient of variation $c_a = 1$, that is, Erlang-2 with $c_a = 1/\sqrt{2}$ [55,123].

The router in addition to checking whether a request is a read or a write can determine other request attributes, such as the addresses disk blocks organized as a single dimensional array. Read accesses with addresses below a certain value can be routed to one disk and others to another. Such affinity-based routing is beneficial for sequential accesses from a file, so that it will minimize the seek distance for such accesses. It is also possible to take advantage of data prefetching to the onboard buffer. This method works well if the disk loads are balanced.

A dynamic policy that takes into account the number of requests at each disk, such as *join the shortest queue* (JSQ), may not be effective, since the queue length is not a good measure of pending processing times at the disk, because requests may be to highly variable file sizes. Performance can be improved by estimating the remaining service time at each disk, which is only feasible if requests are processed in FCFS order. In the case of SATF scheduling, the processing time changes with the arrival of each new request, although the number of requests under consideration may be limited to a finite number of requests.

Simulation studies have shown that the routing policy for PQ has a negligible effect on performance for a workload consisting of random disk accesses and that performance is mainly determined by the local scheduling policy. SQ provides more opportunities than PQ to improve performance, because more requests are available to carry out optimization, but then the PQ may be integrated with disk's controller, while SQ cannot. Mirrored disks with a single controller would be a solution to this problem. SATF scheduling with SQ provides better performance PQ, because SQ provides almost twice the requests for scheduling [101].

The performance of a mirrored disk system without an NVS cache can be improved by using a write anywhere policy on one disk to minimize disk arm movement and also susceptibility to data loss when an NVS cache is not available. Data is written in place later on the primary disk, which allows efficient sequential accesses, while a directory is required to keep track of blocks written anywhere. The distorted mirrors method described in [95] is one of several proposals for improving mirrored disk performance.

Similarly to RAID5, a large NVS caches can be used to improve the performance of mirrored disks. Prioritizing the processing of read requests yields a significant improvement in response time. Deferred writes can be processed efficiently in batches. The scheme proposed in [78] operates mirrored disks in two phases. While one disk is processing read requests, the other disk is processing writes in a batch mode using *Cyclical CSCAN* (CSCAN), that is, SCAN in one direction only [105]. The performance of the above method can be improved as follows [110]: (1) Eliminating the forced idleness by processing write requests individually. This can be carried out opportunistically, as in FS. (2) Using SATF or exhaustive enumeration, which is only possible for sufficiently small batch sizes, instead of CSCAN, to find an optimal destaging sequence to minimize time. (3) Introducing a threshold for the number of read requests, which when exceeded defers the processing of write batches.

Rebuild processing in RAID1 with the BM organization, which is tantamount to copying the contents of the surviving disk on a spare, can be improved by carrying out the rebuild out-of-order, by opportunistic reading of unread tracks, which eliminates seek times [5]. Note that this method is not applicable to RAID5, because of excessive buffer space requirements. Results of an analytic and simulation study using the VSM an PCM methods described in Section 19.4.4.2 without and with opportunistic reading option are reported in [5].

19.6 RAID Reliability Analysis

This section is organized as follows: Section 19.6.1 is a general introduction to reliability analysis. Section 19.6.2 lists expressions for RAID reliabilities. Section 19.6.3 provides the asymptotic reliability analysis of disk arrays emphasizing RAID1. Section 19.6.4 provides an analysis of RAID5 arrays with repair.

19.6.1 General Discussion of Reliability Analysis

From a reliability viewpoint, systems can be classified into two extremes: series and parallel. In the former case, all components are required for the operation of the system, while in the latter case the system is not considered failed as long as one component survives.

Given n components with reliabilities R_i , $1 \leq i \leq n$, we have

$$R_{\text{series}} = \prod_{i=1}^n R_i, \quad R_{\text{parallel}} = 1 - \prod_{i=1}^n (1 - R_i).$$

Each component may be a complex system, whose reliability can be expressed as a function of its subcomponents. The reliability of a system may be specified as a logical expression specifying a minimal configuration for the operation of the system.

Component reliabilities are usually expressed as a function of time. Given the time to failure of the i th component is exponentially distributed with rate δ_i , that is, $R_i(t) = e^{-\delta_i t}$, then the reliability of a series system with n components can be expressed simply using the superposition property of Poisson processes as [123]

$$R_{\text{series}}(t) = \prod_{i=1}^n R_i(t) = \prod_{i=1}^n e^{-\delta_i t} = e^{-\Delta t}, \quad \text{where } \Delta = \sum_{i=1}^n \delta_i.$$

Given that the $\text{MTTF}_{\text{single}} = 1/\delta$, then $\text{MTTF}_{\text{series}} = 1/(n\delta) = \text{MTTF}_{\text{single}}/n$. In the case of a parallel system, the time to failure is the maximum of the times to failure of its components [123]. Given two parallel components with reliabilities $R_i(t) = e^{-\delta_i t}$, $i = 1, 2$ we have

$$R_{\text{par}}(t) = 1 - \prod_{i=1}^2 R_i(t) = e^{-\delta_1 t} + e^{-\delta_2 t} - e^{-(\delta_1 + \delta_2)t},$$

$$\text{MTTF}_2 = \int_{t=0}^{\infty} R_{\text{par}}(t) dt = \frac{1}{\delta_1} + \frac{1}{\delta_2} - \frac{1}{\delta_1 + \delta_2}.$$

For $\delta_1 = \delta_2$ $\text{MTTF}_2 = 1.5/\delta = H_2/\delta$, more generally using the substitution $u = 1 - e^{-\delta t}$ and noting that $\int_0^1 u^{i-1} du = 1/i$ and $du = \delta(1 - u)dt$:

$$\text{MTTF}_n = \int_0^{\infty} [1 - (1 - e^{-\delta t})^n] dt = \frac{1}{\delta} \int_0^1 \frac{1 - u^n}{1 - u} du = \frac{H_n}{\delta}.$$

It is easy to see that incremental increase in reliability decreases rapidly with n .

Most reliability analyses of disk arrays are concerned with disk reliabilities only, although it has been shown in [91] that a significant fraction of disk subsystem failures are due to components other than disks. A possible justification is the assumption that the rest of the systems are equally reliable and the interest is in comparing relative disk reliabilities. A comprehensive study of storage subsystem failure characteristics is reported in [51], which also spreads the blame for data loss to components other than disks.

The Weibull distribution has been determined to provide a good representation for the time to disk failure [27,91]. The exponential distribution is used instead, because of its mathematical tractability, in that it can be incorporated into continuous time Markov chain (CTMC) models [123]. A transient solution of the CTMC provides the time to data loss, which is the passage time from an initial fault-free state to a state where data loss has occurred. Rather than the distribution of time to data loss, most analyses report only the *Mean Time to Data Loss (MTTDL)* as a means of comparing the relative reliabilities of systems (see Section 19.6.4).

It is, however, the reliability of the system during its useful lifetime (t_u), rather than the time to failure that really matters. In a triple modular redundancy (TMR) system at least 2-out-of-3 components

with reliability $r(t)$ are required for the correct operation of the system: $R_{\text{TMR}}(t) = r^3(t) + 3r^2(t)(1 - r(t))$. Given that $r(t) = e^{-\delta t}$ then $\text{MTTF}_{\text{TMR}} = 5/(6\delta)$, which is smaller than the MTTF of a single component: $\text{MTTF}_{\text{single}} = 1/\delta$. Setting $R_{\text{TMR}}(t) = R_{\text{single}}(t)$ yields the crossover point $t_c = \ln(2)/\delta \approx 0.7/\delta$, preceding which $R_{\text{TMR}}(t) > R_{\text{single}}(t)$. The TMR system is preferable to a simplex system provided $t_u \leq t_c$.

The reliability analysis becomes complicated when dealing with nonexponential distributions, such as the Weibull. Estimating the MTDL in RAID5 disk arrays using simulation may be quite costly, as explained below. Consider the simplified case, where data loss occurs when a second disk fails, while rebuild is in progress. This is a rare event since the disk MTTF is much larger than the *Mean Time to Repair (MTTR)* or rebuild time. Given the rarity of this event, very lengthy simulations are required to estimate the MTDL (as reported in [121]). The importance sampling method for dealing with rare events in simulation should be adopted in this case to reduce the simulation cost [73].

19.6.2 Reliability Expressions for RAID Arrays

We use reliability analysis in [108] to compare the reliabilities of various RAID1 organizations. Let r denote the reliability of each disk. The maximum number of disk failures that can be tolerated for a RAID1 with $N = 2M$ disks is $I = M$ in all cases except ID, where it equals the number of clusters $I = c$. The general expression for RAID reliability is as follows:

$$R_{\text{RAID}}(N) = \sum_{i=0}^I A(N, i) r^{N-i} (1-r)^i, \quad (19.3)$$

where $A(N, i)$ is the number of cases out of $\binom{N}{i}$ that i disk failures do not lead to data loss ($A(N, 0) = \binom{N}{0} = 1$):

An interesting special case relevant to storage systems is RAID(4 + k), which does not sustain data loss as long as $N - k$ out of N disks survive:

$$A(N, i) = \binom{N}{i}, \quad 0 \leq i \leq k. \quad (19.4)$$

As far as RAID1 disk arrays are concerned, up to M disk failures can be tolerated by BM, as long as one disk in each pair survives:

$$A(N, i) = \binom{M}{i} 2^i, \quad 0 \leq i \leq M. \quad (19.5)$$

In the case of GRD up to M disks can fail, as long as they are all on one side:

$$A(N, i) = 2 \binom{M}{i}, \quad 0 \leq i \leq M. \quad (19.6)$$

In the case of ID with c clusters and $K = N/c$ disks per cluster, only one disk failure per cluster can be tolerated so that $I = c$:

$$A(N, i) = \binom{c}{i} K^i, \quad 0 \leq i \leq c. \quad (19.7)$$

Data loss in CD is a result of two neighboring disk failures (modulo N). The expression for $A(N, i)$ for CD is derived in [108]:

$$A(N, i) = \binom{N-i-1}{i-1} + \binom{N-i}{i}, \quad 1 \leq i \leq M. \quad (19.8)$$

The behavior of the RAID1 system can be represented by a CTMC, where state \mathcal{S}_i is indexed by the number of failed disks and \mathcal{F} denotes the state with data loss:

$$\begin{aligned} \mathcal{S}_0 &\rightarrow \mathcal{S}_1 \rightarrow \mathcal{S}_2 \rightarrow \dots \rightarrow \mathcal{S}_I \\ \mathcal{S}_i &\rightarrow \mathcal{F}, \quad \text{for } 2 \leq i \leq I. \end{aligned}$$

Starting with the fault-free state: \mathcal{S}_0 , the mean number of visits to \mathcal{S}_i is given as

$$V_i = \frac{A(N, i)}{\binom{N}{i}}, \quad 1 \leq i \leq I. \quad (19.9)$$

Assuming that $r = e^{-\delta t}$, the mean holding time at state \mathcal{S}_i with i failed disks is $h_i = [(N-i)\delta]^{-1}$. The MTTDL is given as

$$\text{MTTDL} = \sum_{i=0}^I V_i h_i = \sum_{i=0}^I \frac{V_i}{(N-i)\delta}. \quad (19.10)$$

The MTTDL can be computed using integration by noting that $R(t) = 1 - F(t)$, where $F(t)$ is the distribution function [123]:

$$\text{MTTDL} = \int_0^{\infty} R_{\text{RAID}}(N) dt = \int_0^{\infty} \sum_{i=0}^I A(N, i) r^{N-i} (1-r)^i dt. \quad (19.11)$$

19.6.3 Approximate Reliability Analysis for RAID

A shortcut method to express the system reliability based on a power series expansion of disk unreliabilities: $\epsilon = 1 - r$ is reported in [102]. For disks with exponential failure rate with MTTF = 10^6 h or 114 years after 3 years $r = e^{-3/114} = 0.975$, so that $\epsilon = 0.025 \ll 1$. The reliability of RAID1 with two disks is: $R_{\text{RAID1}} = 1 - (1 - r)^2 = 1 - \epsilon^2$. Generally, we need to retain the smallest power of ϵ , which represents the probability of data loss with a minimum number of disk failures:

$$R_{\text{RAID}} = 1 - \sum_{i>0} a_i \epsilon^i \approx 1 - a_j \epsilon^j,$$

where j is the minimum i for which $a_i \geq 0$. This term can be interpreted as the probability of data loss with the minimum number of disks:

$$R_{\text{RAID5}} = r^N + N(1-r)r^{N-1} \approx 1 - \frac{N(N-1)}{2}\epsilon^2 + \frac{N(N-1)(N-2)}{3}\epsilon^3 - \dots$$

The approximate reliability equation for RAID(4 + k), $k \geq 1$ can be obtained by induction:

$$R_{\text{RAID}(4+k)} \approx 1 - \binom{N}{k+1}\epsilon^{k+1} + (k+1)\binom{N}{k+2}\epsilon^{k+2} - \dots \tag{19.12}$$

The MTTDL for various RAID1 organizations, but also RAID5/6/7 for systems without repair are given in Table 19.1. It is interesting to note that LSI RAID1 has the highest MTTDL, followed by RAID7, although LSI does not tolerate all three disk failures. We also provide the first term in the series expansion for estimating reliabilities.

19.6.4 RAID5 Reliability Analysis with Repair

The reliability analysis of a storage system may include a repair process, that is, rebuild processing as discussed in detail in Section 19.4.4. In the case of repair on a spare disk, the assumption that an infinite number of spares is available may lead to misleading results. In the case of distributed sparing and restriping the number of rebuilds is constrained by the number of spare areas. RAID7 can tolerate three disk failures, but rather than operating in degraded mode, with an $(i + 1)$ -fold reduction in its throughput in processing read requests it can be restriped into RAID6, RAID5, and RAID0 after each disk failure.

We consider a RAID5 array with N disks, where each disk has an exponentially distributed failure rate δ and an exponentially distributed repair rate μ . The assumption that the repair time is exponentially distributed is justifiable by the fact that as verified by simulation it yields a good approximation to MTTDL. The behavior of the system can be represented by a CTMC with three states: S_n , where $0 \leq n \leq 2$ is the number of failed disks., S_0 is the fault-free state, S_1 is the degraded state, and S_2 is the failed state. The transition $S_1 \rightarrow S_1$ has rate $N\delta$. The transition rate $S_1 \rightarrow S_0$ is μ . which is the inverse of mean rebuild time. Otherwise, we have the transition $S_1 \rightarrow S_2$ with rate $(N - 1)\delta$, which leads to data loss. The probability of a successful rebuild is: $p = \mu/(N - 1)\delta + \mu$, so that the number of successful rebuilds

TABLE 19.1 Summary of MTTDLs and the First Term in Approximate Reliability Expression

RAID5	BM	CD	GRD	ID	RAID6	LSI	RAID7
$\frac{15}{56\delta}$	$\frac{163}{280\delta}$	$\frac{379}{840\delta}$	$\frac{3}{8\delta}$	$\frac{61}{168\delta}$	$\frac{73}{168\delta}$	$\frac{82}{105\delta}$	$\frac{533}{840\delta}$
$0.268\delta^{-1}$	$0.582\delta^{-1}$	$0.451\delta^{-1}$	$0.375\delta^{-1}$	$0.363\delta^{-1}$	$0.435\delta^{-1}$	$0.781\delta^{-1}$	$0.635\delta^{-1}$
$\frac{N(N-1)\epsilon^2}{2}$	$\frac{N\epsilon^2}{2}$	$N\epsilon^2$	$\frac{N(N-1)\epsilon^2}{4}$	$\frac{N(N-c)\epsilon^2}{2c}$	$\frac{N(N-1)(N-2)\epsilon^3}{6}$	$\frac{N\epsilon^3}{2}$	$\frac{N(N-1)(N-2)(N-3)\epsilon^4}{24}$

follows a geometric distribution: $P_n = (1-p)p^{n-1}$ with a mean $\bar{n} = (1-p)^{-1}$. Multiplied by the mean holding time in S_0 we obtain the MTTDL as

$$\text{MTTDL} \approx \frac{(N-1)\delta + \mu}{(N-1)\delta} \times \frac{1}{N\delta} = \frac{(N-1)\delta + \mu}{N\delta^2} \approx \frac{\text{MTTF}^2}{N(N-1)\text{MTTR}}. \quad (19.13)$$

This analysis is extended in [22] to include uncorrectable sector failures with an associated probability P_{uf} :

$$\text{MTTDL} = \frac{(2N-1)\delta + \mu}{N\delta[(N-1)\delta + \mu P_{uf}]} \quad (19.14)$$

Reliability expressions for RAID5 and RAID6 with IDR (intraDisk redundancy) are reported in [22], while the effect of disk scrubbing and IDR on RAID reliability is compared in [48].

19.7 Power Conservation in RAID

Power consumption in disks is mainly due to the 12 V motor for rotating disks, while less power is used by the 5 V electronics. The three states associated with a disk are: Active, Idle, and Standby. Reading and writing to disk is carried out in the Active state. The disk drive continues spinning in the idle state, but significant energy savings are only possible by spinning down the disk to a standby state. According to Table 1 in [21] 15K RPM IBM 36Z15 disks consume 13.5, 10.2, and 2.5 W in the three states, while the IBM 40GNX “mobile” disks consume only 3, 0.85, and 0.25 W in the three states.

Spinning down a disk to a standby state may be counterproductive if the disk does not remain in that state long enough, since spinning up the disks takes significant time and energy, for example, 11 s and 135 W. A timeout strategy is used by OS before spinning down a disk. Power consumption by a disk’s motor is [38]

$$\text{Power} = D^2 \times \text{RPM}^{2.8} \times n,$$

where D is the disk diameter, and n is the number of the platters. Some disk drive models are available with a variable number of platters, with capacities proportional to the number of utilized platter surfaces.

Higher RPMs are required for higher performance by reducing latency for accesses to randomly placed disk blocks by OLTP applications. The power consumption of a SATA and SAS disk drives is compared in Figure 6.3 in [38], where the SAS drive consumes 25 W versus 12 for the SATA drive. The 7200 RPM SATA drives are used for archival storage, while 15,000 RPM SAS drives are used for high-performance storage systems.

Storage devices contribute up to 27% of the total energy consumed in data centers, so that it is important to reduce this power consumption. An early study is massive array of idle disks (MAID), where a small subset of “cache” disks store active files, while the remaining disks are on standby [17].

The Hybernator system takes advantage of Sony’s multispeed disks, which can save more energy (29%) than previous solutions, while still providing a txn throughput for OLTP comparable to a RAID5 array with no energy management [134]. Variable speed disks are, however, not widely available.

Write off-loading redirects requests to spun-down disks to NVS [70]. This study shows a 28%–36% reduction in power consumption by spindown, which increases to 45%–60% with write off-loading.

It is argued in [96] that tape-based archival systems suffer from poor performance due to sequential nature of data access, while most disk systems are unsuited for long-term archival storage, because of their high energy demands. Pergamum is motivated by MAID, but in addition adds NVRAM at each

node to store data signatures, metadata, etc. to allow deferred writes. Pergamum uses both IDR and inter-disk redundancy to guard against data loss and staggered rebuild to reduce peak energy usage, while rebuilding large redundancy stripes.

A recent study of practical power proportionality in storage systems addresses read and write availability, no performance degradation, consistency, and fault tolerance for general I/O workloads [98]. The power-aware layout used is a tradeoff between load balancing, rebuild parallelism, and power savings. A distributed virtual log is used to absorb updates to replicas. Recovery and migration techniques, and predictive gear scheduling are adopted. A large, real service (Hotmail) on a cluster shows power savings of 23%, but savings of 40%–50% are possible with more complex optimizations.

The issue of power consumption is currently addressed in the broader context of Green Computing, which is outside the scope of this discussion.

19.8 Miscellaneous RAID Arrays

The three topics discussed in this section are Grid codes in Section 19.8.1, *Hierarchical RAID (HRAID)* in Section 19.8.2, and *Heterogeneous Disk Arrays (HDAs)* in Section 19.8.3.

19.8.1 Grid Codes

Grid codes use coding in two dimensions to protect strips arranged in this manner to attain a higher reliability [59]. In two dimensions, there are two sets of erasure codes: Horizontal (H) and Vertical (V) codes or HVPC codes [59]. In the simplest case with the single parity code (SPC) over k_2 columns and k_1 rows we have

$$P_{i,*} = D_{i,0} \oplus D_{i,1} \oplus \dots \oplus D_{i,k_2-1}, \quad i = 0, 1, \dots, k_1 - 1;$$

$$P_{*,j} = D_{0,j} \oplus D_{1,j} \oplus \dots \oplus D_{k_1-1,j}, \quad j = 0, 1, \dots, k_2 - 1.$$

The diagonal parity $P_{i,*} = \bigoplus_{i=0}^{k_2-1} P_{i,*} = \bigoplus_{i=0}^{k_1-1} P_{i,*}$. Note that the parities constitute an extra row and column.

Given that H and V codes can protect against K and L strip failures, all $(K + 1)(L + 1) - 1$ strip failures can be tolerated. In other words, $t = (K + 1)(L + 1)$ is the lowest number of strip failures that will lead to data loss. For $K = L = 1$ data loss occurs if the four strips constitute a rectangle.

SPC and X-code [133] are two codes that can be utilized vertically, but X-codes have the limitation that the number of strips and hence the associated number of disks should be prime. Relevant horizontal codes are SPC, which is tantamount to RAID5, EO, and STAR (an extension of EO) [45], which can tolerate single, double, and triple disk failures, respectively. The two-dimensional GRID codes listed in [59] are summarized in Table 19.2. Since $k_1 = k_2$ needs to be a prime number for the X-code, we have modified the example in [59], so that instead of $k_1 = k_2 = 10$ we use $k_1 = k_2 = 11$ with the total number of strips: $d = k_1 \times k_2 = 121$. Then the redundancy ratio is the number of check strips divided by d .

The level of redundancy is quite significant, on the other hand higher levels of redundancy are to be expected.

19.8.2 Hierarchical RAID (HRAID)

It has been observed in [91] that the failure of components other than disks is a significant contributor to system failures and possibly data loss. Hierarchical RAID (HRAID) addresses whole storage node (SN) failures, as well as individual disk failures at each node [120]. The study has a similarity to [82], which is based on IBM's Collective Intelligent Bricks project [126]. There are N SNs and M disks per SN. The disks at

TABLE 19.2 Maximum Number of Failures (t) and the Redundancy Percent ($r\%$) Associated with Miscellaneous Grid Codes

Codes	t	Redundancy Ratio ($r\%$)

FIGURE 19.7 HRAID1/1 with $N = 4$ nodes and $M = 4$ disks per node.

a node are RAID level 0, 5, 6, or 7. The same RAID levels are considered at the internode level. An HRAID with redundancy level k and ℓ at the internode and internode level is specified as HRAID k/ℓ . Figure 19.7 depicts the first four rows in HRAID1/1 with $N = 4$ SNs and $M = 4$ disks per SN, which utilizes a single parity P at the intra-node level and a single parity Q at the intra-node level ($k = \ell = 1$). Internode Q parities protect data strips at other nodes, while intranode P parities protect local data and Q parity strips at that SN.

To update data block $d_{4,1}^2$ in strip $D_{4,1}^2$, with $d_{4,1}^{2\text{new}}$, we have the following steps: (1) Read $d_{4,1}^{2\text{old}}$; (2) Compute the difference $d_{4,1}^{2\text{diff}} = d_{4,1}^{2\text{new}} \oplus d_{4,1}^{2\text{old}}$ and write $d_{4,1}^{2\text{new}}$; (3) Read $p_{4,3}^{2\text{old}}$ and update it: $p_{4,3}^{2\text{new}} = p_{4,3}^{2\text{old}} \oplus d_{4,1}^{2\text{diff}}$, write $p_{4,3}^{2\text{new}}$; (4) Send $d_{4,1}^{2\text{diff}}$ to Node 1, Read $q_{4,1}^{1\text{old}}$ and $p_{4,4}^{1\text{old}}$ and update them: $q_{4,1}^{1\text{new}} = q_{4,1}^{1\text{old}} \oplus d_{4,1}^{2\text{diff}}$, $p_{4,4}^{1\text{new}} = p_{4,4}^{1\text{old}} \oplus q_{4,1}^{1\text{diff}}$. Generally, HRAID k/ℓ requires $(k + 1)(\ell + 1)$ reads if the old data and check blocks are not cached and $(k + 1)(\ell + 1)$ writes to update a data block.

The minimum number of disk failures that can be tolerated by HRAID k/ℓ is: $d_{\min} = (k + 1)(\ell + 1) - 1$ and the maximum number $d_{\max} = N\ell + (M - \ell)k$ or $d_{\max} = N(k + \ell) - k\ell$ for $N = M$. For $N = M$ $k + \ell$ disk per node or $N(k + \ell)$ disks for the HRAID array are dedicated to check codes. Since at most d_{\min} disk failures are tolerated, it follows that the coding in HRAID(k/ℓ) is not MDS.

The failure of the controller at an SN makes the disks controlled by it inaccessible. We consider three options for HRAID recovery. With Option I nodes operate independently and given that each node is an ℓ DFT, data loss occurs if there are more than ℓ failed disks at the SN or the controller fails. With Option II internode recovery is allowed, so that the contents of failed disks, which are unrecoverable at the node level can be reconstructed via internode recovery. Rebuild processing is carried out via restriping both at disk and SN level. Option III does not carry out rebuild processing and instead carries out on demand multistep recovery.

19.8.3 Heterogeneous Disk Arrays (HDAs)

RAID level selection, most importantly RAID1 versus RAID5, was a difficult issue to resolve for early RAID users. RAID1 is suitable for high-performance OLTP applications, because it provides twice the access bandwidth for read requests. RAID5 provides the access parallelism required for high volumes of data accessed by data mining and decision support applications. AutoRAID developed by HP, which

uses RAID1 as a cache to a RAID5 array at the lower level, was proposed as a solution to the RAID selection problem [127]. AutoRAID data is initially held with the space-inefficient RAID1 format, but when storage space is exhausted the system converts the less frequently used storage segments to RAID5/LSA format (see Section 19.4). The fact that RAID5/LSA introduces less load than RAID1 in dealing with large writes is used as the RAID level selection criterion in [116].

There was significant activity in the area of data allocation in storage systems at HP Labs, which led to the *Disk Array Designer (DAD)* [3]. IBM provisioning planners for storage allocation involve determining the number, size, and location of volumes with attention to access paths to meet performance requirements [10]. Disaster recovery is another aspect of the overall process. Introducing a new application into a data center is a complex task, which is however assisted by monitoring tools provided by IBM and EMC. These tools monitor SAN (storage area network) components to determine its configuration and performance. The volume planner takes new workloads space and performance requirements (I/O demand, R/W ratio, response time) and provides a recommendation. These information is used to determine disk utilizations. The selection process' configuration phase selects storage pools, which can potentially hold the new data. The load balancing phase uses a volume allocation algorithm, rather than using first-fit, best-fit, or worst-fit. The path planner determines paths to connect the volumes to the hosts. The zone planner restricts the connectivity to ensure security.

The Panasas *Parallel File System (PFS)* stripes files across *objects*, which are stored according to the RAID1 or RAID5 paradigm. Small files are stored as RAID1 and large files as RAID5, since they provide more parallelism for data access [125]. Note similarity to EMC's Centera file system for reliable storage of fixed content.* Four advantages associated with PFS are: (i) Scalable computing of parities for the files by clients. (ii) Capability for end-to-end data integrity checking. (iii) Parallel rebuild capability for files. (iv) Unrecoverable faults are restricted to individual files. The initial data placement is random. Passive balancing is used to place new data into empty nodes, while active balancing moves objects from node to node to eliminate hotspots.

In [117], we consider the allocation of *Virtual Arrays (VAs)* with different RAID levels in *Heterogeneous Disk Arrays (HDAs)*. HDAs are expected to providing cost savings by consolidating multiple disk arrays. The number of *Virtual Disks (VDs)* required to materialize a VA is determined by upper limits on VD bandwidth and space per physical disk drive in normal operating mode. The synthetic stream of allocation requests for VDs is used by a single-pass data allocation methods for HDA. The allocations are carried out in degraded mode, so that disk loads are not exceeded due to a single disk failure. Only 1DFT RAID1 and RAID5 arrays and single disk failures are considered in the simulation study, but we develop the analytic expressions for allocating other RAID levels. A VA allocation is successful if disks sharing VAs with a failed disk are not overloaded in degraded mode. Experimental results show that allocation methods minimizing the maximum disk bandwidth and capacity utilization or their variance across all disks yield the maximum number of allocated VAs. When the disk bandwidth is the bottleneck resource, the clustered RAID5 paradigm may be adopted to increase the number of allocated VAs (see Section 19.4.2).

19.9 Storage Area Network and Network Attached Storage

A storage area network (SAN) is defined as a set of disk drives connected by a network: a SCSI bus, an Ethernet switch, or a peer-to-peer network, where the disk drives are associated with cooperating servers. Requirements for SANs listed in [86] are summarized in the following:

1. *Space and access balance.* The requirement to store additional data is growing rapidly. Given that disk capacity is cheap, the storage capacity of the network can be easily expanded. There is a need to allocate data carefully to utilize disk capacities and balance their utilizations. This can be accomplished by striping and randomizing [87]. There is also the issue of data reorganization

* <http://www.emc.com/products/family/emc-centera-family.htm>.

to accommodate increased data volumes, larger capacity disks, etc. Given the characteristics of the disk system and the access rates of files, a nearly optimal assignment of files to disks is sought to optimize performance metrics, such as the mean disk response time [130]. Without such an optimized allocation, disks are susceptible to access skew.

2. *Availability.* High data availability can be attained by mirroring or erasure coding. The latter, which provides a much higher storage efficiency, has been adopted by the Zebra distributed file system based on the RAID5/LSA concept [37]. Data from various clients is combined into a single stream, which is written as one stripe, so that the parity strip is computed on the fly.
3. *Resource efficiency.* Higher availability implies wasted disk capacity in the form of check disks and replicated data. This overhead should be quantified against higher performance and availability.
4. *Access efficiency.* This is determined by the time and space requirements to access the data.
5. *Heterogeneity.* New disk drives, possibly with higher capacities, should be introduced with as little disruption as possible. It is not economically viable to replace all old disks with new disks, just for the sake of maintaining homogeneity. RAID5 data layout becomes more complicated with heterogeneous disks: variable stripe sizes and disk load imbalance for updating parity. Solutions to these and other problems are discussed in [19].
6. *Adaptivity.* This is a measure of how fast can the system adapt to increases in the data volume and the addition of more disk capacity. More specifically, a fraction of the existing data must be redistributed, and the efficiency of this process is called adaptivity. The faithfulness property is to balance disk capacity utilizations, so that given m data units and that the i th disk has a fraction d_i of the total capacity, then this disk's share of the data is $(d_i + \epsilon)m$, where ϵ is a small value. The issue of access bandwidth should also be taken into consideration. A relevant study is [94], which poses the disk replacement problem (DRP), that is, minimizing the cost of migrating data following disk additions and removals.
7. *Locality.* This is a measure of the degree of communication required for accessing data.

Network attached storage (NAS) as opposed to direct attached storage (DAS) embeds the file system into storage, while a SAN does not [28]. Four typical NAS systems described in [86] are as follows:

- Storage appliances such as products from *Network Appliance (NetApp)* and SNAP.*
- *Network Attached Secure Devices (NASD)* project at CMU's *Parallel Data Laboratory (PDL)* [29].†
- The goal of the Petal project is to provide easily expandable storage with a block interface [57]. Incidentally, Petal adopts the CD mirroring data layout (see Section 19.5.1).
- The *Internet SCSI (iSCSI)* protocol, which implements the SCSI protocol on top of TCP/IP [88].

19.10 Data Deduplication

Data deduplication is an attempt to reduce wasted storage due to perceived high levels of redundancy in data storage systems. For example, the email server in a large company may hold thousands of copies of the same report sent to all of its employees as an attachment. Deduplication is known as intelligent compression, single-instance storage, data reduction, and capacity optimized storage, replaces the multiple copies to a pointer to a single copy. The need for deduplication could have been alleviated by sending a pointer to the message to start with. Data Domain, now part of EMC, introduced data deduplication software in 2004. Proprietary implementations of data deduplication for Data Domain and Symantec are reported in [135] and [34], respectively.

* <http://www.netapp.com>.

† <http://www.pdl.cmu.edu/NASD/index.shtml>.

Data deduplication is data compression at a coarse granularity, for example, files or blocks. Deduplication at a finer granularity may identify duplicates, which do not exist at a coarser level, as in the case of a lengthy files with minor modifications. File compression methods such as Lempel-Ziv [129], which remove short repeated strings result in a limited compression ratio, while deduplication tends to result in significant reduction in storage space requirements. There is an indirect reduction in power consumption, since fewer disks are required to store the data.

Cryptographic hash functions are applied to determine if two chunks of data are identical. There is a negligibly small possibility that the chunks are not identical due to the *pigeon hole principle*:* The *Secure Hashing Algorithm (SHA)*-1 returns a 20 byte hash value, and is more reliable than the earlier *Message Digest (MD)*-5, which returns 16 bytes. Data deduplication performance can be improved by first applying a weak hash function, followed by a strong hash function to attain a higher confidence. Some systems ascertain that two chunks are identical by a bit by bit comparison.

There have been several performance comparisons of deduplication implementations, with daily backup capacity (TB/day) as perhaps the most important single metric.†

19.11 Solid State Disks (SSDs)

Target specifications for an SCMs based on [25] are: Access time: 50–1000 nanoseconds (ns), Data rate: 100 MB/s, Endurance: 10^9 – 10^{12} cycles, Error rate per TB: 10^{-4} , mean time between failures (MTBF): 2 million hours, Data retention: 10 years, ON/standby power: 100/1 milliwatt (mW), Cost: \$5 per GB, CAGR: 35%.

In what follows, we discuss the more popular NAND flash memories, as opposed to NOR flash, which are used to store code. The smallest unit of writing into a NAND-based flash storage is a 4 KB page. Before a page is written all its bits need to be set to one. This is done at the level of blocks, which are usually much larger than pages, Table II in [21] provides the characteristics of five typical flash memories, but more comprehensive data is provided in [33].

The two varieties of flash SSDs are single-level cell (SLC) and multi-level cell (MLC), where the former stores 1 bit per cell, while the latter stores multiple bits per cell, providing more storage capacity at a higher cost.

Design tradeoffs for flash memories are considered in [1]. A 4 GB Samsung NAND flash is used as an example in this paper (see Figure 1 and Table 1). There are two 2 GB dies packaged together. Data is organized as 256K blocks of thirty-two 4 KB pages. It takes 25 microseconds (μ s) to read from a register or write to it. Block erase is a slow operation and takes 1.5 milliseconds (ms). It takes 100 μ s to transfer a 4 KB page from an on-chip register. Pipelining the two operations leads to 40 MB/s. Writes take 100 μ s per page for transfer time and 200 μ s programming time. Given that there are two dies per chip these operations can be interleaved.

Writes cannot be performed in place in NAND flash and for higher efficiency should be performed in large chunks. Writes are carried out onto individual 4 KB pages from allocation pools, which may be an allocation plane or larger. Writing can only be carried out after the associated block is cleared, so that we maintain a free block list in each allocation pool.

Given that modified blocks in database applications are overwritten, it is advisable to hold such blocks in DRAM buffers or even HDDs, which act as caches for the flash memory. There are techniques to increase the lifespan of flash memories by enhancing the flash translation layer (FTL), which provides virtual to physical address translation. Since update in place is not possible, FTL implements updating out-of-place using an already erased page.

* http://en.wikipedia.org/wiki/Pigeonhole_principle.

† http://wikibon.org/wiki/v/Wikibon_Data_De-duplication_Performance_Tables.

A difficulty associated with FTL is the size of the SRAM cache, which stores the mapping table, for example, 32 MB cache is required for a 16 GB flash to map at the page level. Block-level mapping is costly due to wasted space and performance degradation due to garbage collection. A hybrid approach is used: data blocks are mapped at the block level, while the smaller number of update blocks are mapped at the page level. It is argued in [35] that this scheme suffers from poor garbage collection behavior, requires several workload specific tuning parameters, and does not exploit the temporal locality of most workloads. Four state-of-the-art FTLs are described in this paper and compared to *Demand-based FTL (DFTL)* proposed in this work.

Many existing approaches on flash-memory management are based on RAM-resident tables in which one single granularity size is used for both address translation and space management. As high-capacity flash memory is becoming more affordable than ever, the dilemma of how to manage the RAM space or how to improve the access performance is emerging for many vendors. A tree-based management scheme, which adopts multiple granularities in flash-memory management is proposed in [13], with the objective of not only reducing the run-time RAM footprint, but also managing the write workload, due to housekeeping. The proposed method was evaluated under realistic workloads, where significant advantages over existing approaches were observed, in terms of the RAM space, access performance, and flash-memory lifetime.

A *Fast Array of Wimpy Nodes (FAWN)* is an array of low power processors with local flash memories providing efficient parallel access to data [4]. FAWN provides an efficient implementation for Amazon's Dynamo key-storage system, which represents the key and the actual data in a key-value relationship. FAWN consists of frontend and backend nodes, for example, 80 versus 10,000 nodes. Each frontend is responsible for a range of keys and directs a query to the appropriate backend.

HyStor integrates low-cost HDDs and the more expensive SSDs into a single layer block storage, so that no modifications are required to OS [16]. Blocks have a LBN on HDD and some of the blocks may be cached at the SDD, which is an order of magnitude smaller. The SDD has a remap and a writeback area, the latter area simply holds dirty blocks, while the former area is holds high-value, frequently accessed data blocks.

We are mainly interested in flash memories as a replacement for HDDs, which as SSDs are attractive from the viewpoint of speed, power consumption, and reliability. Flash memories are orders of magnitude more expensive than HDDs, and have a finite number of *Program/Erase (P/E)* cycles. Flash memories (32 GB, 64 GB, and 128 GB) have been introduced with R/W rates of 1400/2500 MB per second have been attained. While in recent years flash-based SSDs have grown enormously, both in capacity and popularity, their adoption in high-performance enterprise storage applications depends on exceeding disk performance, while closing the gap in cost per GB [33]. Although, the latter is becoming a reality, with increasing flash densities, flash reliability, and performance are declining. High-capacity and high-performance flash-based SSDs are not reliable enough to justify their cost in enterprise environments. The conclusions of this study are based on 45 flash chips from 6 manufacturers indicating that: "SSD manufacturers and users will face a tough choice in trading off between cost, performance, capacity and reliability."

We conclude the discussion of flash memories with two techniques to increase their reliability.

19.11.1 Differential RAID for Flash Memories

Diff-RAID is an unconventional RAID array whose design takes into account the fact that flash memories have very different failure characteristics from HDDs, that is, the *Bit Error Rate (BER)* of an SSD increases with more writes [6]. RAID arrays composed from SSDs are subject to correlated failures. By balancing writes evenly across the array, RAID schemes can wear out devices at similar rates, making the RAID susceptible to data loss. Diff-RAID reshuffles the parity distribution on each drive replacement to maintain an age differential when old devices are replaced by new ones. A simulator to evaluate Diff-RAID's reliability by using BERs from 12 flash chips showed that it is more reliable than RAID5 by orders of magnitude.

For MLC technology, the number of erasures is limited to 5,000–10,000 cycles per block. Diff-RAID differs significantly from RAID5 arrays on HDD in that it attains a higher reliability by distributing parity blocks *unevenly* [6]. Diff-RAID masks higher BERs on aging SSDs while: (1) Retaining the low overhead of RAID5; (2) extending the lifetime of commodity SSDs; (3) alleviating the need for expensive error correction hardware.

Load balancing can cause correlated failures, since with balanced writes all SSDs will be susceptible to failure when an SSD fails. Consider $n = 5$ SDDs with 80% of parity allocated on the first SDD and the rest of parities evenly distributed across remaining SDDs, so that we have the following configuration (80,5,5,5,5). After the first disk reaches its limit, it is replaced by the second SSD. Denoting the percentage of parity blocks on the i th and j th device by p_i and p_j , the aging rate of the two devices are

$$a_{i,j} = \frac{p_i(n-1) + (100 - p_i)}{p_j(n-1) + (100 - p_j)}$$

For example, for $n = 4$ and (70,10,10,10) the aging rate of the first device is twice that of the others. For $n = 5$ and with (80,5,5,5,5), after numerous replacements the ages of remaining devices at replacement time converge to (5750,4312.5,2875,1437.5). The implementation of device replacement can be accomplished via rebuild processing, while maintaining the same parity layout. The reduction in data loss probability, as given by Figures 6 and 8 in the paper, is significant.

19.11.2 Partial MDS Coding for SSDs

The *Partial MDS (PMDS)* method was developed in [9] to deal with sector failures in SSDs, since they are more prevalent than HDD sector failures. The sector is the data storage unit protected by a cyclic error correcting code (ECC) such as BCH.* Applying RS codes as in RAID6 is not appropriate for two reasons: (i) too expensive to dedicate an extra SSD to parity to handle sectors errors; (ii) RAID6 cannot handle more than two erased errors.

PMDS similarly to [47] relies on local and global parities, but is more complicated and does not require special consideration for parities being erased. Given an $m \times n$ array of sectors r erasures can be corrected in a horizontal row. As in the case of the EVENODD code $m = n - 1$ and that n should be prime, although this limitation can be easily circumvented [8]. If r columns are erased, an additional s global parities allow correcting s extra erasures. In the case $r = 1$ and $s = 2$ shown in Figure 19.8, necessary and sufficient conditions for finding codes and tables of codes are given in the paper. The r local parities can efficiently deal with failed sectors in a row and the extra s parities are invoked in rare occasions. Given six check sectors as many failed sectors can be corrected, say 4 sectors in a column and two other failed sectors.

In Figure 19.8, $a_{0,4}$, $a_{1,4}$, $a_{2,4}$, $a_{3,4}$ are the four local parities, and $a_{3,2}$ and $a_{3,3}$ placed somewhat arbitrarily are the global parities.† To simplify the notation, we superimpose a one-dimensional vector b_i , $0 \leq i \leq 19$,

$a_{0,0}$	$a_{0,1}$	$a_{0,2}$	$a_{0,3}$	$a_{0,4}$
$a_{1,0}$	$a_{1,1}$	$a_{1,2}$	$a_{1,3}$	$a_{1,4}$
$a_{2,0}$	$a_{2,1}$	$a_{2,2}$	$a_{2,3}$	$a_{2,4}$
$a_{3,0}$	$a_{3,1}$	$a_{3,2}$	$a_{3,3}$	$a_{3,4}$

FIGURE 19.8 Layout of the local and global parities for partial MDS with $r = 1$ and $s = 2$, The four local parities are $a_{i,4} = p_i$, $0 \leq i \leq 3$ and $a_{3,2} = g_1$ and $a_{3,3} = g_2$ are the global parities.

* http://en.wikipedia.org/wiki/BCH_code.

† The following discussion is partially based on Mario Blaum's presentation at Stanford University in July 2012.

which covers the blocks in Figure 19.8 one row at a time. The $m \times n$ codeword should satisfy the following six equations, with the first four for local parities and the last two for global parities:

$$S_j = b_{4j+0} \oplus b_{4j+1} \oplus b_{4j+2} \oplus b_{4j+3} = 0, \quad 0 \leq j \leq 3. \quad S_4 = \sum_{i=0}^{19} \alpha^i b_i \quad S_5 = \sum_{i=0}^{19} \alpha^{2i} b_i.$$

Given that disk two and two random blocks have failed, we designate them as $a_{0,2} = u$, $a_{1,2} = y$, $a_{2,2} = v$, $a_{3,2} = w$, and $a_{1,0} = x$, and $a_{1,3} = z$. The unknowns u , v , and w can be determined by using local parities: S_0 , S_2 , and S_3), while the following three equations can be used to determine x , y , and z :

$$x \oplus y \oplus z = S_1, \quad \alpha^5 x \oplus \alpha^7 y \oplus \alpha^8 z = S_4, \quad \alpha^{10} x \oplus \alpha^{14} y \oplus \alpha^{16} z = S_5.$$

The set of linear equations has a unique solution provided the determinant of the matrix A defined in the following is not zero:

$$\mathcal{A} = \begin{pmatrix} 1 & 1 & 1 \\ \alpha^5 & \alpha^7 & \alpha^8 \\ \alpha^{10} & \alpha^{14} & \alpha^{16} \end{pmatrix}$$

\mathcal{A} is a Vandermonde matrix since powers of α in its rows are different [75], so that $\det(\mathcal{A}) \neq 0$ allowing x , y , and z to be determined.

As a second example, consider two sector errors: $x = a_{1,0}$ and $y = a_{3,1}$ and a failed SSD $u = a_{0,2}$, $z = a_{1,2}$, $v = a_{2,2}$, $w = a_{3,2}$. The values of u and v can be obtained using S_0 and S_2 . We have the additional four equations:

$$x \oplus z = S_1, \quad y \oplus w = S_3, \quad \alpha^5 x \oplus \alpha^7 z \oplus \alpha^{16} y \oplus \alpha^{17} w = S_4, \quad \alpha^{10} x \oplus \alpha^{14} z \oplus \alpha^{32} y \oplus \alpha^{34} w = S_5$$

This system has a unique solution since the determinant is nonzero. A general condition is given by Theorem 4.1 for the necessary and sufficient conditions for the case of RAID5 (single global parity with $r = 1$); plus s global parities). In the special case of $s = 2$ Theorem 5.1 states that the code is PMDS depending on m , n , and the polynomial $f(x)$ defining the underlying field or ring. This polynomial $f(x)$ is not necessarily primitive,* but has a certain exponent, which has to exceed $m \times n$. For example for $f(x) = M_p(x) = 1 + x + x^2 + \dots + x^{p-1}$, the polynomial has a prime exponent p , so that $m \times n$ should be smaller than p . Using Equation 16 in [9] a search is made for different parameters to obtain Table 19.1. The table is not extensive and does not consider all possible irreducible polynomials, but it gives a good idea.

19.12 Conclusions

In spite of the frequently used term “secondary storage,” with main memory being the primary storage, secondary storage in the form of magnetic HDDs provides permanent storage for data. Unlike main memories, which are based on DRAM technology, HDDs are unaffected by occasional power outages and are made immune to rare disk failures using coding methods or replication. There are the additional levels of redundancy, such as replicated sites to protect against software errors, catastrophic failures (earthquakes, fires, floods, wars).

* [http://en.wikipedia.org/wiki/Primitive_polynomial_\(field_theory\)](http://en.wikipedia.org/wiki/Primitive_polynomial_(field_theory)).

High-performance enterprise storage systems are used by applications such as OLTP, which incur high disk arm positioning time. Large-scale archival systems tend to have much higher capacities, but lower performance than enterprise drives. The recent indications are that while flash memories are not suitable replacements for HDDs, they may serve as cache storage with respect to HDDs, in what has been referred to as hybrid storage. According to [11] at least 10 SCMs are under consideration for this purpose.

We have discussed reliable storage systems based on erasure encoding, such as RAID5 and RAID6, and replication. In both cases, we discuss the issue of improving performance in normal, degraded, and rebuild mode of operations.

It is worthwhile to mention that it is easier to deal with erasures (broken disks) and unreadable sectors, than when the wrong data is read from disk or overwrites the wrong sectors. Higher level applications are separated from data being read/written to/from SSDs and HDDs, by many layers of software which complicates the issue of error detection. The narrow and well-defined interface to disk disallows the propagation writing of erroneous data, while faulty software may more easily destroy the contents of SSDs.

There is sufficient material in this chapter to serve as a full semester graduate course on storage systems, supplemented with appropriate reading material from the references.

Glossary

BIBD: Balanced Incomplete Block Design. A data layout method for clustered RAID, which has its origin in combinatorial mathematics and has been applied to design of experiments in statistics.

Clustered RAID (CRAID): A data layout to reduce the increase in disk load when operating in degraded mode, for example, one failed disk in RAID5.

Cryptographic Hash Functions: These are applied as part of data deduplication to determine if two chunks of data are identical. The *Secure Hashing Algorithm (SHA)*-1 returns a 20 byte hash value, and is more reliable than *Message Digest (MD)*-5, which returns 16 bytes. Data deduplication performance can be improved by first applying a weak hash function, followed by a stronger hash function to attain a higher confidence.

DAS: Direct Attached Storage has files directly accessible by a computer, rather than file servers attached to a network.

Dedicated/Distributed Sparing: A hot spare is provided in the case of dedicated sparing, which may be shared among several arrays. Sufficient spare capacity is provided at $N - 1$ out of N disks, to hold the data and parity blocks of a failed disk. Advantage with respect to dedicated sparing is that the bandwidth of the spare disk is not wasted.

Deduplication: Substituting duplicates with pointer to a single shared copy. Hash function are used to determine duplicates. Also known as intelligent compression, single instance storage, data reduction, and capacity optimized storage.

DRAM/SRAM: DRAM is more dense than SRAM and is used in main memories, but SRAM which is faster and more expensive per GB than DRAM is used in main memories.

ECKD: Extended count-key-data (CKD) is a format associated with IBM mainframes, starting with IBM S/360 series in 1960s. The IBM OS/390 or z/OS operates on ECKD disks such as 3990 and disk array controller (DAC) serves the role of simulating ECKD disks on disks with a fixed block architecture (FBA).

EVENODD (EO): Uses a horizontal and a diagonal parity to protect against two disk failure, hence more efficient code than RS for RAID6.

Freeblock Scheduling (FS): A proposal to utilize opportunistic disk accesses as the arm moves in processing regular requests to carry out other tasks. The goal of FS to maximize the efficiency of background processing.

- Grid Codes:** A combination of horizontal and vertical check codes protect against data strip failures in two dimensions.
- HDA:** Heterogeneous disk array allows the sharing of disk space among multiple virtual arrays with different levels.
- HDD:** Hard disk drive as opposed to floppy disk drive, which became popular in conjunction with personal computers.
- HRAID k/ℓ :** Hierarchical RAID uses two levels of erasure coding to tolerate k node failures and ℓ disk failures per node.
- IDR:** IntraDisk Redundancy a RAID paradigm at the level of disk blocks to deal with LSEs. IDR has been referred to as a vertical code in trade literature.
- k DFT:** k Disk Failure tolerant. RAID1 disk arrays are 1DFT, LSI RAID is 2DFT, and RAID($4 + k$), $k \geq 1$ arrays are k DFT.
- LFS:** Log-structured file system is a scheme to improve write efficiency, by buffering modified files and writing them out sequentially in large chunks.
- LSA:** Log-structured arrays extend the LFS concept to RAID5/6. Full stripe writes are utilized in writing out batches of modified files. Data compression is possible because data is not written in place.
- LSE:** Latent sector error, which are unreadable and are the main cause of unsuccessful rebuilds.
- MAID:** Massive array of idle disks, where a small fraction of disks which hold active data remain online.
- MB/GB/TB:** Kilo/mega/giga/tera-byte, which are 10^3 , 10^6 , 10^9 , 10^{12} bytes, respectively. These are followed by petabyte (10^{15}), exabyte (10^{18}), zettabyte (10^{21}), and yottabyte (10^{24}).
- MDS:** Maximum distance separable codes introduce the minimum level of redundancy for erasure coding, such that it is known which disk has failed. EO, RDP, and X-code in addition to Reed-Solomon codes are examples of MDS codes.
- MTBF/MTTF/MTTDL:** Mean time between failures/mean time to failure/mean time to data loss. MTBF implies that the failed component is repaired, but repair in the context of disk arrays implies the copying of a failed disk on a spare.
- NAS:** Network attached storage relies on a specialized computers, that is, network file system (NFS) for storing and serving files.
- NVRAM/NVS:** Non-volatile DRAM or storage. Nonvolatility is attained by backup batteries
- Off/Near/Online Storage:** Offline storage is a tape archive. Nearline storage is an automated tape library. Online storage is usually a SATA drive.
- Parity Sparing:** Combining two RAID5 arrays into one, by utilizing the parity strips of one of two arrays with the strips of the failed disk.
- Parity Striping:** A RAID5 data layout where data blocks are placed sequentially (without striping), but $1/N$ of the capacity of each disk is dedicated to parity blocks. In effect placing RAID5's parity strips on all disks horizontally, following $1 - 1/N$ of the space at each disk dedicated to data. Advantage that large chunks of the user data can be accessed efficiently without disruption.
- Prefailure/Postfailure Replacement:** The former can be carried out efficiently by utilizing Self-Monitoring Analysis and Reporting Technology (SMART),* so that the contents of a disk about to fail are copied, without incurring the usual rebuild process or postfailure replacement.
- Primary/Secondary/Tertiary Storage:** These refer to main memory, disk, and tape storage, respectively.
- Partial MDS (PMDS) Codes:** PMDS codes were developed for SDDs where hard sector errors are more common than in the case of HDDs. In an $m \times n$ array with $r = 1$ and $s = 2$, there is a single parity per row and $s = 2$ global parities. More general cases are considered in [9], while local reconstruction codes (LRCs) consider this special case.
- Pyramid Codes:** In RAID($4 + k$), $k > 1$ have the lowest order check strip, which is a parity, duplicated, such that each parity covers half of the disks in the array.

* <http://en.wikipedia.org/wiki/S.M.A.R.T.>

- RAID:** Redundant array of independent disks has seven levels: 0:6. RAID0 does not tolerate disk failures, RAID1 corresponds to mirrored disks, and RAID(4 + k), $k \geq 1$ are kDFT arrays, so that RAID7 tolerates three disk failures.
- RAID1:** Mirrored disks have different data organizations. A more balanced load following disk failures is attainable by spreading the data of each disk over multiple disks, rather than one in basic mirroring, but this increases the chances of data loss when more disk failures occur. *Basic Mirroring (BM)*, *Group Rotate Declustering (GRD)*, *Interleaved Declustering (ID)*, and *Chained Declustering (CD)* are better known RAID1 organizations, while LSI RAID and SSPiRAL combine mirroring and parity coding.
- ReConstruct Write (RCW):** RCW reads the remaining strips in a stripe to compute and write check blocks.
- Read-modify-write (RMW):** RMW reads, modifies, and overwrites a disk block after a disk rotation. When the modification (an XOR) is done by the DAC, we have a single read followed by a single write.
- Rebuild in RAID5:** Postfailure rebuild is the systematic reconstruction of the contents of a failed disk in the form of rebuild units on a spare disk. See also prefailure replacement.
- RDP:** Rotated Diagonal Parity is a slight improvement on EO, developed at NetApp.
- Reed-Solomon (RS) Code:** An MDS code which is more expensive to implement than parity based codes such as EO and RDP, since it requires Galois field finite arithmetic.
- Restripping:** With successive disk failures in a RAID(4 + K) array with $k > 1$, its check strips are overwritten with the strips of the failed disk.
- RM2:** A nonMDS 2DFT code with adjustable redundancy $p = 1/M$, so that one parity stripe per $M - 1$ data strips. Each data strip participates in two parity groups with $2M - 1$ strips and is hence a 2DFT but not MDS.
- SAN:** A Storage Area Network is a dedicated network that provides access to consolidated, block level data storage. Devices attached to SAN appear as if they are locally attached.
- SAS:** Serial Attached SCSI.
- SATA:** Serial Advanced Technology Attachment.
- SCSI:** Small Computer System Interface is a standard for connecting disks with computer systems.
- Sparing Alternatives:** Dedicated/distributed/parity-sparing/restripping are four sparing alternatives. Parity sparing combines two RAID5 arrays into one. These are discussed under separate headings.
- SSD:** Solid state disks are used to store persistent data and are much faster than HDDs.
- Static/Dynamic Routing:** The routing is in the context of mirrored disks.
- Striping:** Partitioning data into fixed sized strips, which are allocated round-robin across the disks in a disk array. The strips in a row constitute a stripe.
- Small Write Penalty (SWP):** Indicates the high cost of updating small data blocks in RAID(4 + k), $k \geq 1$ disks arrays, where $k + 1$ data blocks, which have to be read (unless they were cached),
- X-code:** An MDS 2DFT code with two vertical parities placed horizontally as ($N - 1$)st and N th stripes of $N \times N$ segments, where N is the number of disks.
- The SNIA Dictionary is a glossary of storage networking, data, and information management terminology.*

Log-structured File System. *LSA*: Log-Structured Array. *LSE*: Latent Sector Error. *MAID*: Massive Array of Idle Disks. *MDS*: Maximum Distance Separable. *MTTDL*: Mean Time to Data Loss. *MTTF*: Mean Time To Failure, *NAS*: Network Attached Storage. *PMDS*: Partial MDS. *RS*: Reed–Solomon (codes). *RU*: Rebuild Unit. *R/W*: Read/Write (head). *SAN*: Storage Area Network. *SAS*: Serial Attached SCSI. *SATA*: Serial Attached SCSI Attachment. *SCSI*: Small Computer System Interface. *SN*: Storage Node. *SSD*: Solid State Disk. *SPA*: Supplementary Parity Augmentation. *SWP*: Small write penalty. *TMR*: Triple Modular Redundancy. *VA*: Virtual Array. *VD*: Virtual Disk.

Abbreviations for Journal and Conference Titles

ACM: Association for Computing Machinery.* *ASPLOS*: Architectural Support for Programming Languages and Systems (ACM). *ATC*: Annual Technical Conference (USENIX). *CAN*: Computer Architecture News (ACM SIGARCH). *Special Interest Group (SIG)*. *CACM*: Communications of the ACM. *DPDB*: Distributed and Parallel Databases. *EUROSYS*: European Conference on Computer Systems.† *FAST*: File and Storage Technologies Conference (USENIX). *HPCA*: High Performance Computer Architecture (IEEE International Symposium). *HPDC*: High Performance Distributed Computing (IEEE International Symposium). *ICDE*: International Conference on Data Engineering (IEEE). *IEEE*: Institute of Electrical and Electronics Engineers.‡ *IEEE Computer Society*.§ *ISCA*: International Symposium on Computer Architecture (ACM). *IBM J. R&D*: IBM Journal of Research and Development (since 2009 includes *IBM Systems Journal*). *ISCA*: International Conference on Computer Architecture (ACM). *JPDC*: Journal Parallel Distributed Computing (Elsevier). *NAS*: Networking, Architecture, and Storage (IEEE International Conference). *OSDI*: Operating System Design and Implementation (USENIX Symposium). *SIGMETRICS*: Conference on Measurement and Modeling of Computer Systems (ACM). *SIGMOD*: International Conference on Management of Data (ACM). *S. P. & E.*: Software Practice and Experience (Wiley). *SOSP*: Symposium on Operating Systems Principles (ACM). *TC*: Transactions on Computers (IEEE). *TDSC*: Transactions on Dependable and Secure Computing (IEEE). *TOCS*: Transactions on Computing Systems (ACM). *TOMCCAP*: Transactions on Multimedia Computing, Communications, and Applications (ACM). *TOS*: Transactions on Storage (ACM). *TPDS*: Transactions Parallel and Distributed Systems (IEEE). *VLDB*: Proceedings of Very Large Data Bases Conference.¶

Further Information

There have been many new recent developments in this field, since the publication of the second edition of the Handbook in 2004. Rather than making a minor modification to that chapter, it was completely rewritten. Sections dealing with performance analysis can be skipped by readers not interested in this topic. Conversely, readers are encouraged to read the chapter on *Performance Evaluation of Computer Systems* in the Handbook for a more detailed discussion of this topic.

Publications on storage systems and storage research in industry and universities are reviewed in [107] and [112]. ACM started publishing *Transactions on Storage (TOS)* in 2005, while articles on this topic appeared in ACM's *Trans. on Computer Systems (TOCS)*, before that year with some minor overlap. USENIX's conference on *File and Storage Technologies (FAST)* was started in 2002.

A good collection of papers on mass storage and parallel I/O is [52]. A new book with a good description of modern disks is [49], but no space is dedicated to flash memories. A follow-up to [15] is [108], which emphasizes two-disk failure tolerant (2DFT) arrays and associated coding methods.

Storage Networking Industry Association (SNIA),* has numerous active technical projects in this area, including: Cloud storage, Hypervisor storage, Storage management, Object-based storage, IP storage Green storage, Solid state storage, Data integrity, and Long-term retention. Object-based storage devices (OSD) working group concerned with the creation of self-managed, heterogeneous, shared storage. This entails moving low-level storage functions to the device itself and providing the appropriate interface.

Web pages, if storage companies have white papers, reports, and presentations on their products. IBM publishes RedBooks online. Several storage-related articles are listed at <http://www.redbooks.ibm.com/portals/storage>.

The *Storage Performance Council (SPC)*† is an organization, which acts similarly to *Transaction Processing Council (TPC)*,‡, but develops storage performance and power efficiency benchmarks, while TPC deals with overall system processing database workloads.

This chapter touches upon the topic of Performance Evaluation of Computer Systems, covered elsewhere in this handbook. Also provided is a self-sufficient discussion of reliability analysis. Additional references on both topics are available from Appendix A: Bibliography in [122].

20.1 Introduction

The speeds of memory and the arithmetic units are the primary determinants of the speed of a computer. Whereas the speed of both units depends directly on the implementation technology, arithmetic unit speed also depends strongly on the logic design. Even for an integer adder, the speed can easily vary by an order of magnitude, while the complexity varies by less than 50%.

This chapter begins with a discussion of binary fixed point number systems in Section 20.2. Section 20.3 provides examples of fixed point implementations of the four basic arithmetic operations (i.e., add, subtract, multiply, and divide). Finally, Section 20.4 briefly describes algorithms for floating-point arithmetic.

Regarding notation, capital letters represent digital numbers (i.e., words), while subscripted lower case letters represent bits of the corresponding word. The subscripts range from $n - 1$ to 0 to indicate the bit position within the word (x_{n-1} is the most significant bit of X , x_0 is the least significant bit [lsb] of X , etc.). The logic designs presented in this chapter are based on positive logic with AND, OR, and invert operations. Depending on the technology used for implementation, different logical operations (such as NAND and NOR) or direct transistor realizations may be used, but the basic concepts do not change significantly.

20.2 Fixed-Point Number Systems

Most arithmetic is performed with fixed point numbers that have constant scaling (i.e., the position of the binary point is fixed). The numbers can be interpreted as fractions, integers, or mixed numbers, depending on the application. Pairs of fixed point numbers are used to create floating-point numbers, as discussed in Section 20.4.

TABLE 20.1 Example of 4 Bit Fractional Fixed-Point Numbers

Number	Two's Complement	Sign-Magnitude
+7/8	0111	0111
+5/8	0101	0101
+1/2	0100	0100
+3/8	0011	0011
+1/4	0010	0010
+1/8	0001	0001
+0	0000	0000
-0	N/A	1000
-1/8	1111	1001
-1/4	1110	1010
-3/8	1101	1011
-1/2	1100	1100
-5/8	1011	1101
-3/4	1010	1110
-7/8	1001	1111
-1	1000	N/A

At the present time, fixed point binary numbers are generally represented using the two's complement number system. This choice has prevailed over the sign-magnitude and other number systems, because the frequently performed operations of addition and subtraction are easily performed on two's complement numbers. Sign-magnitude numbers are more efficient for multiplication, but the lower frequency of multiplication and the development of efficient two's complement multiplication algorithms have resulted in the nearly universal selection of the two's complement number system for most applications. Most of the algorithms presented in this chapter assume the use of two's complement numbers.

Fixed point number systems represent numbers, for example, A , by n bits: a sign bit and $n - 1$ data bits. By convention, the most significant bit a_{n-1} is the sign bit, which is a 1 for negative numbers and a 0 for positive numbers. The $n - 1$ data bits are $a_{n-2}, a_{n-3}, \dots, a_1, a_0$. In the following material, fixed point fractions will be described for the two's complement and sign-magnitude systems.

Table 20.1 compares 4 bit fractional fixed point numbers in the two number systems. Note that the sign-magnitude number system has two zeros (i.e., positive zero and negative zero) and that only two's complement is capable of representing -1 . For positive numbers, both number systems use identical representations.

20.2.1 Two's Complement Number System

In the two's complement fractional number system, the value of a number is the sum of $n - 1$ positive binary fractional bits and a sign bit that has a weight of -1 :

$$A = -a_{n-1} + \sum_{i=0}^{n-2} a_i 2^{i-n+1} \quad (20.1)$$

Two's complement numbers are negated by complementing all bits and adding a 1 to the lsb position, for example, using 4 bit numbers to form $-3/8$:

$$\begin{aligned}
 +3/8 &= 0011 \\
 \text{invert all bits} &= 1100 \\
 \text{add 1 lsb} &\quad \underline{0001} \\
 &1101 = -3/8
 \end{aligned}$$

$$\begin{aligned}
 \text{Check: invert all bits} &= 0010 \\
 \text{Add 1 lsb} &\quad \underline{0001} \\
 &0011 = 3/8
 \end{aligned}$$

20.2.2 Sign-Magnitude Number System

Sign-magnitude numbers consist of a sign bit and $n - 1$ bits that express the magnitude of the number:

$$A = (1 - 2a_{n-1}) + \sum_{i=0}^{n-2} a_i 2^{i-n+1} \tag{20.2}$$

Sign-magnitude numbers are negated by complementing the sign bit. For example, to form $-3/8$,

$$\begin{aligned}
 +3/8 &= 0011 \\
 \text{invert sign bit} &= 1011 = -3/8
 \end{aligned}$$

$$\text{Check: invert sign bit} = 0011 = 3/8$$

A significant difference between the two number systems is their behavior under truncation. Figure 20.1 shows the effect of truncating high-precision fixed point fractions X , to form three-bit fractions $T(X)$. Truncation of two's complement numbers never increases the value of the number (i.e., the truncated numbers have values that are unchanged or shift toward negative infinity), as can be seen from

FIGURE 20.1 Behavior of fixed point fractions under truncation: (a) two's complement and (b) sign-magnitude.

Equation 20.1 since any truncated bits have positive weight. This bias can cause an accumulation of errors for computations that involve summing many truncated numbers (which may occur in scientific and signal processing applications). In the sign–magnitude number system, truncated numbers are unchanged or shifted toward zero, so that if approximately half of the numbers are positive and half are negative, the errors will tend to cancel.

20.3 Fixed-Point Arithmetic Algorithms

This section presents an assortment of typical fixed point algorithms for addition, subtraction, multiplication, and division.

20.3.1 Fixed-Point Addition

Addition is performed by summing the corresponding bits of the two n -bit numbers, including the sign bit. Subtraction is performed by summing the corresponding bits of the minuend and the two's complement of the subtrahend. Overflow is detected in a two's complement adder by comparing the carry signals into and out of the most significant adder stage (i.e., the stage that computes the sign bit). If the carries differ, an overflow has occurred and the result is invalid.

20.3.1.1 Full Adder

The full adder is the fundamental building block of most arithmetic circuits. Its operation is defined by the truth table shown in Table 20.2. The sum and carry outputs are described by the following equations:

$$s_k = c_{k+1} = \overline{a_k} \overline{b_k} c_k + \overline{a_k} b_k \overline{c_k} + \overline{a_k} b_k c_k + a_k \overline{b_k} \overline{c_k} = a_k \oplus b_k \oplus c_k \quad (20.3)$$

$$c_{k+1} = \overline{a_k} b_k c_k + a_k \overline{b_k} c_k + a_k b_k \overline{c_k} + a_k b_k c_k = a_k b_k + a_k c_k + b_k c_k \quad (20.4)$$

where

- a_k , b_k , and c_k are the inputs to the k th full adder stage
- s_k and c_{k+1} are the sum and carry outputs, respectively
- \oplus is the exclusive-OR logic operation

In evaluating the relative complexity of implementations, it is often convenient to assume a nine gate realization of the full adder, as shown in Figure 20.2. For this implementation, the delay from either a_k or b_k to s_k is six gate delays and the delay from c_k to c_{k+1} is two gate delays. Some technologies, such as

TABLE 20.2 Full Adder Truth Table

Inputs			Outputs	
a_k	b_k	c_k	c_{k+1}	s_k
0	0	0	0	0
0	0	1	0	1
0	1	0	0	1
0	1	1	1	0
1	0	0	0	1
1	0	1	1	0
1	1	0	1	0
1	1	1	1	1

FIGURE 20.2 Nine gate full adder.

CMOS, form inverting gates (e.g., NAND and NOR gates) more efficiently than the noninverting gates that are assumed in this chapter. Circuits with equivalent speed and complexity can be constructed with inverting gates.

20.3.1.2 Ripple Carry Adder

A ripple carry adder for n -bit numbers can be implemented by concatenating n full adders, as shown in Figure 20.3. At the k th bit position, bits a_k and b_k of operands A and B and the carry signal from the preceding adder stage, c_k , are used to generate the k th bit of the sum, s_k , and the carry to the next stage, c_{k+1} . This is called a ripple carry adder, since the carry signals “ripple” from the lsb position to the most significant. If the ripple carry adder is implemented by concatenating n of the nine gate full adders, which were shown in Figure 20.2, an n -bit ripple carry adder requires $2n + 4$ gate delays to produce the most significant sum bit and $2n + 3$ gate delays to produce the carry output. A total of $9n$ logic gates are required to implement the n -bit ripple carry adder.

In comparing the delay and complexity of adders, the delay from data input to most significant sum output denoted by $DELAY$ and the gate count denoted by $GATES$ will be used. The $DELAY$ and $GATES$ values are subscripted by RCA to indicate that they are for a ripple carry adder. Although these simple metrics are suitable for first-order comparisons, more accurate comparisons require more exact modeling since the implementations may be effected with transistor networks (as opposed to gates), which will have different delay and complexity characteristics:

$$DELAY_{RCA} = 2n + 4 \tag{20.5}$$

$$GATES_{RCA} = 9n \tag{20.6}$$

FIGURE 20.3 Ripple carry adder.

20.3.1.3 Carry Lookahead Adder

Another popular adder approach is the carry lookahead adder (MacSorley 1961, Weinberger and Smith 1958). Here, specialized logic computes the carries in parallel. The carry lookahead adder uses modified full adders (MFAs) (modified in the sense that a carry is not formed) for each bit position and lookahead modules, which form the carries. The lookahead modules form individual carries and also block generate and block propagate outputs that indicate that a carry is generated within the module or that an incoming carry would propagate across the module, respectively. Rewriting Equation 20.4 with $g_k = a_k b_k$ and $p_k = a_k + b_k$,

$$c_{k+1} = g_k + p_k c_k \quad (20.7)$$

This explains the concept of carry generation and carry propagation. At a given stage, a carry is “generated” if g_k is true (i.e., both a_k and b_k are 1), and a carry is “propagated” from its input to its output if p_k is true (i.e., either a_k or b_k is a 1). The nine gate full adder shown in Figure 20.2 has AND and OR gates that produce a_k and b_k with no additional complexity. Because the carry out is produced by the lookahead logic, the OR gate that produces c_{k+1} can be eliminated. The result is an eight gate MFA. Extending Equation 20.7 to a second stage,

$$\begin{aligned} c_{k+2} &= g_{k+1} + p_{k+1}c_{k+1} \\ &= g_{k+1} + p_{k+1}(g_k + p_k c_k) \\ &= g_{k+1} + p_{k+1}g_k + p_{k+1}p_k c_k \end{aligned} \quad (20.8)$$

Equation 20.8 results from evaluating Equation 20.7 for the $(k + 1)$ th stage and substituting c_{k+1} from Equation 20.7. Carry c_{k+2} exits from stage $k + 1$ if: (1) a carry is generated there or (2) a carry is generated in stage k and propagates across stage $k + 1$ or (3) a carry enters stage k and propagates across both stages k and $k + 1$, etc. Extending to a third stage:

$$\begin{aligned} c_{k+3} &= g_{k+2} + p_{k+2}c_{k+2} \\ &= g_{k+2} + p_{k+2}(g_{k+1} + p_{k+1}g_k + p_{k+1}p_k c_k) \\ &= g_{k+2} + p_{k+2}g_{k+1} + p_{k+2}p_{k+1}g_k + p_{k+2}p_{k+1}p_k c_k \end{aligned} \quad (20.9)$$

Although it would be possible to continue this process indefinitely, each additional stage increases the size (i.e., the number of inputs) of the logic gates. Four inputs (as required to implement Equation 20.9) are frequently the maximum number of inputs per gate for current technologies. To continue the process, block generate and block propagate signals ($g_{k+3:k}$ and $p_{k+3:k}$), respectively, are defined over 4-bit blocks (stages k to $k + 3$):

$$g_{k+3:k} = g_{k+3} + p_{k+3} g_{k+2} + p_{k+3} p_{k+2} g_{k+1} + p_{k+3} p_{k+2} p_{k+1} g_k \quad (20.10)$$

and

$$p_{k+3:k} = p_{k+3} p_{k+2} p_{k+1} p_k \quad (20.11)$$

Equation 20.7 can be expressed in terms of the 4-bit block generate and propagate signals:

$$c_{k+4} = g_{k+3:k} + p_{k+3:k} c_k \quad (20.12)$$

Thus, the carry out from a 4-bit-wide block can be computed in only four gate delays (the first to compute p_i and g_i for $i = k$ through $k + 3$, the second to evaluate $p_{k+3;k}$, the second and third to evaluate $g_{k+3;k}$ and the third and fourth to evaluate c_{k+4} using Equation 20.12).

An n -bit carry lookahead adder implemented with r -bit blocks requires $[(n - 1)/(r - 1)]$ lookahead logic blocks. A 4 bit lookahead logic block is a direct implementation of Equations 20.7 through 20.11, requiring 14 logic gates. In general, an r -bit lookahead logic block requires $1/2 (3r + r^2)$ logic gates. The Manchester carry chain (Kilburn et al. 1960) is an alternative switch-based technique for the implementation of a lookahead logic block.

Figure 20.4 shows the interconnection of 16 MFAs and five 4 bit lookahead logic blocks to realize a 16 bit carry lookahead adder. The sequence of events that occur during an add operation is as follows: (1) apply A , B , and carry in signals; (2) each adder computes P and G ; (3) first-level lookahead logic computes the 4 bit propagate and generate signals; (4) second-level lookahead logic computes c_4 , c_8 , and c_{12} ; (5) first-level lookahead logic computes the individual carries; and (6) each MFA computes the sum outputs. This process may be extended to larger adders by subdividing the large adder into 16 bit blocks and using additional levels of carry lookahead (e.g., a 64 bit adder requires three levels).

The delay of carry lookahead adders is evaluated by recognizing that an adder with a single level of carry lookahead (for 4 bit words if 4 bit blocks are used) has six gate delays and that each additional level of lookahead increases the maximum word size by a factor of four and adds four gate delays. More generally (Waser and Flynn 1982, pp. 83–88), the number of lookahead levels for an n -bit adder is $\lceil \log_r n \rceil$ where r is the maximum number of inputs per gate. Since an r -bit carry lookahead adder has six gate delays and there are four additional gate delays per carry lookahead level after the first,

$$DELAY_{CLA} = 2 + 4 \lceil \log_r n \rceil \quad (20.13)$$

The complexity of an n -bit carry lookahead adder implemented with r -bit lookahead logic blocks is n MFAs (each of which requires eight gates) and $[(n - 1)/(r - 1)]$ lookahead logic blocks (each of which requires $1/2 (3r + r^2)$ gates). In addition, two gates are used to calculate the carry out from the adder, c_n , from $p_{n-1:0}$ and $g_{n-1:0}$:

$$GATES_{CLA} = 8n + \frac{1}{2} (3r + r^2) \left\lceil \frac{n-1}{r-1} \right\rceil \quad (20.14)$$

For the common case of $r = 4$,

$$GATES_{CLA} \approx 12 \frac{2}{3} n - 4 \frac{2}{3} \quad (20.15)$$

The carry lookahead approach reduces the delay of adders from increasing in proportion to the word size (as is the case for ripple carry adders) to increasing in proportion to the logarithm of the word size. As with ripple carry adders, the carry lookahead adder complexity grows linearly with the word size (for $r = 4$, the complexity of a carry lookahead adder is about 40% greater than the complexity of a ripple carry adder). It is important to realize that most carry lookahead adders require gates with up to 4 inputs, while ripple carry adders use only inverters and 2 input gates.

20.3.1.4 Carry Skip Adder

The carry skip adder (Lehman and Burla 1961) divides the words to be added into blocks (like the carry lookahead adder). The basic structure of a 16 bit carry skip adder implemented with five 3 bit blocks and one 1-bit-wide block is shown in Figure 20.5. Within each block, a ripple carry adder is used to produce the sum bits and the carry (which is used as a block generate). In addition, an AND gate is used to form the block propagate signal. These signals are combined using Equation 20.12 to produce a fast carry signal.

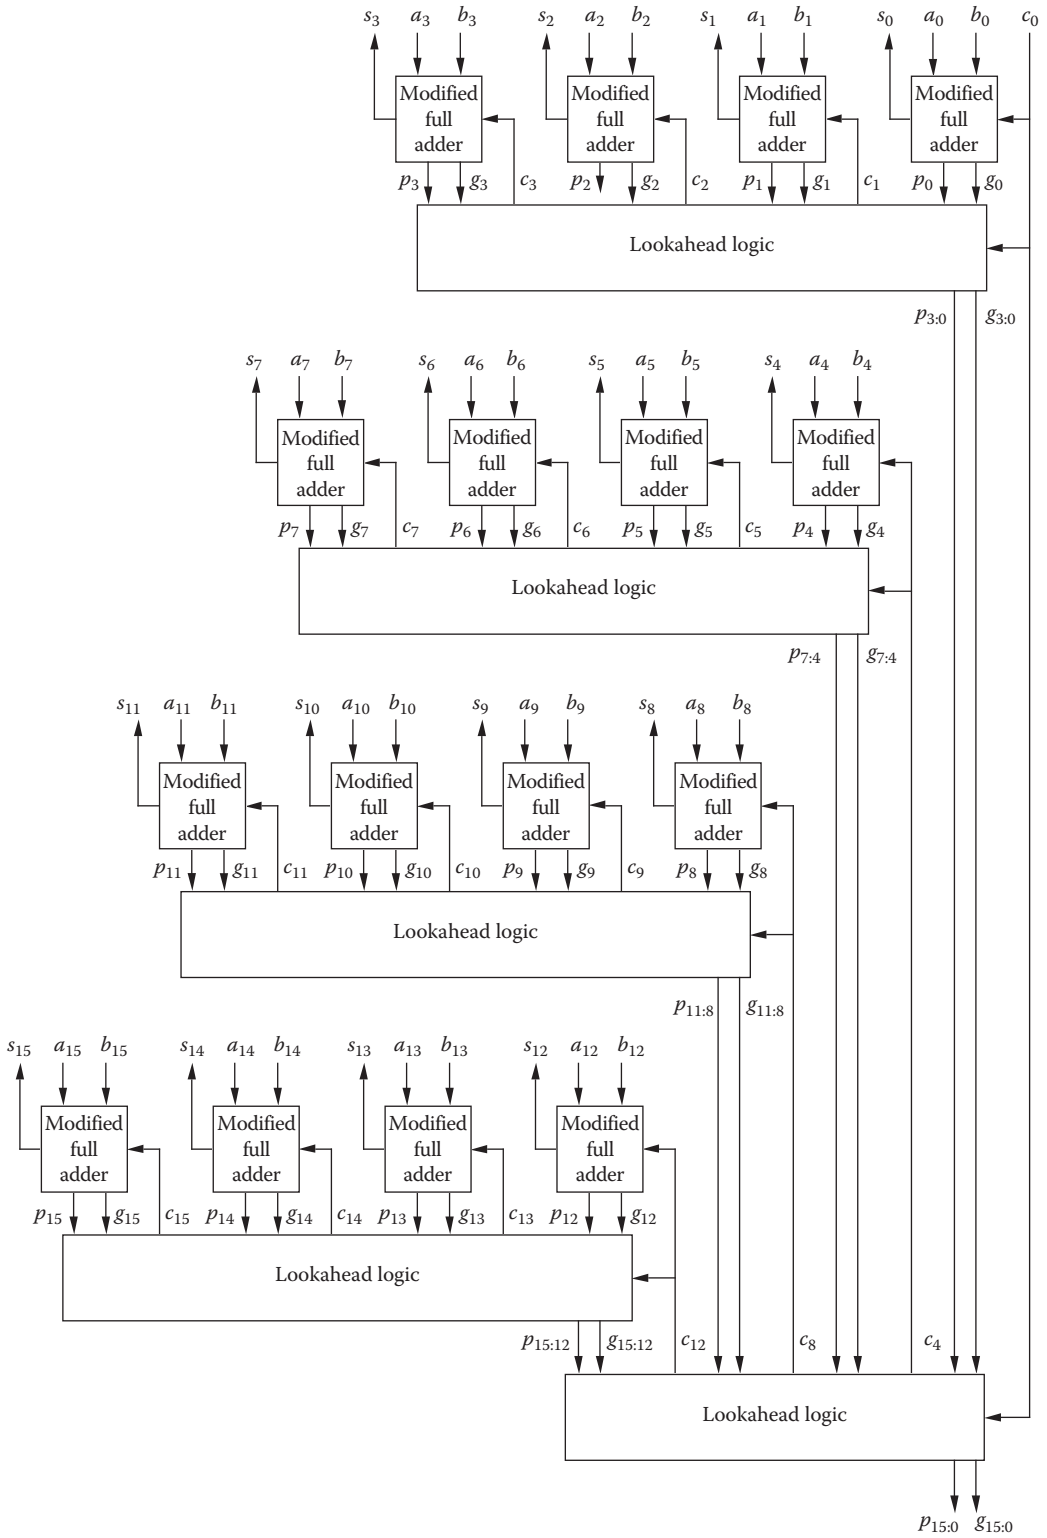

FIGURE 20.4 16 Bit carry lookahead adder.

FIGURE 20.5 16 Bit carry skip adder.

For example, with $k = 4$, Equation 20.12 yields $c_8 = g_{7:4} + p_{7:4} c_4$. The carry out of the second ripple carry adder is a block generate signal if it is evaluated when carries generated by the data inputs (i.e., $a_{7:4}$ and $b_{7:4}$ in Figure 20.5) are valid, but before the carry that results from c_4 . Normally, these two types of carries coincide in time, but in the carry skip adder, the c_4 signal is produced by a 4 bit ripple carry adder, so the carry output is a block generate from 11 gate delays after application of A and B until it becomes c_8 at 19 gate delays after the application of A and B .

In the carry skip adder, the first and last blocks are simple ripple carry adders, whereas the $\lceil n/k \rceil - 2$ intermediate blocks are ripple carry adders augmented with three gates. The delay of a carry skip adder is the sum of $2k + 3$ gate delays to produce the carry in the first block, two gate delays through each of the intermediate blocks, and $2k + 1$ gate delays to produce the most significant sum bit in the last block.

To simplify the analysis, the ceiling function in the count of intermediate blocks is ignored. If the block width is k ,

$$DELAY_{SKIP} = 2k + 3 + 2\left(\frac{n}{k} - 2\right) + 2k + 1$$

$$DELAY_{SKIP} = 4k + 2\frac{n}{k} \quad (20.16)$$

where $DELAY_{SKIP}$ is the total delay of the carry skip adder with a single level of k -bit-wide blocks. The optimum block size is determined by taking the derivative of $DELAY_{SKIP}$ with respect to k , setting it to zero, and solving for k . The resulting optimum values for k and $DELAY_{SKIP}$ are

$$k = \sqrt{\frac{n}{2}} \quad (20.17)$$

$$DELAY_{SKIP} = 4\sqrt{2n} \quad (20.18)$$

Better results can be obtained by varying the block width so that the first and last blocks are smaller, while the intermediate blocks are larger, and also by using multiple levels of carry skip (Chen and Schlag 1990, Turrini 1989).

The complexity of the carry skip adder is only slightly greater than that of a ripple carry adder because the first and last blocks are standard ripple carry adders, while the intermediate blocks are ripple carry adders with three gates added for carry skipping.

$$GATES_{SKIP} = 9n + 3\left(\left\lceil \frac{n}{k} \right\rceil - 2\right) \quad (20.19)$$

20.3.1.5 Carry Select Adder

The carry select adder (Bedrij 1962) divides the words to be added into blocks and forms two sums for each block in parallel (one with a carry in of 0 and the other with a carry in of 1). As shown for a 16-bit carry select adder in Figure 20.6, the carry out from the previous block controls a multiplexer (MUX) that selects the appropriate sum. The carry out is computed using Equation 20.12, because the group propagate signal is the carry out of an adder with a carry input of 1 and the group generate signal is the carry out of an adder with a carry input of 0.

If a constant block width of k is used, there will be $\lceil n/k \rceil$ blocks, and the delay to generate the sum is $2k + 3$ gate delays to form the carry out of the first block, two gate delays for each of the $\lceil n/k \rceil - 2$

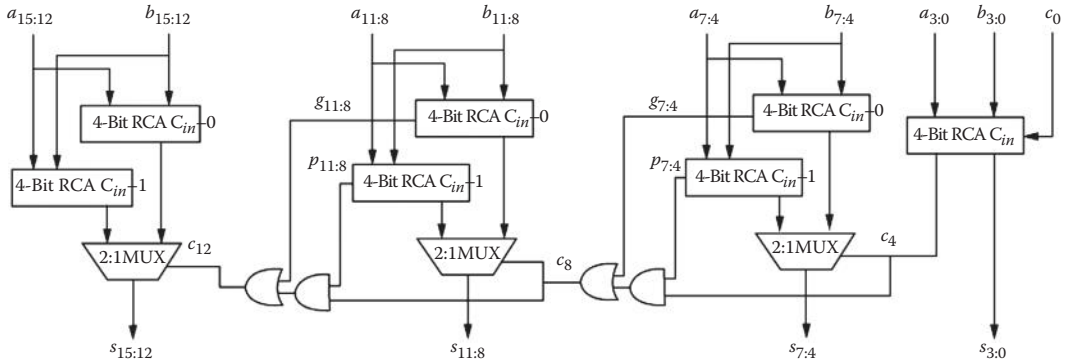

FIGURE 20.6 16 Bit carry select adder.

intermediate blocks, and three gate delays (for the MUX) in the final block. To simplify the analysis, the ceiling function in the count of intermediate blocks is ignored. The total delay is thus

$$DELAY_{C-SEL} = 8k + \frac{2n}{k} + 2 \tag{20.20}$$

where $DELAY_{C-SEL}$ is the total delay. The optimum block size is determined by taking the derivative of $DELAY_{C-SEL}$ with respect to k , setting it to zero, and solving for k . The result is

$$k = \sqrt{n} \tag{20.21}$$

$$DELAY_{C-SEL} = 2 + 4\sqrt{n} \tag{20.22}$$

As for the carry skip adder, better results can be obtained by varying the width of the blocks. In this case, the optimum is to make the two least significant blocks the same size and each successively more significant block 1 bit larger. In this configuration, the delay for each block's most significant sum bit will equal the delay to the MUX control signal (Goldberg 1990, p. A-38).

The complexity of the carry select adder is $2n - k$ ripple carry adder stages, the intermediate carry logic and $(\lceil n/k \rceil - 1)k$ -bit-wide 2:1 MUXs:

$$GATES_{C-SEL} = 9(2n - k) + 2\left(\left\lceil \frac{n}{k} \right\rceil - 2\right) + 3(n - k) + \left\lceil \frac{n}{k} \right\rceil - 1$$

$$GATES_{C-SEL} = 21n - 12k + 3\left\lceil \frac{n}{k} \right\rceil - 5 \tag{20.23}$$

This is slightly more than twice the complexity of a ripple carry adder of the same size.

20.3.1.6 Conditional-Sum Adder

The conditional-sum adder (Sklansky 1960) can be viewed as a carry select adder where each block adder is constructed with smaller carry select adders that are constructed with still smaller carry select adders until the smallest carry select adders are 1 bit wide.

An example of the operation of an 8-bit conditional-sum adder is shown on Figure 20.7. In step 0, the lsb of the sum and c_1 is determined with a conventional full adder. In step 1, the conditional sums and carries for each remaining bit position are computed assuming a carry into the bit position of 0

Operand A	1	0	0	1	1	1	1	0
Operand B	0	0	1	1	1	0	0	0
Step 0: Full Adder for LSB							0,0	= c_1, s_0
Step 1: For each bit:								
Sum ($c_{in} = 0$)	0, 1	0, 0	0, 1	1, 0	1, 0	0, 1	0,1	= c_2, s_1
Sum ($c_{in} = 1$)	1, 0	0, 1	1, 0	1, 1	1, 1	1, 0	1, 0	
Step 2: For pairs of bits:								
Sum ($c_{in} = 0$)	0, 1, 0		1, 0, 0		1, 0, 1			= c_4, s_3, s_2
Sum ($c_{in} = 1$)	0, 1, 1		1, 0, 1		1, 1, 0			
Step 3: For quads:								
Sum ($c_{in} = 0$)	0, 1, 1, 0, 0							
Sum ($c_{in} = 1$)	0, 1, 1, 0, 1							= c_8, s_7, s_6, s_5, s_4
Thus: $C_{out} = 0$, Sum =	1, 1, 0, 1, 0, 1, 1, 0							

FIGURE 20.7 Conditional-sum addition example.

and assuming a carry into the bit position of 1. In step 2, pairs of conditional sums and carries from step 1 are combined to make groups of two adjacent sum bits and a carry out assuming a carry into the group of 0 and assuming a carry into the group of 1. This process of combining pairs of conditional-sum groups continues until there is only a single group.

As the groups are being computed, the correct least significant conditional group is selected by the carry from the previous stage.

Figure 20.8 shows an 8 bit conditional-sum adder. Along the top, there are seven modified half adders (MHAs), one at each bit position above the lsb, which has a full adder (FA). Each MHA produces two pairs of outputs, the sum, s_i^0 , and carry, c_{i+1}^0 , that are the sum and carry that would result if there is a carry of 0 into that bit (i.e., the sum and carry conditioned on a carry of 0 into the stage) and the sum, s_i^1 , and carry, c_{i+1}^1 , that are conditioned on a carry of 1 into the stage. Trees of MUXs are used to select the appropriate sum and carry outputs for the adder.

Assuming that the word size, n , is an integer power of 2, the delay of an n -bit conditional-sum adder, $DELAY_{COND}$, is given by

$$DELAY_{COND} = Delay C_1 + \log_2 n Delay MUX \tag{20.24}$$

The delay of the conditional-sum adder grows in proportion to the logarithm of the word size. This is attractive if fast (transistor level) MUXs are used. Although gate-level MUX designs have a delay of 3 from the select input to the output, transistor level designs can be significantly faster.

The complexity of the conditional-sum adder has two components, the MHAs that are proportional to the data word size and the MUXs that are roughly proportional to $n \log_2 n$ where n is the data word size.

20.3.2 Fixed-Point Subtraction

To produce an adder/subtractor, the adder is modified as shown in Figure 20.9 by including Exclusive-OR gates to complement operand B when performing subtraction. It forms either $A + B$ or $A - B$. In the case of $A + B$, the mode selector is set to logic 0, which causes the Exclusive-OR gates to pass operand B through unchanged to the adder. The carry into the least significant adder stage is also set to ZERO, so standard addition occurs. Subtraction is implemented by setting the mode selector to logic ONE,

FIGURE 20.8 8-Bit conditional-sum adder.

FIGURE 20.9 Adder/subtractor.

which causes the Exclusive-OR gates to complement the bits of B; formation of the two's complement of B is completed by setting the carry into the least significant adder stage to ONE.

20.3.3 Fixed-Point Multiplication

Multiplication is generally implemented by direct logic implementations. Array multipliers have a very regular layout but are slower than “fast” multipliers.

20.3.3.1 Array Multipliers

A direct approach to multiplication involves the combinational generation of all bit products and their summation with an array of full adders. The block diagram for an unsigned 8-by-8 array multiplier is shown in Figure 20.10. It has an 8-by-8 array of cells (15 G cells, 7 HA cells, and 42 FA cells) in the upper portion of the diagram and a 7 bit ripple carry adder (constructed with 1 HA cell and 6 FA cells) along the bottom row. The upper portion uses an 8-by-8 array of AND gates to form the bit products (some of the AND gates are in the G cells and the remainder are contained within the FA and HA blocks). The output of the upper portion of the circuit is a pair of 7 bit words whose sum is the most significant 8 bit of the product $p_8 - p_{15}$. The complete product is available after 14 adder delays.

Modification of the array multiplier to multiply two's complement numbers requires using NAND gates instead of AND gates to form the bit products in the most significant row (the b_7 row) and column (the a_7 column) (an AND gate is used for the a_7b_7 bit product) and also adding two correction terms (Parhami 2010, p. 223).

The delay of the array multiplier is evaluated by following the pathways from the inputs to the outputs. The longest path starts at the upper-left corner, progresses to the lower-right corner, and then across the bottom to the lower-left corner. If it is assumed that the delay from any adder input (for either half or full adders) to any adder output is k gate delays, then the total delay of an n -bit by n -bit array multiplier is

$$DELAY_{ARRAY\ MPY} = k(2n - 2) + 1 \quad (20.25)$$

The complexity of the array multiplier is n^2 AND gates, n half adders, and $n^2 - 2n$ full adders. If a half adder comprises four gates and a full adder comprises nine gates, the total complexity of an n -bit by n -bit array multiplier is

$$GATES_{ARRAY\ MPY} = 10n^2 - 14n \quad (20.26)$$

Array multipliers are easily laid out in a cellular fashion, making them suitable for very large scale integrated (VLSI) circuit implementation, where minimizing the design effort may be more important than maximizing the speed.

FIGURE 20.10 Unsigned 8 bit by 8 bit array multiplier.

20.3.3.2 Wallace/Dadda Fast Multiplier

A method for fast multiplication was developed by Wallace (1964) and refined by Dadda (1965). With this method, a three-step process is used to multiply two numbers: (1) the bit products are formed, (2) the bit product matrix is reduced to a two-row matrix in which the sum of the rows equals the sum of the bit products, and (3) the two numbers are summed using a fast adder to produce the product. Although this may seem to be a complex process, it yields multipliers with delay proportional to the logarithm of the operand word size, which is faster than array multipliers that have delay that is proportional to the word size.

The second step in the fast multiplication process is shown for an unsigned 8-by-8 Dadda multiplier in Figure 20.11. An input 8-by-8 matrix of dots (each dot represents a bit product) is shown as Matrix 0.

FIGURE 20.11 Unsigned 8 bit by 8 bit Dadda multiplier.

Columns having more than six dots (or that will grow to more than six dots due to carries) are reduced by the use of half adders (each half adder takes in two dots from a given column and outputs one dot in the same column and one dot in the next more significant column) and full adders (each full adder takes in three dots from a given column and outputs one in the same column and one in the next more significant column) so that no column in Matrix 1 will have more than six dots. Half-adders are shown by two dots connected with a crossed line in the succeeding matrix and full adders are shown by two dots connected with a line in the succeeding matrix. In each case, the rightmost dot of the pair connected by a line is in the column from which the inputs were taken for the adder. In the succeeding steps, reduction to Matrix 2 with no more than four dots per column, Matrix 3 with no more than three dots per column, and finally Matrix 4 with no more than two dots per column is performed. The height of the matrices is determined by working back from the final (two-row) matrix and limiting the height of each matrix to the largest integer that is no more than 1.5 times the height of its successor (i.e., 2, 3, 4, 6, 9, 13, 19, 28, 42, etc.). Each matrix is produced from its predecessor in one adder delay. Because the number of matrices is logarithmically related to the number of bits in the words to be multiplied, the delay of the matrix reduction process is proportional to $\log n$. Because the adder that reduces the final two-row matrix can be implemented as a carry lookahead adder (which also has logarithmic delay), the total delay for this multiplier is proportional to the logarithm of the word size.

The delay of a Dadda multiplier is evaluated by following the pathways from the inputs to the outputs. The longest path starts at the center column of bit products (which require one gate delay to be formed) and progresses through the successive reduction matrices (which requires approximately $\log_{1.44}(n) - 2$ full adder delays) and finally through the $2n - 2$ -bit carry propagate adder. If the delay from any adder input (for either half or full adders) to any adder output is k gate delays and if the carry propagate adder is realized with a carry lookahead adder implemented with 4-bit lookahead logic blocks (with delay given by Equation 20.13), the total delay (in gate delays) of an n -bit by n -bit Dadda multiplier is

$$DELAY_{DADDA\ MPY} = 1 + k(\log_{1.44}(n) - 2) + 2 + 4 \lceil \log_r(2n - 2) \rceil \quad (20.27)$$

The complexity of a Dadda multiplier is determined by evaluating the complexity of its parts. There are n^2 gates ($2n - 2$ are NAND gates, the rest are AND gates) to form the bit product matrix, $(n - 2)^2$ full adders, $n - 1$ half adders, and a $2n - 2$ bit carry propagate adder for the addition of the final two-row matrix. If the carry propagate adder is realized with a carry lookahead adder (implemented with 4 bit lookahead logic blocks) and if the complexity of a full adder is nine gates and the complexity of a half adder (either regular or special) is four gates, then the total complexity is

$$GATES_{DADDA\ MPY} = 10n^2 - 6\frac{2}{3}n - 26 \quad (20.28)$$

The Wallace multiplier is very similar to the Dadda multiplier, except that it does more reduction in the first stages of the reduction process, it uses more half adders, and it uses a slightly smaller carry propagating adder. A dot diagram for an unsigned 8 bit by 8 bit Wallace multiplier is shown on Figure 20.12. This reduction (which like the Dadda reduction requires four full adder delays) is followed by an 8-bit carry propagating adder. The total complexity of the Wallace multiplier is slightly greater than the total complexity of the Dadda multiplier. In most cases the Wallace and Dadda multipliers have the same delay.

20.3.4 Fixed-Point Division

There are two types of division algorithms in common use: digit recurrence and convergence methods. The digit recurrence approach computes the quotient on a digit-by-digit basis; hence, they have a delay proportional to the precision of the quotient. In contrast, the convergence methods compute an approximation that converges to the value of the quotient. For the common algorithms, the convergence is quadratic, meaning that the number of accurate bits approximately doubles on each iteration.

The digit recurrence methods that use a sequence of shift, add, or subtract and compare operations are relatively simple to implement. On the other hand, the convergence methods use multiplication on each cycle. This means higher hardware complexity, but if a fast multiplier is available, potentially higher speed.

20.3.4.1 Digit Recurrent Division

The digit recurrent algorithms (Robertson 1958) based on selecting digits of the quotient Q (where $Q = N/D$) to satisfy the following equation:

$$P_{k+1} = rP_k - q_{n-k-1}D \quad \text{for } k = 1, 2, \dots, n-1 \quad (20.29)$$

where

P_k is the partial remainder after the selection of the k th quotient digit

$P_0 = N$ (subject to the constraint $|P_0| < |D|$)

r is the radix

q_{n-k-1} is the k th quotient digit to the right of the binary point

D is the divisor

FIGURE 20.12 Unsigned 8 bit by 8 bit Wallace multiplier.

In this subsection, it is assumed that both N and D are positive; see Ercegovic and Lang (1994) for details on handling the general case.

20.3.4.2 Binary SRT Divider

The binary SRT division process (also known as radix-2 SRT division) selects the quotient from three candidate quotient digits $\{\pm 1, 0\}$. The divisor is restricted to $0.5 \leq D < 1$. A flowchart of the basic binary SRT scheme is shown in Figure 20.13. Block 1 initializes the algorithm. In steps 3 and 5, $2P_k$ is used to select the quotient digit. In steps 4 and 6, $P_{k+1} = 2P_k - q_k D$. Step 8 tests whether all bits of the quotient have been formed and goes to step 2 if more need to be computed. Each pass through steps 2–8 forms one digit of the quotient. The result upon exiting from step 8 is a collection of n signed binary digits.

Step 9 converts the n digit signed digit number into an n -bit two's complement number by subtracting N , which has a 1 for each bit position where $q_i = -1$ and 0 elsewhere, from P , which has a 1 for each bit position where $q_i = 1$ and 0 elsewhere. For example,

$$Q = 0.11 - 101 = 21/32$$

$$P = 0.11001$$

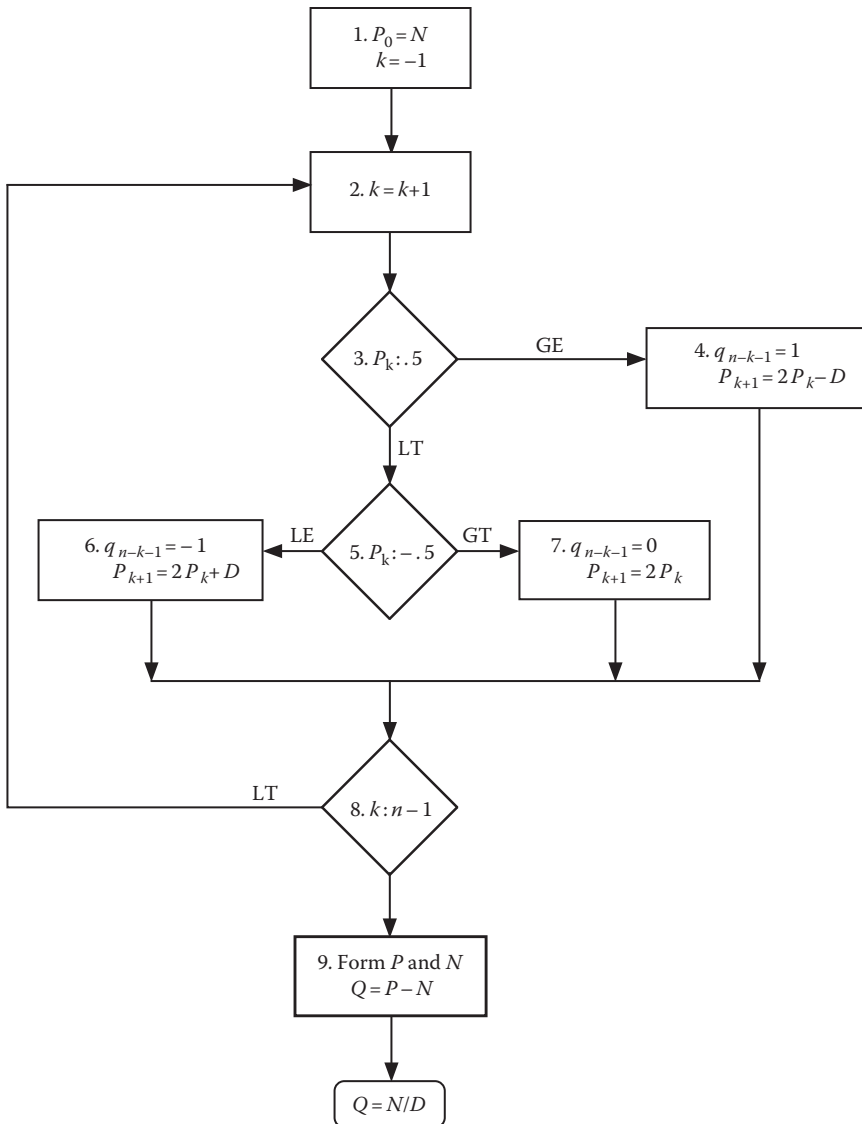

FIGURE 20.13 Flowchart of binary SRT division.

$$N = 0.00100$$

$$Q = 0.11001 - 0.00100$$

$$Q = 0.11001 + 1.11100$$

$$Q = 0.10101 = 21/32$$

The selection of the quotient digit can be visualized with a P - D plot such as the one shown in Figure 20.14. The plot shows the divisor along the x-axis and the shifted partial remainder (in this

FIGURE 20.14 P - D Plot for binary SRT division.

case $2P_k$) along the y -axis. In the area where $0.5 \leq D < 1$, values of the quotient digit are shown as a function of the value of the shifted partial remainder. In this case, the relations are especially simple. The digit selection and resulting partial remainder are given for the k th iteration by the following relations:

$$\text{If } P_k \geq 0.5, \quad q_{n-k-1} = 1 \quad \text{and} \quad P_{k+1} = 2P_k - D \quad (20.30)$$

$$\text{If } -0.5 < P_k < 0.5, \quad q_{n-k-1} = 0 \quad \text{and} \quad P_{k+1} = 2P_k \quad (20.31)$$

$$\text{If } P_k \leq -0.5, \quad q_{n-k-1} = -1 \quad \text{and} \quad P_{k+1} = 2P_k + D \quad (20.32)$$

Computing an n -bit quotient will involve selecting n quotient digits and up to $n + 1$ additions.

20.3.4.3 Radix-4 SRT Divider

The higher radix SRT division process is similar to the binary SRT algorithm. Radix 4 is the most common higher radix SRT division algorithm with either a minimally redundant digit set of $\{\pm 2, \pm 1, 0\}$ or the maximally redundant digit set of $\{\pm 3, \pm 2, \pm 1, 0\}$. The operation of the algorithm is similar to the binary SRT algorithm shown on Figure 20.13, except that in steps 3 and 5, $4P_k$ and D are used to determine the quotient digit. A P - D Plot is shown on Figure 20.15 for the maximum redundancy version of radix-4 SRT division. There are seven possible values for the quotient digit at each stage. The test for completion in step 8 becomes $k: n/2 - 1$. Also, the conversion to two's complement in step 9 is modified slightly since each quotient digit occupies two bits of the P and N numbers that are used to form the two's complement number.

20.3.4.4 Newton–Raphson Divider

The second category of division techniques uses a multiplication-based iteration to compute a quadratically convergent approximation to the quotient. In systems that include a fast multiplier, this process may be faster than the digit recurrent methods (Ferrari 1967). One popular approach is the Newton–Raphson

FIGURE 20.15 P-D Plot for radix-4 maximally redundant SRT division.

algorithm that computes an approximation to the reciprocal of the divisor that is then multiplied by the dividend to produce the quotient. The process to compute $Q = N/D$ consists of three steps:

1. Calculate a starting estimate of the reciprocal of the divisor, $R_{(0)}$. If the divisor, D , is normalized (i.e., $1/2 \leq D < 1$), then $R_{(0)} = 3 - 2D$ exactly computes $1/D$ at $D = .5$ and $D = 1$ and exhibits maximum error (of approximately 0.17) at $D = \sqrt{1/2}$. Adjusting $R_{(0)}$ downward to by half the maximum error gives

$$R_{(0)} = 2.915 - 2D \tag{20.33}$$

This produces an initial estimate, that is, within about 0.087 of the correct value for all points in the interval $1/2 \leq D < 1$.

2. Compute successively more accurate estimates of the reciprocal by the following iterative procedure:

$$R_{(i+1)} = R_{(i)} (2 - DR_{(i)}) \quad \text{for } i = 0, 1, \dots, k \quad (20.34)$$

3. Compute the quotient by multiplying the dividend times the reciprocal of the divisor:

$$Q = NR_{(k)} \quad (20.35)$$

where

k is the iteration count

N is the numerator

Figure 20.16 illustrates the operation of the Newton–Raphson algorithm. For this example, three iterations (involving a total of four subtractions, and seven multiplications) produce an answer accurate to nine decimal digits (approximately 30 bits).

With this algorithm, the error decreases quadratically, so that the number of correct bits in each approximation is roughly twice the number of correct bits on the previous iteration. Thus, from the $3\frac{1}{2}$ bit initial approximation of Equation 20.33, two iterations produce a reciprocal estimate accurate to 14 bits, four iterations produce a reciprocal estimate accurate to 56 bits, etc.

The efficiency of this process is dependent on the availability of a fast multiplier, since each iteration of Equation 20.34 requires two multiplications and a subtraction. The complete process for the initial

FIGURE 20.17 Example of Goldschmidt division.

estimate, three iterations, and the final quotient determination requires four subtraction operations and seven multiplication operations to produce a 16 bit quotient. This is faster than a conventional nonrestoring divider if multiplication is roughly as fast as addition, a condition that is satisfied for some systems that include a hardware multiplier.

20.3.4.5 Goldschmidt Divider

The Goldschmidt divider (Anderson et al. 1967) is another division algorithm that forms a quadratically convergent approximation to the quotient. It treats the division problem as a fraction whose numerator and denominator are multiplied by a succession of numbers so that the final denominator is approximately 1 and the final numerator is approximately equal to the quotient.

The steps to compute a quotient using the Goldschmidt method are as follows:

1. Scale the numerator, N_0 , and the denominator, D_0 , so that the value of the denominator is “close” to 1 (e.g., $\frac{3}{4} < D_0 < 1\frac{1}{4}$). Use a table to find a factor, F_1 , that will make $D_0 \cdot F_1 \approx 1$. Set $i = 0$.
2. Multiply N_i and D_i by F_{i+1} forming N_{i+1} and D_{i+1} , respectively.
3. Increment i . Calculate $F_{i+1} = 2 - D_i$.

Repeat steps 2 and 3 until $D_n = 1$ within the desired precision.

This process is illustrated by the decimal example shown in Figure 20.17.

Like the Newton–Raphson algorithm, the value of N_k quadratically approaches the value of the quotient. If F_1 in step 1 results in $D_1 \approx 1$ within a maximum error, the number of iterations to achieve a specific accuracy of the quotient can be predetermined. In the example, D_1 is within 2.5% of 1, D_2 is within 0.06%, etc. Thus, each iteration (which requires 1 subtract and 2 multiplies) doubles the number of accurate bits to which N_k approximates the quotient. If the initial accuracy is known, the final multiplication that forms D_k is not needed.

20.4 Floating-Point Arithmetic

Recent advances in VLSI have increased the feasibility of hardware implementations of floating-point arithmetic units. The main advantage of floating-point arithmetic is that its wide dynamic range virtually eliminates overflow for most applications.

20.4.1 Floating-Point Number Systems

A floating-point number, A , consists of a significand (or mantissa), S_a , and an exponent, E_a . The value of a number, A , is given by the equation

$$A = S_a r^{E_a} \quad (20.36)$$

where r is the radix (or base) of the number system. The significand is generally normalized by requiring that the most significant digit be nonzero. Use of the binary radix (i.e., $r = 2$) gives maximum accuracy but may require more frequent normalization than higher radices.

The IEEE Standard 754 single precision (32-bit) floating-point format, which is widely implemented, has an 8 bit biased integer exponent that ranges between 0 and 255 (IEEE 2008). The exponent is expressed in excess 127 code so that its effective value is determined by subtracting 127 from the stored value. Thus, the range of effective values of the exponent is -127 to 128 , corresponding to stored values of 0 to 255, respectively. A stored exponent value of 0 (E_{\min}) serves as a flag indicating that the value of the number is 0 if the significand is 0 and for denormalized numbers if the significand is nonzero. A stored exponent value of 255 (E_{\max}) serves as a flag indicating that the value of the number is infinity if the significand is 0 or “not a number” if the significand is nonzero. The significand is a 25 bit sign-magnitude mixed number (the binary point is to the right of the most significant bit). The leading bit of the significand is always a 1 (except for denormalized numbers). As a result, when numbers are stored, the leading bit can be omitted, giving an extra bit of precision. More details on floating-point formats and on the various considerations that arise in the implementation of floating-point arithmetic units are given in Gosling (1980), Goldberg (1990), Parhami (2010), Flynn and Oberman (2001), and Koren (2002).

20.4.1.1 Floating-Point Addition

A flow chart for the functions required for floating-point addition is shown in Figure 20.18. For this flowchart, the operands are assumed to be IEEE Standard 754 single precision numbers that have been “unpacked” and normalized with significand magnitudes in the range $[1, 2)$ and exponents in the range $[-126, 127]$.

On the flow chart, the operands are (E_a, S_a) and (E_b, S_b) , the result is (E_s, S_s) , and the radix is 2. In step 1, the operand exponents are compared; if they are unequal, the significand of the number with the smaller exponent is shifted right in step 3 or 4 by the difference in the exponent values to properly align the significands. For example, to add the decimal operands 0.867×10^5 and 0.512×10^4 , the latter would be shifted right by one digit and 0.867 added to 0.0512 to give a sum of 0.9182×10^5 . The addition of the significands is performed in step 5. Step 6 tests for overflow and step 7 corrects, if necessary, by shifting the significand one position to the right and incrementing the exponent. Step 9 tests for a zero significand. The loop of steps 10–11 scales unnormalized (but nonzero) significands upward to normalize the result. Step 12 tests for underflow.

It is important to recognize that the flowchart shows the basic functions that are required, but not necessarily the best way to perform those functions. For example, the loop in steps 10–11 is not a good way to normalize the significand of the sum. It is a serial loop that is executed a variable number of times depending on the data value. A much better way is to determine the number of leading zeros in the significand and then use a barrel shifter to do the shift in a single step in hardware.

Floating-point subtraction is implemented with a similar algorithm. Many refinements are possible to improve the speed of the addition and subtraction algorithms, but floating-point addition and subtraction will, in general, be much slower than fixed point addition as a result of the need for operand alignment and result normalization and rounding.

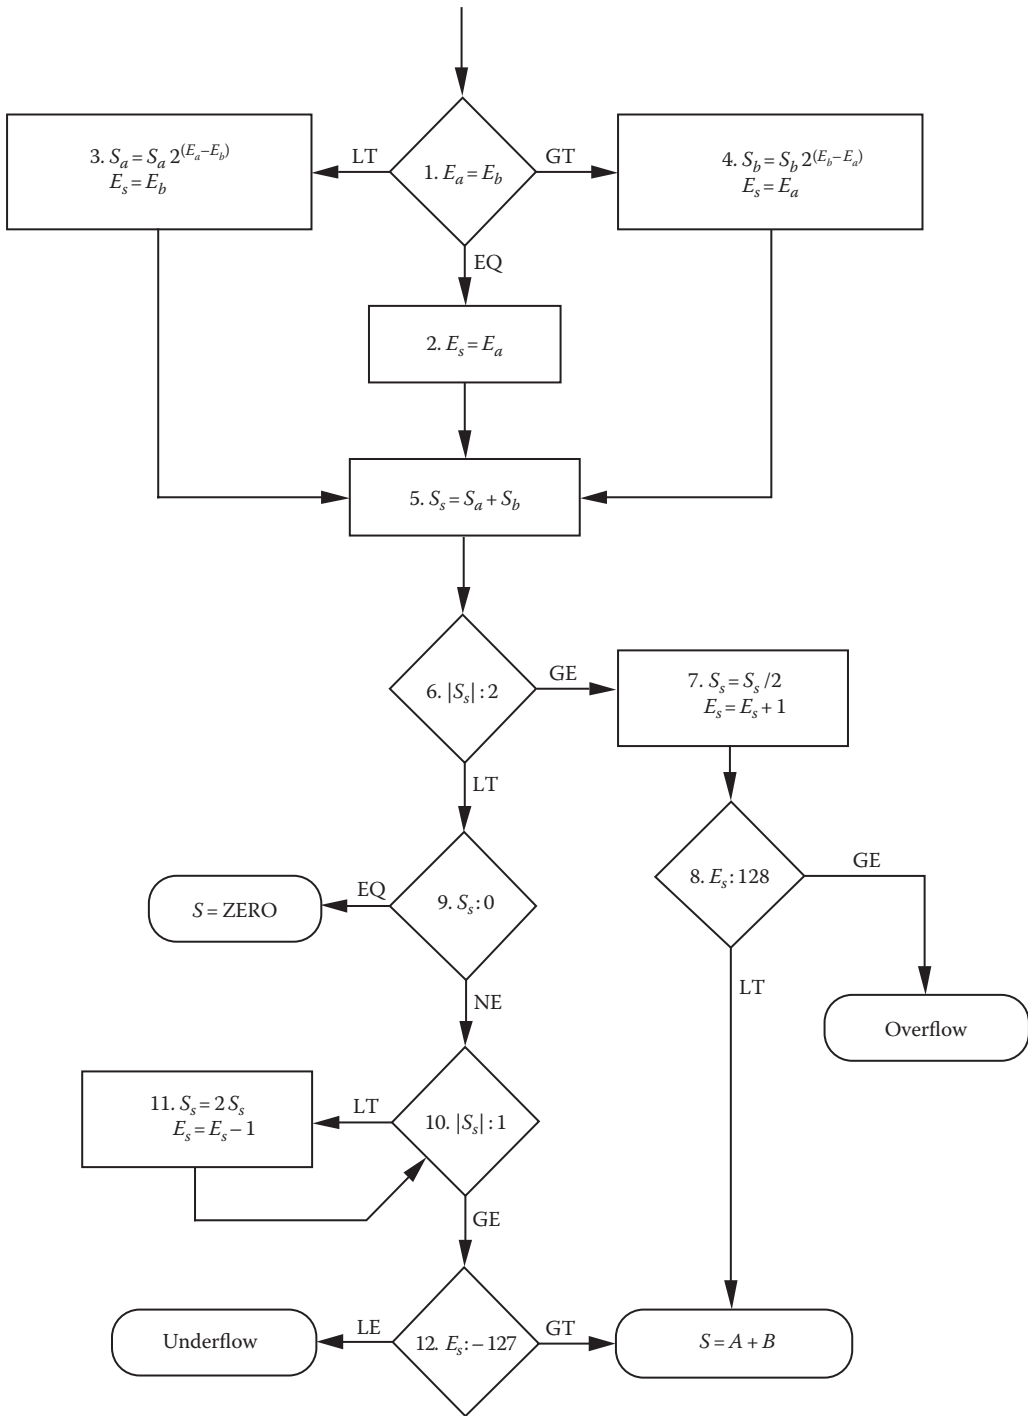

FIGURE 20.18 Floating-point adder.

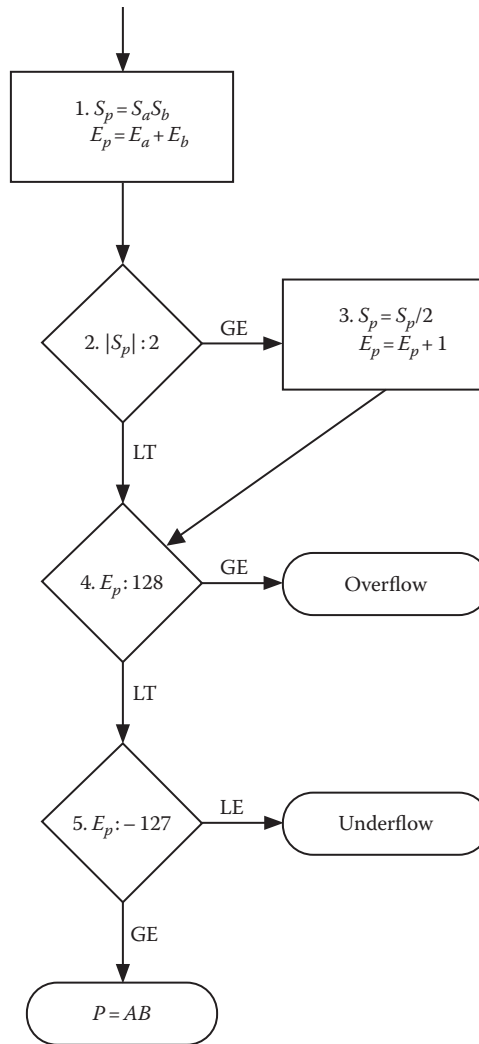

FIGURE 20.19 Floating-point multiplier.

20.4.1.2 Floating-Point Multiplication

The algorithm for floating-point multiplication is shown in the flowchart of Figure 20.19. In step 1, the product of the operand significands and the sum of the operand exponents are computed. Steps 2 and 3 normalize the significand if necessary. For radix-2 floating-point numbers, if the operands are normalized, at most a single shift is required to normalize the product. Step 4 tests the exponent for overflow. Finally, step 5 tests for underflow.

20.4.1.3 Floating-Point Division

The floating-point division algorithm is shown in the flowchart of Figure 20.20. The quotient of the significands and the difference of the exponents are computed in step 1. The quotient is normalized (if necessary) in steps 2 and 3 by shifting the quotient significand, while the quotient exponent is adjusted appropriately. For radix-2, if the operands are normalized, only a single shift is required to normalize the quotient. The computed exponent is tested for underflow in step 4. Finally, the fifth step tests for overflow.

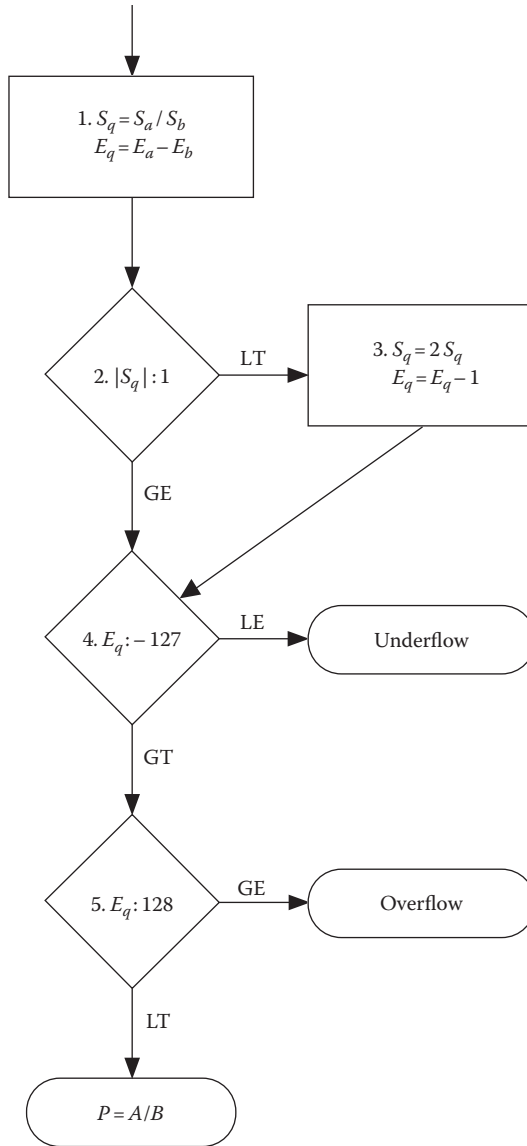

FIGURE 20.20 Floating-point divider.

20.4.1.4 Floating-Point Rounding

All floating-point algorithms may require rounding to produce a result in the correct format. A variety of alternative rounding schemes have been developed for specific applications. Round to nearest with ties to even, round to nearest with ties away from 0, round toward ∞ , round toward $-\infty$, and round toward 0 are all available in implementations of the IEEE floating-point standard (IEEE 2008).

20.5 Conclusions

This chapter has presented an overview of the two's complement number system; algorithms for the basic integer arithmetic operations of addition, subtraction, multiplication, and division; and a very brief discussion of floating-point operations. When implementing arithmetic units, there is often an

opportunity to optimize the performance and the complexity to match the requirements of the specific application. In general, faster algorithms require more area or more complex control; it is often useful to use the fastest algorithm that will fit the available area.

21.1 Introduction

The computing literature often draws a sharp distinction between input and output; computer scientists are used to regarding a screen as a passive output device and a mouse as a pure input device. However, nearly all examples of human–computer interaction (HCI) require *both* input and output to do anything useful. For example, what good would a mouse be without the corresponding feedback embodied by the cursor on the screen, as well as the sound and feel of the buttons when they are clicked? The distinction between output devices and input devices becomes even more blurred in the real world. A sheet of paper can be used to both record ideas (input) and display them (output). Clay reacts to the sculptor’s fingers yet also provides feedback through the curvature and texture of its surface. Indeed, the complete and seamless integration of input and output is becoming a common research theme in advanced computer interfaces such as ubiquitous computing (Weiser, 1991) and tangible interaction (Ishii and Ullmer, 1997). And of course, with the modern commercial success of mobile touch screen devices such as the Apple iPhone and various Android units, people everywhere experience input and output as entirely inseparable and collocated concepts, their fingers acting directly on virtual widgets displayed on a responsive piece of glass. It is no accident that we should address input and output in the same chapter. Further, as the space required for a powerful computer has plummeted, new form factors have emerged. In mobile devices, the desire to provide large screens to maximize media consumption experiences has marginalized dedicated control surfaces, replacing physical keyboards and pointing devices with ad hoc screen-rendered controls manipulated through touch input. Although measurably inferior at nearly all input tasks, touch screens have nonetheless emerged as a dominant form of mobile computing.

Although inextricably linked, for the ease of discussion, we consider separately the issues of input and output. Input and output bridge the chasm between a computer’s inner world of bits and the real world perceptible to the human senses. *Input* to computers consists of sensed information about the physical environment. Familiar examples include the mouse, which senses movement across a surface, and the keyboard, which detects a contact closure when the user presses a key. However, any sensed information about physical properties of people, places, or things can also serve as input to computer systems, for example the location of a user carrying a GPS-enabled mobile phone to inform recommendations for nearby restaurants. *Output* from computers can comprise any emission or modification to the physical environment, such as a display (including the cathode ray tube [CRT], flat-panel displays, or even light emitting diodes), speakers, or tactile and force feedback devices (sometimes referred to as *haptic displays*). There have even been olfactory displays such as the Smell Vision machine that debuted at the World’s Fair in Stockholm in 1976. Finally, an *interaction technique* is a fusion of input and output, consisting of all hardware and software elements, that provides a way for the user to accomplish a low-level task. For example, in the traditional graphical user interface (GUI), users can scroll through a document by clicking or dragging the mouse (input) within a scrollbar displayed on the screen (output).

A fundamental task of HCI is to shuttle information between the brain of the user and the silicon world of the computer. Progress in this area attempts to increase the useful bandwidth across that interface by seeking faster, more natural, and more convenient means for users to transmit information to computers, as well as efficient, salient, and pleasant mechanisms to provide feedback to the user. On the user’s side of the communication channel, interaction is constrained by the nature of human attention, cognition, and perceptual motor skills and abilities; on the computer side, it is constrained only by the technologies and methods that we can invent.

Research in input and output centers around the two ends of this channel: the devices and techniques computers can use for communicating with people and the perceptual abilities, processes, and organs people can use for communicating with computers.

It then attempts to find the common ground through which the two can be related by studying new modes of communication and expression that could be used for HCI and developing devices and techniques to use such modes. Basic research seeks theories and principles that inform us of the parameters of human cognitive and perceptual facilities, as well as models that can predict or interpret user

performance in computing tasks (e.g., Wobbrock et al., 2008). Advances can be driven by the need for new modalities to support the unique requirements of specific application domains, by technological breakthroughs that HCI researchers apply to improving or extending the capabilities of interfaces, or by theoretical insights suggested by studies of human abilities and behaviors, or even problems uncovered during careful analyses of existing interfaces. These approaches complement one another, and all have their value and contributions to the field, but the best research seems to have elements of all of these.

21.2 Interaction Tasks, Techniques, and Devices

A designer looks at the *interaction tasks* necessary for a particular application (Foley et al., 1984). Interaction tasks are low-level primitive inputs required from the user, such as entering a text string or choosing a command. For each such task, the designer chooses an appropriate interaction technique. In selecting an interaction device and technique for each task in a human–computer interface, simply making an optimal choice for each task individually may lead to a poor overall design, with too many different or inconsistent types of devices or dialogues. Therefore, it is often desirable to compromise on the individual choices to reach a better overall design. Design is fundamentally about managing trade-offs in complex solution spaces, and it is often said that designs that are best for something are often worst for something else.

There may be several different ways of accomplishing the same task. For example, one could use a mouse to select a command by using a pop-up menu, a fixed menu (a palette or command bar), multiple clicking, circling the desired command, or even writing the name of the command with the mouse. Software might even detect patterns of mouse use in the background, such as repeated “surfing” through menus, to automatically suggest commands or help topics (Horvitz et al., 1998). The latter suggests a shift from the classical view of interaction as direct manipulation where the user is responsible for all actions and decisions to one that uses *background sensing* techniques to allow technology to support the user with semiautomatic or implicit actions and services (Buxton, 1995a).

21.3 Composition of Interaction Tasks

Early efforts in HCI sought to identify elemental tasks that appear repeatedly in human–computer dialogues. Foley et al. (1984) proposed that user interface transactions are composed of the following elemental tasks:

Selection: Choosing objects from a set of alternatives.

Position: Specifying a position within a range. This includes picking a screen coordinate with a pointing device.

Orient: Specifying an angle or 3D orientation.

Path: Specifying a series of positions and/or orientations over time.

Quantify: Specifying an exact numeric value.

Text: Entry of symbolic data.

While these are commonly occurring tasks in many direct-manipulation interfaces, a problem with this approach is that the level of analysis at which one specifies “elemental” tasks is not well defined. For example, for *Position* tasks, a screen coordinate could be selected using a pointing device such as a mouse, but might be entered as a pair of numeric values (*Quantify*) using a pair of knobs (like an Etch-A-Sketch) where precision is paramount. But if these represent elemental tasks, why do we find that we must subdivide *Position* into a pair of *Quantify* subtasks for some devices but not for others?

Treating all tasks as hierarchies of subtasks, known as *compound tasks*, is one way to address this. With appropriate design and by using technologies and interaction techniques that parallel the way the user thinks about a task as closely as possible, the designer can phrase together a series of elemental tasks into a single *cognitive chunk*. For example, if the user’s task is to draw a rectangle, a device such as an

Etch-A-Sketch is easier to use. For drawing a circle, a pen is far easier to use. Hence the choice of device influences the level at which the user is required to think about the individual actions that must be performed to achieve a goal. See Buxton (1986) for further discussion of this important concept.

The six elemental tasks previously enumerated may be a complete list of “fundamental” low-level tasks that underlie most interaction with computers, but it could be argued that this list is not complete; for example, which of these six tasks does a fingerprint scanner support? Perhaps, if used for password replacement, it could be viewed as supporting the *Text* task; alternatively, one might add “Establishment of Identity” to the list. This points to a problem with the fundamental task approach. While identifying “elemental tasks” can be useful for thinking about interaction techniques in general, a problem with viewing tasks as assemblies of elemental tasks is that it typically only considers explicit input in the classical direct-manipulation paradigm. Where do devices like cameras, microphones, and the fingerprint scanner previously discussed fit in? These support higher-level data types and concepts (e.g., images, audio, and identity). Advances in technology will continue to yield new “elemental” inputs. However, these new technologies also may make increasing demands on systems to move from individual samples to synthesis of meaningful structure from the resulting data (Fitzmaurice et al., 1999).

21.4 Properties of Pointing Devices

The breadth of input devices and displays on the market today can be bewildering. It is important to understand that, when considering these devices, they are not all created equal. We must remember that the traditional mouse-based user interface, the Windows–Icons–Menus–Pointers (WIMP), has as perhaps its most essential component an abstraction of the logical target of user actions. This abstraction has gone by many names. The inventors of the mouse, Engelbart and English, named it the *bug* and later referred to it as the *telepointer*. In Windows, it is the pointer. In OSX, it is alternately the pointer and the cursor. But by whatever name, it remains a focal point for user-generated events in the system. A funny thing has happened with the pointer: a kind of abstraction has grown up around it, where a plethora of hardware can control it, and it is the movement of the pointer, rather than the hardware, around which software designers create their experiences. This has led to widespread misunderstanding that the design of the GUI itself is abstract. It’s not. It has been designed over more than 40 years of iteration to be highly optimized for a particular piece of hardware.

Thus, when considering input devices, one must be careful to avoid thinking of them in the overly simplistic terms of how they will control a cursor. Instead, we consider a number of organizing properties and principles in order to make sense of the design space and performance issues. First, we consider continuous, manually operated pointing devices (as opposed to discrete input mechanisms such as buttons or keyboards, or other devices not operated with the hand, which we will discuss briefly later). For further insight readers may also wish to consult complete taxonomies of devices (Buxton, 1983; Card et al., 1991). As we shall see, however, it is nearly impossible to describe properties of input devices without reference to output—especially the resulting feedback on the screen—since after all input devices are only useful insofar as they support interaction techniques that allow the user to accomplish something.

21.4.1 Physical Property Sensed

Traditional pointing devices typically sense position, motion, or force. A tablet senses position, a mouse measures motion (i.e., change in position), and an isometric joystick senses force. An isometric joystick is a unmoving force sensing joystick such as the IBM TrackPoint (“eraser head”) found on many laptops. For a rotary device, the corresponding properties are angle, change in angle, and torque. Position-sensing devices are also known as *absolute input devices*, whereas motion-sensing devices are *relative input devices*. An absolute device can fully support relative motion, since it can calculate changes to position, but a relative device cannot fully support absolute positioning and in fact can only emulate “position” at all by introducing a cursor on the screen. Note that it is difficult to move the mouse cursor

to a particular area of the screen (other than the edges) without looking at the screen, but with a tablet one can easily point to a region with the stylus using the kinesthetic sense (Balakrishnan and Hinckley, 1999), informally known as “muscle memory.”

21.4.2 Transfer Function

A device, in combination with the host operating system, typically modifies its signals using a mathematical transformation that scales the data to provide smooth, efficient, and intuitive operation. An appropriate mapping is a transfer function that matches the physical properties sensed by the input device. Appropriate mappings include force-to-velocity, position-to-position, and velocity-to-velocity functions. For example, an isometric joystick senses force; a nonlinear rate mapping transforms this into a velocity of cursor movement (Rutledge and Selker, 1990; Zhai and Milgram, 1993; Zhai et al., 1997). Ideally, the device should also be self-centering when using a rate mapping, with a spring return to the zero input value, so that the user can stop quickly by releasing the device. A common inappropriate mapping is calculating a speed of scrolling based on the position of the mouse cursor, such as extending a selected region by dragging the mouse close to the edge of the screen. The user has no feedback of when or to what extent scrolling will accelerate, and the resulting interaction can be hard to learn how to use and difficult to control.

Gain entails a simple multiplicative transfer function known as the device gain, which can also be described as a *control-to-display (C:D) ratio*, the ratio between the movement of the input device and the corresponding movement of the object it controls. For example, if a mouse (the control) must be moved 1 cm on the desk to move a cursor 2 cm on the screen (the display), the device has a 1:2 control-display ratio. However, on commercial pointing devices and operating systems, the gain is rarely constant*; an *acceleration function* is often used to modulate the gain depending on velocity. An acceleration function is a transfer function that exhibits an exponential relationship between velocity and gain. Experts believe the primary benefit of acceleration is to reduce the *footprint*, or the physical movement space, required by an input device (Hinckley et al., 2001; Jellinek and Card, 1990). One must also be very careful when studying the possible influence of gain settings on user performance: experts have criticized gain as a fundamental concept, since it confounds two separate concepts (device size and display size) in one arbitrary metric (Accot and Zhai, 2001). Furthermore, user performance may exhibit speed–accuracy trade-offs, calling into question the assumption that there exists an “optimal” C:D ratio (MacKenzie, 1995).

21.4.3 Number of Dimensions

Devices can measure one or more linear and angular dimensions. For example, a mouse measures two linear dimensions, a knob measures one angular dimension, and a six degree-of-freedom (6 DOF) magnetic tracker measures three linear dimensions and three angular (for examples of 6 DOF input and design issues, see Green and Liang, 1994; Hinckley et al., 1994b; Serra et al., 1997; Ware and Jessome, 1988). If the number of dimensions required by the user’s interaction task does not match the number of dimensions provided by the input device, then special handling (e.g., interaction techniques that may require extra buttons, graphical widgets, and mode switching) will need to be introduced. A lack of control degrees-of-freedom is a particular concern for 3D user interfaces and interaction (Hinckley et al., 1994b; Zhai, 1998). Numerous interaction techniques have been proposed to allow standard 2D pointing devices to control 3D positioning or orientation tasks (e.g., Bukowski and Sequin, 1995; Chen et al., 1988; Conner et al., 1992). Well-designed interaction techniques using specialized multiple degree-of-freedom input devices can sometimes offer superior performance (Hinckley et al., 1997; Ware and Rose, 1999), but may be ineffective for standard desktop tasks, so overall performance must be considered (Balakrishnan et al., 1997; Hinckley et al., 1999).

* Direct input devices (see next page) are an exception, since the C:D ratio is typically fixed at 1:1 (but see also Sears and Shneiderman, 1991 and Forlines et al., 2006).

21.4.4 Pointing Speed, Accuracy, and Throughput

The standard way to characterize pointing device performance employs *Fitts' law* paradigm (Fitts, 1954; Soukoreff and MacKenzie, 2004; Wobbrock et al., 2011). Fitts' law relates the *movement time* to point at a target, the *amplitude* of the movement (the distance to the target), and the *width* of the target (i.e., the precision requirement of the pointing movement). The movement time is proportional to the logarithm of the distance divided by the target width, with constant terms that vary from one device to another. While not emphasized in this chapter, Fitts' law is the single most important quantitative analysis, testing, and prediction tool available to input research and device evaluation. For an excellent overview of its application to the problems of HCI, including use of Fitts' law to characterize throughput (a composite measure of both speed and accuracy often informally called bandwidth), see MacKenzie (1992). For discussion of other accuracy metrics, see MacKenzie et al. (2001). Recently Fitts' law testing paradigm has been proposed as an international standard for evaluating pointing devices (Douglas et al., 1999; Keates et al., 2002).

Recent years have seen a number of new insights and new applications for Fitts' law (Guiard, 2009). Fitts' law was originally conceived in the context of rapid, aimed movements, but Fitts' law can also be applied to tasks such as scrolling (Hinckley et al., 2001), multi-scale navigation (Guiard et al., 2001), crossing boundaries (Accot and Zhai, 2002) and predicting pointing error rates instead of movement time (Wobbrock et al., 2008, 2011). Researchers have also recently applied Fitts' law to expanding targets that double in width as the user approaches them. Even if the expansion begins after the user has already covered 90% of the distance from a starting point, the expanding target can be selected as easily as if it had been fully expanded since the movement began (McGuffin and Balakrishnan, 2002); see also Zhai et al. (2003). However, it remains unclear if this can be successfully applied to improve pointing performance for multiple targets that are closely packed together (as typically found in menus and tool palettes). For tasks that exhibit continuous speed-accuracy requirements, such as moving through a hierarchical menu, Fitts' law cannot be applied, but researchers have recently formulated the steering law, which does address such tasks. In fact, the steering law was independently discovered outside the computing fields twice before (Accot and Zhai, 1997, 1999, 2001).

21.4.5 Input Device States

To select a single point or region with an input device, users need a way to signal when they are selecting something versus when they are just moving over something to reach a desired target. The need for this fundamental signal of intention is often forgotten by researchers eager to explore new interaction modalities such as empty-handed pointing (e.g., using camera tracking or noncontact proximity sensing of hand position). The *three-state model* of input (Buxton, 1990b) generalizes the states sensed by input devices as *tracking*, which causes the cursor to move; *dragging*, which allows selection of objects by clicking (as well as moving objects by clicking and dragging them); and *out of range*, which occurs when the device moves out of its physical tracking range (e.g., a mouse is lifted from the desk, or a stylus is removed from a tablet). Most pointing devices sense only two of these three states: for example, a mouse senses tracking and dragging, but a touchpad senses tracking and the out-of-range state. Hence, to fully simulate the functionality offered by mice, touchpads need special procedures, such as tapping to click, which are prone to inadvertent activation (e.g., touching the pad by accident causes a click [MacKenzie and Oniszczak, 1998]). For further discussion and examples, see Buxton (1990b) and Hinckley et al. (1998a).

21.4.6 Direct versus Indirect Control

A mouse is an *indirect input device* (one must move the mouse to point to a spot on the screen); a touch screen is a *direct input device* (the display surface is also the input surface). Direct devices raise several unique issues. Designers must consider the possibility of parallax error resulting from a gap between the input and display surfaces, reduced transmissivity of the screen introduced by a sensing layer, or occlusion of the display by the user's hands. Another issue is that touch screens can support a cursor tracking state,

or a dragging state, but not both; typically, touch screens move directly from the out-of-range state to the dragging state when the user touches the screen, with no intermediate cursor feedback (Buxton, 1990b). Techniques for touch-screen cursor feedback have been proposed, but typically require that selection occurs on lift-off (Potter et al., 1988; Sears and Shneiderman, 1991; Sears et al., 1992). See Section 21.5.4.

21.4.7 Device Acquisition Time

The average time to pick up or put down an input device is known as **acquisition time** (or sometimes homing time). It is often assumed to be a significant factor for user performance, but Fitts' law throughput of a device tends to dominate human performance time unless switching occurs frequently (Douglas and Mithal, 1994). However, one exception is stylus or pen-based input devices; pens are generally comparable to mice in general pointing performance (Accot and Zhai, 1999), or even superior for some high-precision tasks (Guiard et al., 2001), but these benefits can easily be negated by the much greater time it takes to switch between using a pen and using a keyboard.

21.4.8 Modeling of Repetitive Tasks

The keystroke-level model (KLM) is commonly used to model expert user performance in repetitive tasks such as text editing. The KLM includes standard operators that represent average times required for pointing with an input device, pressing a button, pauses for decision making, and device acquisition time, but the model does not account for errors or nonexpert behaviors such as problem solving (Card et al., 1980). Good examples of research that apply the KLM include Wang et al. (2001) and MacKenzie and Soukoreff (2002). Another approach called GOMS modeling is an extension of the KLM that can handle more complex cases (Olson and Olson, 1990), but many practitioners still use the KLM to evaluate input devices and low-level interaction techniques because of KLM's greater simplicity.

21.4.9 Hardware Criteria

Various other characteristics can distinguish input devices, but are perhaps less important in distinguishing the fundamental types of interaction techniques that can be supported. Engineering parameters of a device's performance such as sampling rate, resolution, accuracy, and linearity can all influence performance. **Latency** is the end-to-end delay between the user's physical movement, sensing this and providing the ultimate system feedback to the user. Latency can be a devious problem as it is impossible to completely eliminate from system performance; latency of more than 75–100 ms significantly impairs user performance for many interactive tasks (MacKenzie and Ware, 1993; Robertson et al., 1989). For vibrotactile or haptic feedback, users may be sensitive to much smaller latencies of just a few milliseconds (Cholewiak and Collins, 1991). The effects of latency can also be magnified in particular interaction techniques; for example, when dragging on a touch screen, users notice latency as a separation between their finger and the dragged object, even for extremely low latencies (Ng et al., 2012).

21.5 Discussion of Common Pointing Devices

Here, we briefly describe commonly available pointing devices and some issues that can arise with them in light of the properties previously discussed.

21.5.1 Mouse

A mouse senses movement relative to a flat surface. Mice exhibit several properties that are well suited to the demands of desktop graphical interfaces (Balakrishnan et al., 1997). The mouse is stable and does not fall over when released (unlike a stylus on a tablet). A mouse can also provide integrated buttons for selection, and since the force required to activate a mouse's buttons is orthogonal to the plane of

movement, it helps minimize accidental clicking or interference with motion. Another subtle benefit is the possibility for users to employ a combination of finger, hand, wrist, arm, and even shoulder muscles to span the range of tasks from short precise selections to large, ballistic movements (Balakrishnan and MacKenzie, 1997; Zhai et al., 1996). Finally, Fitts' law studies show that users can point with the mouse about as well as with the hand itself (Card et al., 1978).

21.5.2 Trackball

A trackball is like a roller-ball mouse that has been turned upside down, with a mechanical ball that rolls in place. Trackballs, like mice, are indirect relative pointing devices. The main advantage of trackballs is that they can be used on an inclined surface and they often require a smaller physical footprint than mice. They also employ different muscle groups, which some users find more comfortable, especially users with motor impairments caused by, e.g., spinal cord injuries (Fuhrer and Fridie, 2001; Sperling and Tullis, 1988; Wobbrock and Myers, 2006). However, rolling the trackball while holding down any of its buttons requires significant dexterity, especially when trying to do so with only one hand. Therefore, tasks requiring moving the trackball with a button held down, for example, dragging an icon across the desktop, can be awkward or even impossible for some users (MacKenzie et al., 1991).

21.5.3 Tablets

Touch-sensitive tablets (that are not also touch screens) are indirect pointing devices and may be used in either absolute or relative pointing modes. In absolute mode, each position on the tablet maps directly to a corresponding position on the screen (e.g., the top-right corner). In relative mode, movements on the tablet move a cursor on the screen according to a transfer function, as with a mouse. Most tablets sense the absolute position of a mechanical intermediary such as a stylus or puck on the tablet surface. A puck is a mouse that is used on a tablet; the only difference is that it senses absolute position and it cannot be used on a surface other than the tablet. Absolute mode is generally preferable for tasks such as tracing, digitizing, drawing, freehand inking, and signature capture. Tablets that sense contact of the bare finger are known as touch tablets (Buxton et al., 1985); touchpads are miniature touch tablets, as commonly found on portable computers (MacKenzie and Oniszczak, 1998). A touch screen is a touch-sensitive tablet collocated with an information display, but demands different handling than a tablet (see Section 21.4.6).

21.5.4 Pen Input

Pen-based input for mobile devices is an area of increasing practical concern. Pens effectively support activities such as inking, marking, and gestural input (see Section 21.8.2), but raise a number of problems when supporting graphical interfaces originally designed for mouse input. Pen input raises the concerns of direct input devices as previously described. There is no way to see exactly what position will be selected before selecting it: pen contact with the screen directly enters the dragging state of the three-state model (Buxton, 1990b). There is no true equivalent of a "hover" state for tool tips* nor an extra button for context menus. Pen dwell time on a target can be used to provide one of these two functions. When detecting a double-tap, one must allow for longer interval between the taps (as compared to double-click on a mouse), and one must also accommodate a significant change to the screen position between taps. Finally, users often want to touch the screen of small devices using a bare finger,

* Tool tips are small explanatory labels or balloons that appear next to a button, icon, or other interface widget when the user holds the cursor still over that object. The "hover" state is detected when there is little or no cursor movement for a fixed time-out (many systems use a time-out of approximately 1 s).

so applications should be designed to accommodate imprecise selections. Note that some pen-input devices, such as the Tablet PC, use an inductive sensing technology that can only sense contact from a specially instrumented stylus and thus cannot be used as a touch screen. However, this deficiency is made up for by the ability to track the pen when it is close to (but not touching) the screen, allowing support for a tracking state with cursor feedback (and hence ToolTips as well).

21.5.5 Joysticks

There are many varieties of joysticks. As previously mentioned, an isometric joystick senses force and returns to center when released. Because isometric joysticks can have a tiny footprint, they are often used when space is at a premium, allowing integration with a keyboard and hence rapid switching between typing and pointing (Douglas and Mithal, 1994; Rutledge and Selker, 1990). Isotonic joysticks sense the angle of deflection of the stick; they tend to move more than isometric joysticks, offering better feedback to the user. Such joysticks may or may not have a mechanical spring return to center. Some joysticks even include both force and position sensing and other special features. For a helpful organization of the complex design space of joysticks, see Lipscomb and Pique (1993).

21.5.6 Alternative Means of Pointing

Researchers have explored using the feet (Pearson and Weiser, 1988), head tracking, (Bates and Istance, 2003; LoPresti et al., 2000) and eye tracking (Jacob, 1990; Kumar et al., 2007; Lankford, 2000) as alternative approaches to pointing. Head tracking has much lower pointing bandwidth than the hands and may require the neck to be held in an awkward fixed position, but has useful applications for intuitive coupling of head movements to virtual environments (Brooks, 1988; Sutherland, 1968) and interactive 3D graphics (Hix et al., 1995; Ware et al., 1993). Eye movement-based input, properly used, can provide an unusually fast and natural means of communication, because we move our eyes rapidly and almost unconsciously. The human eye fixates visual targets within the fovea, which fundamentally limits the accuracy of eye gaze tracking to 1 degree of the field of view (Zhai et al., 1999). Eye movements are subconscious and must be interpreted carefully to avoid annoying the user with unwanted responses to his actions, known as the Midas touch problem (Jacob, 1991). Current eye-tracking technology is expensive and has numerous technical limitations, confining its use thus far to research labs and disabled persons with few other options.

21.6 Feedback and Perception-Action Coupling

The ecological approach to human perception (Gibson, 1986) asserts that the organism, the environment, and the tasks the organism performs are inseparable and should not be studied in isolation. Hence, perception and action are intimately linked in a single motor-visual feedback loop, and any separation of the two is an artificial one. The lesson for interaction design is that techniques must consider both the motor control (input) and feedback (output) aspects of the design and how they interact with one another.

From the technology perspective, one can consider feedback as passive or active. Active feedback is under computer control. This can be as simple as presenting a window on a display or as sophisticated as simulating haptic contact forces with virtual objects when the user moves an input device. We will return to discuss active feedback techniques later in this chapter, when we discuss display technologies and techniques.

Passive feedback may come from sensations within the user's own body, as influenced by physical properties of the device, such as the shape, color, and feel of buttons when they are depressed. The industrial design of a device suggests the purpose and use of a device even before a user touches it (Norman, 1990). Mechanical sounds and vibrations that result from using the device provide confirming feedback

of the user's action. The shape of the device and the presence of landmarks can help users orient a device without having to look at it (Hinckley et al., 1998b). Proprioceptive and kinesthetic feedback are somewhat imprecise terms, often used interchangeably, that refer to sensations of body posture, motion, and muscle tension (MacKenzie and Iberall, 1994). These senses allow users to feel how they are moving an input device without looking at the device and indeed without looking at the screen in some situations (Balakrishnan and Hinckley, 1999; Kane et al., 2008; Mine et al., 1997). This may be important when the user's attention is divided between multiple tasks and devices (Fitzmaurice and Buxton, 1997). Sellen et al. (1992) report that muscular tension from depressing a foot pedal makes modes more salient to the user than purely visual feedback. Although all of these sensations are passive and not under the direct control of the computer, these examples nonetheless demonstrate that they are relevant to the design of devices, and interaction techniques can consider these qualities and attempt to leverage them.

21.6.1 Impoverished Physicality

Modern input devices such as touch-screens and in-air gesture systems lack some of the tactile and kinesthetic feedback inherently present in traditional input devices. Such feedback is an essential element of the user experience, especially when users are attempting to understand why the system response may not be as expected. Many commercial mobile devices use audio to compensate with phones that beep or click when a virtual key is pressed.

To understand the role that feedback plays, consider the following table (Table 21.1), which describes various states of a system and the feedback that is provided by either the cursor or the hardware itself. As is immediately evident, most touch-based platforms shift a great deal of the feedback burden onto the application developer.

Some work has addressed this issue by providing haptic sensations using piezoelectric actuators, electrovibration, or deformable fluids (Bau et al., 2010; Jansen et al., 2010; Poupyrev and Maruyama, 2003; Poupyrev et al., 2002). Others have supplied physical cutouts as templates to provide passive haptic sensations to a finger (or stylus) (Buxton et al., 1985; Wobbrock et al., 2003). Still others have placed transparent physical plastics, ranging in feel from “squishy” to “rigid,” on touch-screen surfaces to provide for haptic sensations (Bilton, 2011; Jansen et al., 2012; Weiss, 2010; Weiss et al., 2009). If haptic possibilities are not available, well-designed visual feedback indicating when and where touches were perceived by the system is crucial for effective interaction (Wigdor et al., 2009).

User performance may be influenced by correspondences between input and output. Some correspondences are obvious, such as the need to present confirming visual feedback in response to the user's

TABLE 21.1 Potential Causes of Unexpected Behavior (Left) and the Source of Feedback That Users Receive to Refute Those Causes in Representative Mouse versus Touch Input Systems

Cause of Unexpected Behavior	Feedback Refuting Cause	
	Mouse	Touch
System is nonresponsive	OS: pointer movement	Application
Hardware failed to detect input	HW: activation of button	Application
Input delivered to wrong location	OS: visible pointer	Application
Input does not map to expected function	Application	Application
System is in a mode	OS + application: pointer icon	Application
Max size reached	OS: pointer moves past edge	Application
Accidental input (arm brushing)	N/A	Application
Over constrained (too many contacts)	N/A	Application
Stolen capture (second user captures control)	N/A	Application

actions. Ideally, feedback should indicate the results of an operation before the user commits to it (e.g., highlighting a button or menu item when the cursor moves over it). Kinesthetic correspondence and perceptual structure, described later, are less obvious.

21.6.1.1 Kinesthetic Correspondence

Kinesthetic correspondence refers to the principle that graphical feedback on the screen should correspond to the direction that the user moves the input device, particularly when 3D rotation is involved (Britton et al., 1978). Users can easily adapt to certain non-correspondences: when the user moves a mouse forward and back, the cursor actually moves up and down on the screen; if the user drags a scrollbar downward, the text on the screen scrolls upward. With long periods of practice, users can adapt to almost anything (e.g., for over 100 years psychologists have known of the phenomena of prism adaptation, where people can eventually adapt to wearing prisms that cause everything to look upside down [Stratton, 1897]). However, one should not force users to adapt to a poor design.

21.6.1.2 Perceptual Structure

Researchers have also found that the interaction of the input dimensions of a device with the control dimensions of a task can exhibit perceptual structure. Jacob et al. (1994) explored two input devices: a 3D position tracker with integral (x, y, z) input dimensions and a standard 2D mouse, with (x, y) input separated from (z) input by holding down a mouse button. For selecting the position and size of a rectangle, the position tracker is most effective: here, the integral 3D position input matches the integral presentation of the feedback on the screen. But for selecting the position and grayscale color of a rectangle, the mouse is most effective: here, the user perceives the position and grayscale color of the rectangle as separate quantities and can more easily perform the task when the input device provides separate controls. Hence neither a 3D integral input nor a 2D (x, y) plus 1D (z) input is uniformly superior; the better performance results when the task and device are both integral or both separable.

21.7 Pointing Facilitation Techniques

In an effort to improve the performance of pointing devices, particularly devices for indirect relative pointing (e.g., mice), researchers have invented numerous *pointing facilitation techniques*. Such techniques attempt to improve on the “raw” pointing performance one would exhibit with one’s hand or finger by utilizing various means for making targets easier to acquire. Such techniques are sometimes said to “beat Fitts’ law” (Balakrishnan, 2004), which refers to performing better than Fitts’ law, the widespread quantitative model of human movement time, would predict (Fitts, 1954; MacKenzie, 1992).

Pointing facilitation techniques can be divided into two flavors: those that are *target-agnostic* and those that are *target-aware* (Balakrishnan, 2004; Wobbrock et al., 2009a). Target-agnostic techniques require no knowledge of target identities, locations, or dimensions, working instead only with information directly available from the input device and on-screen cursor. Such techniques are relatively easy to deploy in real-world systems. Target-aware techniques, on the other hand, require knowledge of targets, often target locations and dimensions. Such techniques may also manipulate targets in some way, such as by expanding them (McGuffin and Balakrishnan, 2005). As a result, target-aware techniques are exceedingly difficult to deploy across commercial systems and, until recently, have mostly been confined to research laboratories. Recent efforts, however, have shown that target-aware techniques *can* be deployed on real-world systems by using an underlying architecture for target identification and interpretation (Dixon et al., 2012). Nevertheless, an ongoing theoretical challenge with target-aware techniques is that what constitutes a target is not easily defined. In a word processor, for example, a target may be every character or every word or perhaps even the space *between* characters. In a calendar program, every half hour slot may be a target. In a paint program, every pixel on the paint canvas is a target. Even on the open desktop, icons are not the only targets; every pixel is a candidate for the start of a drag-rectangle operation or a right-click menu. What constitutes a target is a more complex question than at first it may seem.

Target-agnostic techniques avoid the aforementioned issues but are relatively few in number, as only information from the input device and on-screen cursor is available to techniques. Target-agnostic techniques include conventional pointer acceleration (Casiez et al., 2008), dynamic gain adjustment based on the spread of movement angles (Wobbrock et al., 2009a), dynamic gain adjustment based on velocity changes (Hourcade et al., 2008), freezing the mouse cursor in place when the mouse button is down (Trewin et al., 2006), and visual-and-motor-space magnification of pixels with a lens (Findlater et al., 2010; Jansen et al., 2011). Click histories in the form of “magnetic dust” have also been used as a means for providing target-agnostic gravity (Hurst et al., 2007). Placing targets along impenetrable screen edges is also a target-agnostic pointing facilitation strategy, as edges constrain, guide, and trap on-screen cursors (e.g., in screen corners) (Appert et al., 2008; Farris et al., 2001; Froehlich et al., 2007; Walker and Smelcer, 1990). Related to but not strictly a pointing facilitation technique in itself, *kinematic endpoint prediction* (Lank et al., 2007) predicts the endpoints of mouse movements en route to targets using motion kinematic formulae like the minimum-jerk law (Flash and Hogan, 1985).

Target-aware techniques are more numerous than their impoverished target-agnostic brethren. With target identities, locations, and dimensions available to them, target-aware techniques contain the highest-performing pointing techniques in the world. One strategy for target-aware pointing is to modify the mouse cursor. For general-purpose pointing, the *bubble cursor*, which operates using a simple rule that “the closest target is always selected,” still remains unbeaten (Grossman and Balakrishnan, 2005). It is rivaled by the *DynaSpot*, which is a speed-dependent bubble cursor that also transitions to being a point cursor after stopping, making it capable of selecting specific pixels, not just objects (Chapuis et al., 2009). Both are variations on the static *area cursor*, which is target-aware so that when its large area overlaps multiple targets, it can degrade to a point cursor at its center (Kabbash and Buxton, 1995; Worden et al., 1997). Other explorations of area cursors have incorporated *goal crossing* (Accot and Zhai, 1997, 2002) into the cursors themselves (Findlater et al., 2010).

Other target-aware schemes modify the targets themselves. Mouse gain is dropped inside *sticky icons* (Blanch et al., 2004; Worden et al., 1997). Even more aggressive, *gravity wells* and *force fields* actually “pull” cursors into themselves (Ahlström et al., 2006; Hwang et al., 2003). *Bubble targets* and, more generally, *target expansion* enlarge targets as the cursor approaches (Cockburn and Firth, 2003; McGuffin and Balakrishnan, 2002, 2005; Zhai et al., 2003). A more extreme form of target expansion is to simply bring targets close to the mouse cursor as it begins its movement (Baudisch et al., 2003). More radically, the mouse cursor can be made to “jump over” the open space between targets, bypassing nontarget pixels altogether (Guiard et al., 2004). There are a great many ways to “beat Fitts’ law” and it is likely that new pointing facilitation techniques will be invented for years to come.

21.8 Keyboards, Text Entry, and Command Input

For over a century, keyboards, whether on typewriters, desktop computers, laptops, or mobile devices, have endured as the mechanism of choice for text entry. The resiliency of the keyboard, in an era of unprecedented technological change, is the result of how keyboards complement human skills and may make keyboards difficult to supplant with new input devices or technologies. We summarize some general issues surrounding text entry later, with a focus on mechanical keyboards; see also Lewis et al. (1997) and MacKenzie and Tanaka-Ishii (2007).

21.8.1 Skill Acquisition and Skill Transfer

Procedural memory is a specific type of memory that encodes repetitive motor acts. Once an activity is encoded in procedural memory, it requires little conscious effort to perform (Anderson, 1980). Because procedural memory automates the physical act of text entry, touch typists can rapidly type words without interfering with the mental composition of text. The process of encoding an activity in procedural

memory can be formalized as the *power law of practice*: $T_n = T_1 \times n^{(-\alpha)}$, where T_n is the time to perform the n th task, T_1 is the time to perform the first task, and α reflects the learning rate (Card et al., 1983; De Jong, 1957; Snoddy, 1926). The power law of practice is sometimes recast as $Y = aX^b$, called the power law of learning, as it produces “learning curves” for which Y is an increasing measure of proficiency (e.g., words per minute), X is a measure of the amount of practice (e.g., trial, block, or session), and a and b are regression coefficients. See MacKenzie and Zhang (1999) for an example in text entry. This suggests that changing the keyboard can have a high relearning cost. However, a change to the keyboard can succeed if it does not interfere with existing skills or allows a significant transfer of skill. For example, some ergonomic keyboards preserve the basic key layout, but alter the typing pose to help maintain neutral postures (Honan et al., 1995; Marklin and Simoneau, 1996), whereas the Dvorak key layout may have some small performance advantages, but has not found wide adoption due to high retraining costs (Lewis et al., 1997).

21.8.2 Eyes-Free Operation

With practice, users can memorize the location of commonly used keys relative to the home position of the two hands, allowing typing with little or no visual attention (Lewis et al., 1997). By contrast, soft keyboards (small on-screen virtual keyboards found on many handheld devices) require nearly constant visual monitoring, resulting in a secondary focus-of-attention (FoA), where the primary focus is on the user’s work, that is, the text being composed. A third FoA may consist of a source document that the user is transcribing. Furthermore, with stylus-driven soft keyboards, the user can only strike one key at a time. Thus the design issues for soft keyboards differ tremendously from mechanical keyboards (Zhai et al., 2000).

21.8.3 Tactile Feedback

On a mechanical keyboard users can feel the edges and gaps between the keys, and the keys have an activation force profile that provides feedback of the key strike. In the absence of such feedback, as on touch-screen keyboards (Sears, 1993), performance may suffer and users may not be able to achieve eyes-free performance (Lewis et al., 1997).

21.8.4 Combined Text, Command, and Navigation Input

Finally, it is easy to forget that keyboards provide many secondary command and control actions in addition to pure text entry, such as navigation keys (Enter, Home/End, Delete, Backspace, Tab, Esc, Page Up/Down, Arrow Keys, etc.), chord key combinations (such as Ctrl + C for Copy) for frequently used commands, and function keys for miscellaneous functions defined by the current application. Without these keys, frequent interleaving of mouse and keyboard activity may be required to perform these secondary functions.

21.8.5 Ergonomic Issues

Many modern information workers suffer from repetitive strain injury (RSI). Researchers have identified many risk factors for such injuries, such as working under stress or taking inadequate rest breaks. People often casually associate these problems with keyboards, but the potential for RSI is common to many manually operated tools and repetitive activities (Putz-Anderson, 1988). Researchers have advocated themes for ergonomic design of keyboards and other devices (Pekelney and Chu, 1995), including reducing repetition, minimizing force required to hold and move the device or press its buttons, avoiding sharp edges that put pressure on the soft tissues of the hand, and designing for natural and neutral postures of the user’s hands and wrists (Honan et al., 1995; Marklin et al., 1997). Communicating a clear

orientation for gripping and moving the device through its industrial design also may help to discourage inappropriate, ergonomically unsound grips.

21.8.6 Other Text Entry Mechanisms

One-handed keyboards can be implemented using simultaneous depression of multiple keys; such *chord keyboards* can sometimes allow one to achieve high peak performance (e.g., court stenographers), but take much longer to learn how to use (Buxton, 1990a; Mathias et al., 1996; Noyes, 1983). They are often used in conjunction with wearable computers (Smailagic and Siewiorek, 1996) to keep the hands free as much as possible (but see also Section 21.8.1). With complex written languages, such as Chinese and Japanese, key chording and multiple stages of selection and disambiguation are currently necessary for keyboard-based text entry (Wang et al., 2001). Handwriting and character recognition may ultimately provide a more natural solution, but for Roman languages handwriting (even on paper, with no recognition involved) is much slower than skilled keyboard use. To provide reliable stylus-driven text input, some systems have adopted unistroke (single-stroke) gestural “alphabets” (Goldberg and Richardson, 1993; Wobbrock et al., 2003) that reduce the demands on recognition technology, while remaining relatively easy for users to guess and learn (MacKenzie and Zhang, 1997; Wobbrock et al., 2005). However, small “two-thumb” keyboards (MacKenzie and Soukoreff, 2002) or fold-away peripheral keyboards are becoming increasingly popular for mobile devices. Recently, hybrid stroke-keyboard combinations have emerged that enable users to tap conventionally on keys or, without explicitly switching modes, to make unistroke gestures over the keys that form the desired word (Kristensson and Zhai, 2004; Zhai and Kristensson, 2003). Precise gestures over keys are not required as the stroke is pattern-matched to produce the intended word. Stroke keyboards have even been commercialized (e.g., ShapeWriter and Swype, both acquired in 2012 by Nuance Corporation) and generally have received a welcome response from consumers. Dictation using continuous speech recognition is available on the market today, but the technology still has a long way to go; a recent study found that the corrected words-per-minute rate of text entry using a mouse and keyboard are about twice as fast as dictation input (Karat et al., 1999). We further discuss speech interaction in the next section.

21.9 Modalities of Interaction

Here, we briefly review a number of general strategies and input modalities that have been explored by researchers. These approaches generally transcend a specific type of input device, but rather span a range of devices and applications.

21.9.1 Speech and Voice

Carrying on a full conversation with a computer as one might do with another person is well beyond the state of the art today and, even if possible, may be a naive goal. Yet even without understanding the content of the speech, computers can digitize, store, edit, and replay segments of speech to augment human-human communication (Arons, 1993; Buxton, 1995b; Stifelman, 1996). Conventional voice mail and the availability of MP3 music files on the web are simple examples of this. Computers can also infer information about the user’s activity from ambient audio, such as determining if the user is present or perhaps engaging in a conversation with a colleague, allowing more timely delivery of information or suppression of notifications that may interrupt the user (Horvitz et al., 1999; Sawhney and Schmandt, 2000; Schmandt et al., 2000).

Understanding speech as input has been a long-standing area of research. While progress is being made, it is slower than optimists originally predicted, and daunting unsolved problems remain. For limited vocabulary applications with native English speakers, speech recognition can excel at recognizing words that occur in the vocabulary. Error rates can increase substantially when users employ

words that are out-of-vocabulary (i.e., words the computer is not “listening” for), when the complexity of the grammar of possible phrases increases or when the microphone is not a high-quality close-talk headset. Even if the computer could recognize all of the user’s words, the problem of understanding natural language is a significant and unsolved one. It can be avoided by using an artificial language of special commands or even a fairly restricted subset of natural language. But, given the current state of the art, the closer the user moves toward full unrestricted natural language, the more difficulties will be encountered.

Speech input is not the only form of voice-based input researchers have explored. Nonspeech voice input has been examined as well, particularly for scenarios in which speech commands are not well suited. Such scenarios may involve continuous control responses, as opposed to discrete responses. Since speech utterances themselves are discrete, they are well mapped to discrete commands (e.g., “save document”) but poorly mapped to continuous activities (e.g., painting in a voice-driven paint program, maneuvering in a first-person shooter, or panning or zooming into documents or photographs). In addition, nonspeech voice has numerous qualities often ignored in speech: loudness, pitch, intonation, nasality, duration, timbre, prosody, vowel quality, and so on. Some of these qualities have been utilized, for example, in the *Vocal Joystick*, a voice control engine enabling continuous omnidirectional control by making vowel sounds that form a continuous circular phonetic space (Harada et al., 2006). Explorations utilizing the *Vocal Joystick* include drawing programs (Harada et al., 2007) and video games (Harada et al., 2011). Others also have explored controlling video games using nonspeech voice (Igarashi and Hughes, 2001). Even humming and whistling have been explored as forms of nonspeech input for text entry and gaming (Sporka et al., 2004, 2006a,b).

21.9.2 Pens

Pen-based input can emulate mouse-based input, for example, on a Tablet PC, or can support gesture-based input (see Section 21.9.4). Pens afford acting on documents, for example, crossing out a word to delete it or circling a paragraph and drawing an arrow to move it. Besides commands, pens can also provide *ink*, where strokes are not interpreted as commands but left as annotations. Pens thus constitute a versatile input modality, not just an isolated input device.

Pens have been employed in numerous specific interaction techniques besides just the emulation of mice or general gestural input. One of the most compelling is the *marking menu*. Marking menus use directional pen motion to provide rapid menu selection (Kurtenbach and Buxton, 1993; Kurtenbach et al., 1993). Marking menus have been incorporated into composite pen-based systems for indicating targets of an action and the action itself (Hinckley et al., 2005). Entire pen-specific interfaces for Tablet PCs have been explored that incorporate marking menus among other features (Hinckley et al., 2007). Marking menus have been improved or extended in numerous ways, for example, by enabling access to hierarchical menus with multiple discrete strokes (Zhao and Balakrishnan, 2004), using relative position and orientation (Zhao et al., 2006) or using two hands on a touch surface (Lepinski et al., 2010) (see also Section 21.9.3).

Of course, pen-specific interaction techniques go beyond marking menus. Multiple Tablet PCs can be “stitched” together using pen strokes that begin on the screen of one device, cross the bezel boundary, and end on the screen of an adjacent device (Hinckley et al., 2004). Pen pressure has been used in different ways, for example, to activate a magnifying lens for easier target acquisition (Ramos et al., 2007). Pen-based target acquisition has also been facilitated by slip-resistant bubble cursors (Moffatt and McGrenere, 2010) and target-directional beams (Yin and Ren, 2007).

The need for frequent mode switching in pen interfaces has inspired numerous interaction techniques. Barrel buttons, pen dwell time, pen pressure, and the “eraser end” of pens have been explored for mode switching (Li et al., 2005). Pens themselves have been made into multi-touch devices for grip sensing (Song et al., 2011). Even the tilt angle and azimuth of pens have been studied and used to control modes (Xin et al., 2011, 2012). Researchers have also explored multimodal pen and voice input; this is a

powerful combination because pen and voice have complementary strengths and weaknesses and can disambiguate one another (Cohen and Sullivan, 1989; Cohen et al., 1997; Harada et al., 2007; Kurihara et al., 2006; Oviatt, 1997).

An important benefit of pen-based interfaces is their support for *sketching*. Sketching interfaces often raise the difficult issue of how to disambiguate users' marks as ink versus as commands (Kramer, 1994; Moran et al., 1997; Mynatt et al., 1999). One solution to this is *hover widgets* (Grossman et al., 2006), which uses the pen hover state on Tablet PCs for command and property selection, separate from inking on the screen. Pen input, via sketching, has been used to define 3D objects (Igarashi et al., 1999; Zeleznik et al., 1996). Computational support for pen-based sketching has a rich history. For a comprehensive review, readers are directed to a recent survey (Johnson et al., 2009).

21.9.3 Touch Input

With the widespread adoption of mobile touch-screen devices, particularly mobile phones based on Apple's iOS operating system or the Android operating system, touch interaction has become the mainstream. Although touch and gesture are often thought of together—and rightly so, as many gestures employ touch—they are not inherently the same thing, as one may have touch without gesture and gesture without touch. In the former case, incidental contact with no intended meaning such as brushing up against an object involves touch but not gesture. In the latter case, one may perform gestures in midair using a computer vision system without touching anything. Despite these examples, for many of today's interactions, touch and gesture are meaningfully coupled together. We cover touch in this section and gesture in the next (Section 21.9.4).

The earliest explorations of touch interaction were on touch tablets that were input-sensing surfaces separated from their output graphical displays. Such tablets often employed relative pointing with a cursor on the display. Although some tablets supported the use of pens, pucks, or other objects, touch tablets, as their name suggests, required no such apparatuses, enabling fingers to directly act on their surfaces (Buxton et al., 1985). Although touch tablets still exist, they are far outnumbered today by touch screens whose input and output surfaces are collocated.

Direct-touch interfaces on touch-screen devices or interactive tabletops usually operate without a cursor in absolute positioning mode. Although styli and pens have been used with touch-screen devices for many years (see Section 21.9.2), often on resistive touch screens, today's devices often employ capacitive touch-sensing techniques enabling the human finger to interact directly. Using the finger in direct-touch interfaces raises many challenges. One challenge is the “fat finger problem,” in which the user's relatively large fingertip proves to be insufficiently precise when selecting small on-screen targets. A related challenge is the “occlusion problem,” in which the user's finger or hand occludes any objects beneath it (Vogel and Casiez, 2012). Numerous explorations of these issues have been conducted with a variety of proposals for their amelioration. Such proposals include offset cursors and lift-off selection (Potter et al., 1988; Sears and Shneiderman, 1991), magnifying lenses (Roudaut et al., 2008; Vogel and Baudisch, 2007), zooming (Olwal et al., 2008), precision handles (Albinsson and Zhai, 2003), picture-in-picture-style “radar views” (Karlson and Bederson, 2007), probabilistic hit testing (Schwarz et al., 2010, 2011), and techniques utilizing finger orientation (Wang et al., 2009). In addition, a stream of work has studied and exploited interaction on the *backsides* of devices (or, in the case of interactive tabletops, the *undersides*), where fingers cannot possibly occlude portions of the graphical display (Baudisch and Chu, 2009; Hiraoka et al., 2003; Sugimoto and Hiroki, 2006; Wigdor et al., 2006, 2007; Wobbrock et al., 2007, 2008).

Finally, while the aforementioned work has innovated to ameliorate the challenges of touch, others have studied the properties of human touch itself (Wang and Ren, 2009). Findings indicate that users touch with consistent offsets from their perceived target location depending on their finger angle (Holz and Baudisch, 2010), and users align visible features on the *tops* of their fingers with the underlying target on the screen (Holz and Baudisch, 2011). Extracting fingerprints for modeling users and their touch

styles can double touch accuracy (Holz and Baudisch, 2010), and if cameras can be used (e.g., above a tabletop), features atop users' fingers can be correlated with their perceived touch point for improved accuracy (Holz and Baudisch, 2011). It is also possible to distinguish with which *part* of a user's finger he or she touches the screen from the acoustic signature of touches (e.g., fingertip, finger pad, fingernail, or knuckle) (Harrison et al., 2011). Rather than distinguishing single touch points, it can be useful to support whole-hand touches that create entire touch regions (Cao et al., 2008).

21.9.4 Gestural Input

Gesture is a powerful input modality that takes place in a variety of forms: as strokes on 2D surfaces or as motions made in 3D space. Depending on the sensing technologies employed, gestures may require holding or wearing an object (e.g., a stylus or a Nintendo Wiimote), or gestures may be performed with the bare fingers or hands (e.g., on a capacitive touch screen or in the air before a Microsoft Kinect). Gestures are highly expressive, rapid, capable of symbolic or metaphorical association, and often entertaining for performers and observers alike. Although gestures have been part of HCI for years, in the last decade, gestures have become a mainstream input modality on commercialized platforms.

Gestures have a powerful property in that they can designate both the *object* of an action and the *action itself* in one fluid motion (Buxton et al., 1983). Thus, gestures support cognitive chunking by integrating command selection with specification of the command's scope (Kurtenbach and Buxton, 1991a,b).

Gestures may be defined in the simplest case by a single point, as in a *tap gesture* performed by a finger on a capacitive touch screen. At this level, the concepts of "touch" and "gesture" are trivially the same. It does not take long, however, for a touch unfolding over time to become a complex gesture involving *paths* or ordered sequences of points over time. Paths may be *unistrokes* (Goldberg and Richardson, 1993), meaning they begin upon receiving the first input point (e.g., "touch down"), unfold as that point moves (e.g., "touch move"), and end when the input points cease (e.g., "touch up"). Of course, a "touch" is only exemplary; a unistroke may be made with a stylus or in midair with a wand or entire hand. The defining aspect of a unistroke is that it is segmented (separated) from gestures that precede or succeed it by a clear signal equivalent to "begin" and "end" with no intervening segmentation signals. Gestures that comprise multiple *successive* unistrokes are called *multistrokes* (see, e.g., Hinckley et al., 2006). Gestures that comprise multiple *concurrent* unistrokes using fingers on a touch screen are called *multi-touch gestures*. The famous "pinch" gesture for resizing photographs is an example of a multi-touch gesture, where the user's thumb and forefinger each perform a unistroke concurrently.

Besides paths, gestures may be composed of *poses*. In the case of hand gestures, poses involve certain positions of the hand that convey meaning, such as a fist or flat palm. Whole-body gestures may also entail poses, such as raising one's hands above one's head (Cohn et al., 2012). Poses may be preserved over a path, such as a fist pose held while punching in a boxing game. Or poses themselves may be dynamic, changing either in place or over a path. Of course, as devices or other objects are incorporated into gestures, the possibilities grow according to the properties available. Gestures made with a rigid remote may be different than those available when using a bendable computer (Schwesig et al., 2004).

In an attempt to organize the high variation possible in gestures, numerous gesture taxonomies have been erected both within and outside the computing field. Early taxonomies by sociolinguists included categories such as Efron's *physiographics*, *kinetographics*, *ideographics*, *deictics*, and *batons* (Efron, 1941). Similarly, McNeill's taxonomy contained *iconics*, *metaphorics*, *deictics*, and *beats* (McNeill, 1992). Kendon placed his gestures on a spectrum of formality, identifying *sign languages* as the most formal and *gesticulation* as the least (Cadoz, 1994; Kendon, 1988) broadly categorizes hand gestures as *semiotic*, *ergotic*, and *epistemic*. Semiotic gestures are those used to communicate meaningful information, such as "thumbs up." Ergotic gestures are those used to manipulate physical objects. Epistemic gestures are exploratory movements to acquire haptic or tactile information; see also D. Kirsh (1995a,b).

The aforementioned gesture categories are not entirely foreign to those developed with computer input in mind. Deictic gestures in particular have received much attention, with several efforts using pointing, typically captured using instrumented gloves or camera-based recognition to interact with “intelligent” environments (Baudel and Beaudouin-Lafon, 1993; Freeman and Weissman, 1995; Jovic et al., 2000; Maes et al., 1996). Deictic gestures in combination with speech recognition have also been studied (Bolt, 1980; Hauptmann, 1989; Lucente et al., 1998; Wilson and Shafer, 2003). Explorations of tangible interaction techniques (Ullmer and Ishii, 1997) and efforts to sense movements and handling of sensor-enhanced mobile devices may be considered ergotic gestures (Harrison et al., 1998; Hinckley et al., 2000, 2003). Most research in hand gesture recognition focuses on empty-handed semiotic gestures (Cassell, 2003), which (Rime and Schiaratura, 1991) are further classified as follows:

Symbolic—conventional symbolic gestures such as “OK”

Deictic—pointing to fill in a semantic frame, analogous to deixis in natural language

Iconic—illustrating a spatial relationship

Pantomimic—mimicking an invisible tool, such as, pretending to swing a golf club

Wobbrock et al. studied gestures that users make on an interactive tabletop for accomplishing common actions like “move,” “copy,” and “delete” (Wobbrock et al., 2009b). Over 1000 gestures were collected from 20 people for 27 common commands. Findings indicated that apart from (Cadoz, 1994) *ergotic* gestures in which simulated physical objects are manipulated (e.g., moving a virtual object from one screen location to another), users employed widely varying gestures and had little gestural agreement. This led Wobbrock et al. to formulate the following taxonomy of surface gestures with four dimensions, each with various properties. Note that the “Nature” dimension represents a similar classification to those seen thus far:

Form—static pose, dynamic pose, static pose and path, dynamic pose and path, one-point touch, one-point path

Nature—symbolic, physical, metaphorical, abstract

Binding—object-centric, world-dependent, world-independent, mixed dependencies

Flow—discrete, continuous

Freeman et al. extended Wobbrock et al.’s “Form” dimension with the following categories that capture how a gesture begins and unfolds over time (Freeman et al., 2009):

Registration pose—single finger, multi-finger, single shape, multi-shape

Continuation pose—static, dynamic

Movement—no path, path

Not surprisingly, the use of gestures for computer input raises numerous challenges. With most forms of gestural input, errors of user intent and errors of computer interpretation seem inevitable (Bellotti et al., 2002). The learnability of gestures is another persistent challenge, as unlike visible buttons, menus, or hyperlinks, gestures are not trivially discoverable by users. Rather like speech commands, gestures must be *articulated* by users. Numerous efforts have explored how to teach gestures to users (Bau and Mackay, 2008; Bragdon et al., 2009; Fothergill et al., 2012; Freeman et al., 2009; Martin and Isokoski, 2008; Plimmer et al., 2011). Other work has attempted to assess and improve the guessability, learnability, and “naturalness” of gestures in the first place (Alexander et al., 2012; Grandhi et al., 2011; Kane et al., 2011; Költringer and Grechenig, 2004; MacKenzie and Zhang, 1997; Wobbrock et al., 2005, 2009b). Yet another challenge with gestures has been for system designers to choose appropriate and distinct gestures that avoid collision in the *feature-space* utilized by gesture recognizers (Long et al., 1999, 2000). Given the popularity of gestures, some researchers have worked to make gesture recognizers easier to incorporate into software prototypes (Anthony and Wobbrock, 2010, 2012; Henry et al., 1990; Landay and Myers, 1993; Li, 2010; Myers et al., 1997; Swigart, 2005; Wobbrock et al., 2007).

21.9.5 Bimanual Input

Aside from touch typing, most of the devices and modes of operation discussed thus far and in use today involve only one hand at a time. But people use both hands in a wide variety of the activities associated with daily life. For example, when writing, a right-hander writes with the pen in the right hand, but the left hand also plays a crucial and distinct role. It holds the paper and orients it to a comfortable angle that suits the right hand. In fact, during many skilled manipulative tasks, Guiard observed that the hands take on asymmetric, complementary roles (Guiard, 1987): for right-handers, the role of the left hand precedes the right (the left hand first positions the paper), the left hand sets the frame of reference for the action of the right hand (the left hand orients the paper), and the left hand performs infrequent, large-scale movements compared to the frequent, small-scale movements of the right hand (writing with the pen). Most applications for bimanual input to computers are characterized by asymmetric roles of the hands, including compound navigation/selection tasks such as scrolling a web page and then clicking on a link (Buxton and Myers, 1986), command selection using the nonpreferred hand (Bier et al., 1993; Kabbash et al., 1994), as well as navigation, virtual camera control, and object manipulation in 3D user interfaces (Balakrishnan and Kurtenbach, 1999; Hinckley et al., 1998b; Kurtenbach et al., 1997). Researchers have also applied this approach to keyboard design (MacKenzie and Guiard, 2001; McLoone et al., 2003). For some tasks, such as banging together a pair of cymbals, the hands may take on symmetric roles; for further discussion of bimanual symmetric tasks, see Guiard (1987) and Balakrishnan and Hinckley (2000).

21.9.6 Direct Muscle-Based Input and Brain-Computer Interfaces

Traditional input devices can be thought of as secondary sensors, in that they sense a physical action that is the consequence of cognition and muscle movements. An alternative approach is to attempt primary sensing by detecting brain activity and muscle movements directly. Muscle sensing is accomplished through electromyography, a technique previously employed for measuring muscular activity or controlling prosthetics. Saponas et al. demonstrated its use to enable sensing of muscle activation as fine-grained as detecting and identifying individual fingers (Saponas et al., 2009) and used in combination with touch-screen input to provide a richer data stream (Benko et al., 2009). Brain-computer interfaces (BCI) typically employ electroencephalography or functional near-infrared spectroscopy to detect input. Projects have used the technique to detect workload and user engagement (Hirshfield et al., 2009a) in order to conduct usability studies, as well as to explore the possible dynamic adaptation of user interfaces based on such metrics (Hirshfield et al., 2009b). Such work remains in its infancy, but appears to hold great promise (particularly as assistive technologies for users suffering from devastating injuries or other significant physical limitations) as sensing and signal processing techniques improve.

21.9.7 Passive Measurement: Interaction in the Background

Not all interactions with computers need consist of explicit, intentionally communicated commands. Think about walking into a grocery store with automatic doors. You approach the building; the doors sense this motion and open for you. No explicit communication has occurred, yet a computer has used your action of walking toward the store as an “input” to decide when to open the door. Intentional, explicit interaction takes place in the *foreground*, while implicitly sensed interaction takes place in the *background*, behind the fore of the user’s attention (Buxton, 1995a). *Background sensing techniques* will be a major emphasis of future research in automation and sensing systems as users become increasingly mobile and become saturated with information from many sources. Researchers are currently exploring ways of providing context awareness through location sensing; ambient sensing of light, temperature, and other environmental qualities; movement and handling of devices (Goel et al., 2012); detecting the identity of the user and physical objects in the environment; and possibly even

physiological measures such as heart-rate variability. This type of information potentially can allow technology to interpret the context of a situation and respond more appropriately (Dey et al., 2001; Hinckley et al., 2003; Schilit et al., 1994; Schmidt, 1999). However, like other recognition-based technologies, there is a risk of errors of user intent or computer interpretation: returning to the automatic door, for example, if you walk by (parallel to) the doors, they may sense your motion and open even if you have no intention of entering the building.

Background interaction can also be applied to explicit input streams through passive behavioral measurements, such as observation of typing speed, manner of moving the cursor (Evans and Wobbrock, 2012), sequence and timing of commands activated in a graphical interface (Horvitz et al., 1998), and other patterns of use. For example, a carefully designed user interface could make intelligent use of such information to modify its dialogue with the user, based on inferences about the user's alertness or expertise. These measures do not require additional input devices, but rather gleaning of additional, typically neglected, information from the existing input stream. These are sometimes known as intelligent or adaptive user interfaces, but mundane examples also exist. For example, cursor control using the mouse or scrolling using a wheel can be optimized by modifying the device response depending on the velocity of movement (Hinckley et al., 2001; Jellinek and Card, 1990).

We must acknowledge the potential for misuse or abuse of information collected in the background. Users should always be made aware of what information is or may potentially be observed as part of a human-computer dialogue. Users should have control and the ability to block any information that they want to remain private (Nguyen and Mynatt, 2001).

21.10 Displays and Perception

We now turn our attention to focus on the fundamental properties of displays and techniques for effective use of displays. We focus on visual displays and visual human perception, since these represent the vast majority of displays, but we also discuss feedback through the haptic and audio channels.

21.10.1 Properties of Displays and Human Visual Perception

Display requirements, such as resolution in time and space, derive from the properties of human vision. Thus, we begin with the basic issues relating to display brightness, uniformity, and spatial and temporal resolution.

21.10.1.1 Dynamic Range

The human eye has an enormous dynamic range. The amount of light reflected from surfaces on a bright day at the beach is about five orders of magnitude higher than the amount available under dim lamp-lights. Yet the shapes, layouts, and colors of objects look nearly identical to the human eye across much of this range. Most displays in common use are self-luminous CRTs or back-lit liquid crystal displays (LCDs). The best of these devices has a dynamic range (the ratio between the maximum and minimum values produced) of a little more than two orders of magnitude. In practice, under typical room lighting conditions, 15%–40% of the light reaching the user's eye is actually ambient room light reflected by the front surface of the phosphors or off of the screen surface. This means that the effective dynamic range of most devices, unless viewed in dark rooms, is no better than three or four to one. Fortunately the human eye can tolerate extreme variation in the overall level of illumination, as well as the amount of contrast produced by the display.

21.10.1.2 Spatial Frequency

The ability of the human visual system to resolve fine targets is known as *visual acuity*. A standard way of measuring visual acuity is to determine how fine a sinusoidal striped pattern can be discriminated from a uniform gray. Humans are capable of perceiving targets as fine as 50–60 cycles/degree of visual angle

FIGURE 21.1 Spatial contrast sensitivity function of the human visual system. There is a falloff in sensitivity both to detailed patterns (high-spatial frequencies) and to gradually changing gray values (low spatial frequencies).

when the pattern is of very high contrast. Figure 21.1 illustrates the spatial sensitivity of the human eye as a function of spatial frequency. Specifically, it illustrates the degree of contrast required for sinusoidal gratings of different spatial frequencies to be perceived. The function has an inverted U shape with a peak at about two cycles per degree of visual angle. This means that 5 mm stripes at arm's length are optimally visible. The falloff at low spatial frequencies indicates that the human visual system is insensitive to gradual changes in overall screen luminance. Indeed, most CRTs have a brightness falloff toward the edges of as much as 20%, which we barely notice. This nonuniformity is even more pronounced with rear projection systems, due to the construction of screens that project light primarily in a forward direction. This is called the *screen gain*; a gain of 3.0 means that three times as much light is transmitted in the straight through direction compared to a perfect *Lambertian* diffuser. At other angles, less light is transmitted so that at a 45° off-axis viewing angle, only half as much light may be available compared to a perfect diffuser. Screen gain is also available with front projection with similar nonuniformities as a consequence, although the use of curved screens can compensate to some extent.

21.10.1.3 Spatial Resolution

The receptors in the human eye have a visual angle of about 0.8 s of arc. Modern displays provide approximately 40 pixels/cm. A simple calculation reveals that at about a 50 cm viewing distance, pixels will subtend about 1.5 s of arc, about two times the size of cone receptors in the center of vision. Viewed from 100 cm, such a screen has pixels that will be imaged on the retina at about the same size as the receptors. This might suggest that we are in reach of the perfect display in terms of spatial resolution; such a screen would require approximately 80 pixels/cm at normal viewing distances. However, under some conditions the human visual system is capable of producing *superacutities* that imply resolution better than the receptor size. For example, during fusion in stereo vision, disparities smaller than 5 s of arc can be detected (Westheimer, 1979); see also Ware (2000) for a discussion of stereopsis and stereo displays aimed at the practitioner. Another example of superacuity is known as aliasing, resulting from the division of the screen into discrete pixels; for example, a line on the display that is almost (but not quite) horizontal may exhibit a jagged “stairstep” pattern that is very noticeable and unsatisfying. This effect can be diminished by *anti-aliasing*, which computes pixel color values that are averages of all the different objects that contribute to the pixel, weighted by the percentage of the pixel they cover. Similar techniques can be applied to improve the appearance of text, particularly on LCD screens, where individual red, green, and blue display elements can be used for sub-pixel anti-aliasing (Betrissey et al., 2000; Platt, 2000).

21.10.1.4 Temporal Resolution, Refresh, and Update Rates

The *flicker fusion frequency* represents the least rapidly flickering light that the human eye does not perceive as steady. Flicker fusion frequency typically occurs around 50 Hz for a light that turns completely on and off (Wyszecki and Styles, 1982). In discussing the performance of monitors, it is important to differentiate the *refresh rate* and the *update rate*. The refresh rate is the rate at which a screen is redrawn and it is typically constant (values of 60 Hz up to 120 Hz are common). By contrast, the update rate is the rate at which the system software updates the output to be refreshed. Ideally, this should occur at or above the refresh rate, but with increasingly demanding applications and complex data sets, this may not be possible. A rule of thumb states that a 10 Hz update rate is a minimum for smooth animation (Robertson et al., 1989). Motion blur (also known as temporal anti-aliasing) techniques can be applied to reduce the jerky effects resulting from low frame rates (Cook, 1986).

21.11 Color Vision and Color Displays

The single most important fact relating to color displays is that human color vision is trichromatic; our eyes contain three receptors sensitive to different wavelengths. For this reason, it is possible to generate nearly all perceptible colors using only three sets of lights or printing inks. However, it is much more difficult to exactly specify colors using inks than using lights because, whereas lights can be treated as a simple vector space, inks interact in complex nonlinear ways.

21.11.1 Luminance, Color Specification, and Color Gamut

Luminance is the standard term for specifying brightness, that is, how much light is emitted by a self-luminous display. The luminance system in human vision gives us most of our information about the shape and layout of objects in space. The international standard for color measurement is the Commission Internationale de L'Éclairage (CIE) standard. The central function in Figure 21.2 is the CIE $V(\lambda)$ function, which represents the amount that light of different wavelengths contributes to the overall

FIGURE 21.2 The CIE tristimulus functions. These are used to represent the standard observer in colorimetry. Short wavelengths at the left-hand side appear blue, in the middle they are green, and to the right they are red. Humans are most sensitive to the green wavelengths around 560 nm.

sensation of brightness. As this curve demonstrates, short wavelengths (blue) and long wavelengths (red) contribute much less than green wavelengths to the sensation of brightness. The CIE tristimulus functions, also shown in Figure 21.2, are a set of color-matching functions that represent the color vision of a typical person. Humans are most sensitive to the green wavelengths around 560 nm. Specifying luminance and specifying a color in CIE tristimulus values are complex technical topics; for further discussion, see Ware (2000) and Wyszecki and Styles (1982).

A chromaticity diagram can be used to map out all possible colors perceptible to the human eye, as illustrated in Figure 21.3. The pure spectral hues are given around the boundary of this diagram in nanometers (10^{-9} m). While the spacing of colors in tristimulus coordinates and on the chromaticity diagram is not perceptually uniform, *uniform color spaces* exist that produce a space in which equal metric distances are closer to matching equal perceptual differences (Wyszecki and Styles, 1982). For example, this can be useful to produce color sequences in map displays (Robertson, 1988).

The gamut of all possible colors is the dark-gray region of the chromaticity diagram, with pure hues at the edge and neutral tones in the center. The triangular region represents the gamut achievable by a particular color monitor, determined by the colors of the phosphors given at the corners of the triangle. Every color within this triangular region is achievable, and every color outside of the triangle is not. This diagram nicely illustrates the trade-off faced by the designer of color displays. A phosphor that produces a very narrow wavelength band will have chromaticity coordinates close to the pure spectral colors, and this will produce more saturated colors (thus enlarging the triangle). However, this narrow band also means that little light is produced.

FIGURE 21.3 A CIE chromaticity diagram with a monitor gamut and a printing ink gamut superimposed. The range of available colors with color printing is smaller than that available with a monitor, and both fall short of providing the full range of color that can be seen.

The irregular shape inside the triangle illustrates the gamut of colors obtainable using printing inks. Notice that this set of colors is still smaller, causing difficulties when we try to obtain a hard copy reproduction of the colors on the monitor. Because the eye is relatively insensitive to overall color shifts and overall contrast changes, we can take the gamut from one device and map it into the gamut of the printing inks (or some other device) by compressing and translating it. This is known as gamut mapping, a process designed to preserve the overall color relationships while effectively using the range of a device (Stone et al., 1988). However, it should be noted that the original colors will be lost in this process and that after a succession of gamut mappings, colors may become distorted from their original values.

A process known as chromatic adaptation occurs in the human eye receptors and in the early stages of visual processing: for example, we hardly notice that daylight is much bluer than the yellow cast of tungsten light produced from ordinary light bulbs. The CIE standard does not account for chromatic adaptation nor does it account for color contrast (colors appear differently to the human eye depending on the surrounding visual field). The practical implication is that we can get by with color monitors and printers that are grossly out of calibration. However, accurate color is essential in some applications. It is possible to precisely calibrate a color device so that the particular inputs required to produce a color may be specified in CIE tristimulus values. For monitor calibration, see Cowan (1983); for calibrating print devices, see Stone et al. (1988). It is also possible to correct for the nonlinear response of CRT displays, a process known as *gamma correction*, but keep in mind that CRT designers intentionally insert this nonlinearity to match the human eye's sensitivity to relative changes in light intensity. If one desires a set of perceptually equal gray steps, it is usually best to omit gamma correction. See Ware (2000) for further discussion.

21.12 Information Visualization

Researchers and practitioners have become increasingly interested in communicating large quantities of information quickly and clearly by leveraging the tremendous capabilities of the human visual system, a field known as information visualization. Thanks to advances in computer graphics hardware and algorithms, virtually all new desktop machines available today have sophisticated full-color displays with transparency and texture mapping for complex 2D or 3D scenes, and it now seems inevitable these capabilities will become commonplace on laptop computers, and ultimately even on handheld devices.

21.12.1 General Issues in Information Coding

The greatest challenge in developing guidelines for information coding is that there are usually effective alternatives, such as color, shape, size, texture, blinking, orientation, and gray value. Although a number of studies compare one or more coding methods separately, or in combination, there are so many interactions between the task and the complexity of the display that guidelines based on science are not generally practical. However, Tufte provides excellent guidelines for information coding from an aesthetic perspective (Tufte, 1983, 1990, 1997). For further discussion, examples, and case studies, see also Ware (2000) and Card et al. (1999).

A theoretical concept known as *preattentive processing* has interesting implications for whether or not the coding used can be processed in parallel by the visual system. The fact that certain coding schemes are processed faster than others is called the pop-out phenomenon, and this is thought to be due to early preattentive processing by the visual system. Thus, for example, the shape of the word "bold" is not processed preattentively, and it will be necessary to scan this entire page to determine how many times the word appears. However, if all of the instances of the word *bold* are emphasized, they pop out at the viewer. This is true as long as there are not too many other emphasized words on the same page: if there are less than seven or so instances, they can be processed at a single glance. Preattentive processing is done for color, brightness, certain aspects of texture, stereo disparities, and object orientation and size. Codes that are preattentively discriminable are very useful if rapid search for information

is desired (Triesman, 1985). The following visual attributes are known to be preattentive codes and, therefore, useful in differentiating information belonging to different classes:

- *Color*: Use no more than 10 different colors for labeling purposes.
- *Orientation*: Use no more than 10 orientations.
- *Blink coding*: Use no more than 2 blink rates.
- *Texture granularity*: Use no more than 5 grain sizes.
- *Stereo depth*: The number of depths that can be effectively coded is not known.
- *Motion*: Objects moving out of phase with one another are perceptually grouped. The number of usable phases is not known.

However, coding multiple dimensions by combining different pop-out cues is not necessarily effective (Ware, 2000).

21.12.2 Color Information Coding

When considering information display, one of the most important distinctions is between chromatic and luminance information, because these are treated quite differently in human perception. Gray scales are not perceived in the same way as rainbow-colored scales. A purely chromatic difference is one where two colors of identical luminance, such as red and green, are placed adjacent to one another. Research has shown that we are insensitive to a variety of information if it is presented through purely chromatic changes. This includes shape perception, stereo depth information, shape from shading, and motion. However, chromatic information helps us classify the material properties of objects. A number of practical implications arise from the differences in the way luminance and chromatic information is processed in human vision:

- Our spatial sensitivity is lower for chromatic information, allowing image compression techniques to transmit less information about hue relative to luminance.
- To make text visible, it is important to make sure that there is a luminance difference between the color of the text and the color of the background. If the background may vary, it is a good idea to put a contrasting border around the letters (e.g., Harrison and Vicente, 1996).
- When spatial layout is shown either through a stereo display or through motion cues, ensure adequate luminance contrast.
- When fine detail must be shown, for example, with fine lines in a diagram, ensure that there is adequate luminance contrast with the background.
- Chromatic codes are useful for labeling objects belonging to similar classes.
- Color (both chromatic and gray scale) can be used as a quantitative code, such as on maps, where it commonly encodes height and depth. However, simultaneous contrast effects can change the appearance of a patch of color depending on the surrounding colors; careful selection of colors can minimize this (Ware, 1988).

A number of empirical studies have shown color coding to be an effective way of identifying information. It is also effective if used in combination with other cues such as shape. For example, users may respond to targets faster if they can be identified by both shape and color differences (for useful reviews, see Christ [1975]; Stokes et al. [1990]; and Silverstein [1977]). Color codes are also useful in the perceptual grouping of objects. Thus, the relationship between a set of different screen objects can be made more apparent by giving them all the same color. However, it is also the case that only a limited number of color codes can be used effectively. The use of more than about 10 will cause the color categories to become blurred. In general, there are complex relationships between the type of symbols displayed (e.g., point, line, area, or text), the luminance of the display, the luminance and color of the background, and the luminance and color of the symbol (Spiker et al., 1985).

21.12.3 Integrated Control-to-Display Objects

When the purpose of a display is to allow a user to integrate diverse pieces of information, it may make sense to integrate the information into a single visual object or glyph (Wickens, 1992). For example, if the purpose is to represent a pump, the liquid temperature could be shown by changing the color of the pump, the capacity could be shown by the overall size of the pump, and the output pressure might be represented by the changing height of a bar attached to the output pipe, rather than a set of individual dials showing these attributes separately. However, perceptual distortions can result from an ill-chosen display mapping, and the object display may introduce visual clutter: if there are 50 pumps to control, then the outlines of all the pumps may interfere with the data of interest (Tufte, 1983). In object displays, input and output can be integrated in a manner analogous to widgets such as the scrollbar, or even more directly by having input devices that resemble the physical object being handled, known as a prop (Hinckley et al., 1994a). For some good examples of the linking of output and input, see Ahlberg and Shneiderman (1994) as well as Ishii and Ullmer (1997).

This style of presentation and interaction can be especially relevant for telepresence or augmented reality applications, where the user needs to interact with actual physical objects that have attributes that must be viewed and controlled (Feiner et al., 1993; Tani et al., 1992). For more abstract data representation tasks, choosing the color, size, orientation, or texture to represent a particular data attribute may be difficult, and there seem to be practical limits on the number of attributes that one can encode simultaneously. Thus, object displays must usually be custom designed for each different display problem. In general, this means that the display and controls should somehow match the user's cognitive model of the task (Cole, 1986; Norman, 1990).

21.12.4 3D Graphics and Virtual Reality

Much research in 3D information visualization and **virtual reality** is motivated by the observation that humans naturally operate in physical space and can intuitively move about and remember where things are (an ability known as spatial memory). However, translating these potential benefits to artificially generated graphical environments is difficult because of limitations in display and interaction technologies. Virtual environment research pushed this to the limit by totally immersing the user in an artificial world of graphics, but this comes at the cost of visibility and awareness of colleagues and objects in the real world. This has led to research in so-called *fish tank virtual reality* displays by using a head tracking system in conjunction with a stereo display (Deering, 1992; Ware et al., 1993) or a mirrored setup, which allows superimposition of graphics onto the volume where the user's hands are located (Schmandt, 1983; Serra et al., 1997). However, much of our ability to navigate without becoming lost depends upon the vestibular system and spatial updating as we physically turn our bodies, neither of which is engaged with stationary displays (Chance et al., 1998; Loomis et al., 1999). For further discussion of navigation in virtual environments, see Darken and Sibert (1993, 1995); for application of spatial memory to 3D environments, see Robertson et al. (1998, 1999).

Outside of virtual reality, *volumetric displays* present imagery in true 3D space, by illuminating "voxels" (volumetric pixels) in midair. Favalora provides a thorough survey of the various technological implementations of volumetric displays (Favalora, 2005). The true 3D imagery in volumetric displays has been shown to improve depth perception (Grossman and Balakrishnan, 2006b) and shape recognition (Rosen et al., 2004). Besides providing true 3D images, the main difference from the other 3D tabletop displays is that volumetric display is generally enclosed by a surface. This means that users cannot directly interact with the 3D imagery. Balakrishnan et al. explored the implications of this unique difference to interaction design by using physical mock-ups (Balakrishnan et al., 2001). More recent working implementations have allowed users to interact with the display by using hand and finger gestures on and above the display surface (Grossman et al., 2004) and by using a handheld six degree-of-freedom input device (Grossman and Balakrishnan, 2006a). Another key differentiator is that volumetric displays better support collocated multiuser interaction, given a shared view of 3D imagery, without the

need to wear glasses or head-mounted displays that can interfere with natural collaboration. Grossman and Balakrishnan describe various techniques that can overcome the limitations of multiuser interaction with volumetric displays (Grossman and Balakrishnan, 2008).

21.12.5 Augmented Reality

Augmented reality superimposes information on the surrounding environment rather than blocking it out. For example, the user may wear a semitransparent display that has the effect of projecting labels and diagrams onto objects in the real world. It has been suggested that this may be useful for training people to use complex systems or for fault diagnosis. For example, when repairing an aircraft engine, the names and functions of parts could be made to appear superimposed on the parts seen through the display together with a maintenance record if desired (Caudell and Mizell, 1992; Feiner et al., 1993). The computer must obtain a detailed model of the environment; otherwise it is not possible to match the synthetic objects with the real ones. Even with this information, correct registration of computer graphics with the physical environment is an extremely difficult technical problem due to measurement error and system latency. This technology has been applied to heads-up displays for fighter aircraft, with semitransparent information about flight paths and various threats in the environment projected on the screen in front of the pilot (Stokes et al., 1990), as well as digitally augmented desk surfaces (Wellner, 1993).

21.13 Scale in Displays

It is important to consider the full range of scale for display devices and form factors that may embody an interaction task. Computer displays increasingly span orders of magnitude in size and available computational resources, from watches, handheld personal data assistants (PDAs), tablet computers, and desktop computers, all the way up to multiple-monitor and wall-size displays. A technique that works well on a desktop computer, such as a pull-down menu, may be awkward on a small handheld device or even unusable on a wall-size display (where the top of the display may not even be within the user's reach). Each class of device seems to raise unique challenges, and the best approach may ultimately be to design special-purpose, appliance-like devices (see Want and Borriello [2000] for a survey) that suit specific purposes.

21.13.1 Small Displays

Users increasingly want to do more and more on handheld devices, mobile phones, pagers, and watches that offer less and less screen real estate. Researchers have investigated various strategies for conserving screen real estate. Transparent overlays allow divided attention between foreground and background layers (Harrison and Vicente, 1996; Harrison et al., 1995a,b; Kamba et al., 1996), but some degree of interference seems inevitable. This can be combined with sensing which elements of an interface are being used, such as presenting widgets on the screen only when the user is touching a pointing device (Hinckley and Sinclair, 1999). Researchers have also experimented with replacing graphical interfaces with *graspable* interfaces that respond to tilting, movement, and physical gestures that do not need constant on-screen representations (Fitzmaurice et al., 1995; Harrison et al., 1998; Hinckley et al., 2000; Rekimoto, 1996). Much research in focus plus context techniques, including fish-eye magnification (Bederson, 2000) and zooming metaphors (Bederson et al., 1996; Perlin and Fox, 1993; Smith and Taivalsaari, 1999), has also been motivated by providing more space than the boundaries of the physical screen can provide. Researchers have started to identify principles and quantitative models to analyze the trade-offs between multiple views and zooming techniques (Baudisch et al., 2002; Plumlee and Ware, 2002). There has been considerable effort devoted to supporting web browsing in extremely limited screen space (Baudisch et al., 2004; Buyukkokten et al., 2001; Jones et al., 1999; Trevor et al., 2001; Wobbrock et al., 2002).

21.13.2 Multiple Displays

Researchers have recently recognized that some very interesting design issues arise when multiple displays are considered, rather than the traditional single display of desktop computers. Having multiple monitors for a single computer is not like having one large display (Grudin, 2001). Users employ the boundary between displays to partition their tasks, with one monitor being reserved for a primary task and other monitors being used for secondary tasks. Secondary tasks may support the primary task (e.g., reference material, help files, or floating tool palettes), may provide peripheral awareness of ongoing events (such as an e-mail client), or may provide other background information (to-do lists, calendars, etc.). Switching between applications has a small time penalty (incurred once to switch and again to return), and perhaps more importantly, it may distract the user or force the user to remember information while switching between applications. Having additional screen space “with a dedicated purpose, always accessible with a glance” (Grudin, 2001), reduces these burdens (Czerwinski et al., 2003), and studies suggest that providing multiple, distinct foci for interaction may aid users’ memory and recall (Tan et al., 2001, 2002). Finally, small displays can be used in conjunction with larger displays (Myers et al., 1998, 2000; Rekimoto, 1998), with controls and private information on the small device and shared public information on the larger display. This shows how displays of different dimensions support completely different user activities and social conventions. It is also possible to dynamically join multiple displays for collaboration or to create a larger but temporary tiled display (Hinckley, 2003a,b; Tandler et al., 2001).

21.13.3 Large-Format Displays

Trends in display technology suggest that large-format displays will become increasingly affordable and common. A recent journal special issue includes numerous articles on implementing large-format displays using projection, application design for large displays, and specific application domains such as automotive design (Funkhouser and Li, 2000). Large displays often implicitly suggest multiple simultaneous users, with many applications revolving around collaboration (Funkhouser and Li, 2000; Swaminathan and Sato, 1997) and giving a large-scale physical presence to virtual activities (Buxton et al., 2000). To support input directly on whiteboard-size displays, researchers have explored gestural interaction techniques for pens or touch screens (Guimbretiere et al., 2001; Moran et al., 1997). Some technologies cannot handle more than one point of contact, so system developers must check this carefully if simultaneous use by multiple persons is desired. Large displays also seem to lend themselves to interaction at a distance, although using laser pointers to support such interaction (Myers et al., 2002; Olsen and Nielsen, 2001) has met with mixed success due to the lack of separation between tracking versus dragging states (Buxton, 1990b); using small handheld devices to interact with the full area of a large display also is problematic as the ratio of the display size to the control surface size may be very large (Myers et al., 1998). Environmentally situated ambient displays share some properties of large displays, but emphasize subtle presentation of information in the periphery of attention (Ishii and Ullmer, 1997; Wisneski et al., 1998). Large-format displays and virtual realities also share some design issues; see the taxonomy of Buxton and Fitzmaurice for further discussion (Buxton and Fitzmaurice, 1998).

Unless life-size viewing of large objects is necessary (Buxton et al., 2000), in general it is not yet clear what performance benefits a single large display may offer as compared to multiple monitors with the same screen area partitioned by bezels (Czerwinski et al., 2003). One recent study suggests that the increased field of view afforded by large-format displays can lead to improved 3D navigation performance, especially for women (Czerwinski et al., 2002).

21.14 Force and Tactile Displays

Haptic feedback research has sought to provide an additional channel of sensory feedback by synthesizing forces on the skin of the operator. The touch sensation is extraordinarily complex.

In fact, the sense of “touch” is a very imprecise term: it includes an amalgamation of multiple sensory systems, including sensitivity to pressure, small shear forces in the skin, heat and cold, pain, kinesthesia and proprioception, and the vestibular system (Burdea, 1996; MacKenzie and Iberall, 1994).

There appears to be no physical means by which a complex tactile stimulus can be delivered except in a very localized way. As a result, most haptic feedback devices are limited to simulation of a single point of contact, analogous to feeling the world with the tip of a pencil, although a few examples of whole-hand force feedback devices exist (Burdea, 1996; Iwata, 1990). Efforts in haptic feedback include force feedback (active presentation of forces to the user) and tactile feedback (active presentation of vibrotactile stimuli to the user). Haptic feedback is popular for gaming devices, such as force feedback steering wheels and joysticks, but general-purpose pointing devices with force or tactile feedback remain uncommon. For a comprehensive discussion of force and tactile feedback technologies and techniques, as well as perceptual properties of the skin and joints, see Burdea (1996).

Adding force feedback to a mouse or stylus may impose constraints on the mechanical design, since a physical linkage is typically needed to reflect true forces. This may prevent a force feedback mouse from functioning like a traditional mouse, as it may limit range of motion or preclude clutching by lifting the device. Some devices instead increase resistance between the mouse and the pad, but this prevents simulation of hard contact forces. One can also use a vibrotactile stimulus, such as a vibrating pin under the mouse button or a vibrating shaft of an isometric joystick (Campbell et al., 1999). Combination devices have also been explored (Akamatsu and MacKenzie, 1996). Vibrotactile feedback seems especially promising for small mobile devices, for example, to provide the user with feedback of command recognition when the user’s attention may not be focused on the screen (Poupyrev et al., 2002). Applications for remote controls and augmented handles also look promising (MacLean et al., 2000; Snibbe and MacLean, 2001).
